Eggs deposited by the adult worms are passed to the outside in the feces (Fig. 18.1). All intestinal trematode eggs have an operculum, or "lid," from which the miracidium larva can escape. Eggs hatch in freshwater, and these larvae must find their way into the snail (intermediate host) through penetration of the snail tissues; in some cases, the snail ingests the eggs before they hatch. Over a period of weeks, a series of developmental stages occur within the snail, eventually producing cercariae, which are released from the snail. Typical features of cercariae include the tail, mouth, gut, suckers, flame cells, and glands. These cercariae then encyst on aquatic plant material or encyst in the tissues of freshwater mollusks or fish and become metacercariae; infectivity lasts from 1 h to several months. When the plants or mollusks are ingested raw, the metacercariae then infect the human host, where they excyst in the small intestine and develop into mature adult trematodes within the intestinal tract.

The trematode body surface is covered by a syncytial epithelium, the tegument. The tegument is involved in nutrient absorption, synthesis, secretion, and osmoregulation and has sensory functions. Moreover, the tegument protects the parasite from the immune system of the host. Further typical characteristics of trematodes are the presence of an oral sucker, often a ventral sucker, and a lack of respiratory and circulatory systems.

Algorithm 18.1 Trematode infection.
doi:10.1128/9781555819002.ch18.Alg18.1

Adult worms vary in shape and size and can be distinguished from one another (Table 18.1; Fig. 18.2). The adult worms are hermaphroditic, containing both male and female reproductive systems.

Fasciolopsis buski

Fasciolopsiasis was first noted by Busk in 1843, when worms were detected in the duodenum of a deceased East Indian sailor (3). *F. buski* has also been known as the giant intestinal fluke and is one of the largest parasites to infect humans, measuring 20 to 75 mm in length, 8 to 20 mm in width, and 0.5 to 3 mm in thickness.

Life Cycle and Morphology

The adult worms live in the small intestine of pigs and humans, where the worms lay unembryonated eggs that are then passed from the intestinal lumen with the feces. The eggs are ellipsoidal, operculate, and yellow-brown. They measure 130 to 140 μm by 80 to 85 μm, with the operculum found at the more pointed end of the transparent eggshell (Fig. 18.3, 18.4, 18.5, and 18.6; Table 18.1). Depending on the temperature, the

TABLE 18.1 Characteristics of intestinal trematodes

Species	Distribution	Agent of infection	Reservoir host	Egg		
				Size (µm)	Morphology	Comments
Fasciolopsis buski	Far East	Water chestnut, bamboo shoots, water caltrop	Dogs, pigs, rabbits	130–140 by 80–85	Unembryonated operculated	The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the "breaks" in the shell may be difficult to identify. This egg has no opercular shoulders, and so it is difficult to see where the operculum "breaks" in the shell actually occur.
Echinostoma ilocanum	Far East	Freshwater fish, frogs, mussels, snails, snakes, tadpoles	Rats, dogs	86–116 by 59–69	Unembryonated operculated	Although *E. ilocanum* eggs are considerably smaller than *F. buski* eggs, some strains produce eggs that overlap in size; the operculum may be difficult to see (as indicated above for *F. buski*).
Heterophyes heterophyes	Far East, Middle East	Freshwater fish	Fish-eating mammals	27–30 by 15–17	Embryonated operculated with very subtle opercular shoulders; no "seated" operculum	These eggs have very inconspicuous opercular shoulders and, unlike *C. sinensis*, lack the "seated" operculum and knob at the abopercular end. *H. heterophyes* eggs are some of the smallest trematode eggs seen and may be missed using the low power of the microscope; high dry power may be required for identification.
Metagonimus yokogawai	Far East, former USSR, Israel, Spain	Freshwater fish	Fish-eating mammals	26–28 by 15–17	Embryonated operculated with minimal opercular shoulders; no "seated" operculum	These eggs have inconspicuous opercular shoulders but a more obvious operculum than *H. heterophyes* eggs and are some of the smallest trematode eggs. They do not really have the "seated" operculum and knob at the abopercular end like those seen in *C. sinensis* eggs. They may be missed using the low power of the microscope, and high dry power may be required for identification.
Gastrodiscoides hominis	Far East, Middle East, former USSR	Freshwater fish	Pigs, deer mice, rats	60–70 by 150	Unembryonated operculated	The egg of *G. hominis* tends to be more slender than that of *F. buski*, but they are very much alike; this egg has no opercular shoulders, and so it is difficult to see where the operculum "breaks" in the shell actually occur.

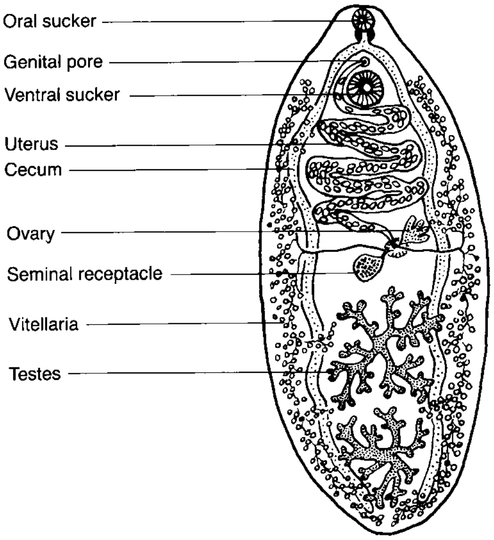

Figure 18.2 Diagram of a general intestinal/liver trematode. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch18.f2

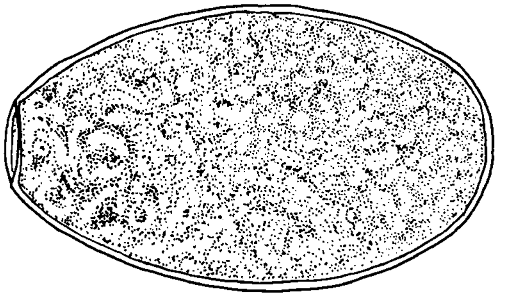
eggs embryonate within 3 to 7 weeks. Once in the water, the mature miracidium hatches from the egg and tries to locate the appropriate snail species to infect (*Segmentina* and *Hippeutis* spp.). Once the miracidium has penetrated the soft tissues of the snail (first intermediate host), it begins to develop into a first-generation sporocyst. The sporocyst is an elongated sac, without distinct internal structures, in which germ balls proliferate. These germ balls develop into rediae that contain a mouth, pharynx, blind cecum, and birth pore. Within the rediae, the germ balls again proliferate, developing into cercariae. Unlike some of the other intestinal trematodes, *Fasciolopsis* rediae develop a second generation of rediae before forming cercariae. On reaching maturity, the cercariae escape from the snail host into the water. The cercariae encyst on water plants such as water caltrops, water chestnuts, and water bamboo, where they develop into metacercariae in approximately 4 weeks (Fig. 18.7). Humans become infected by ingesting the raw or undercooked plants containing the metacercariae. The metacercariae excyst, attach to the duodenal or jejunal mucosa, and develop into adult worms within 3 months (Fig. 18.6). The adult life span seldom exceeds 6 months to a year (3).

Figure 18.3 *Fasciolopsis buski* egg. (Illustration by Nobuko Kitamura.) doi:10.1128/9781555819002.ch18.f3



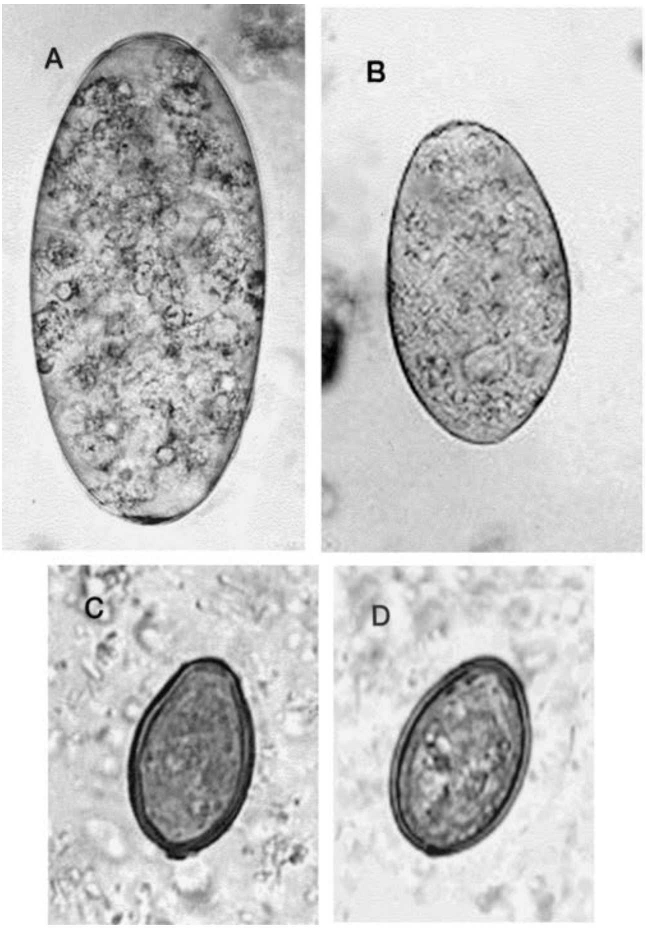


Figure 18.4 Intestinal trematode eggs. (A) *Fasciolopsis buski*; (B) *Echinostoma ilocanum*; (C) *Heterophyes heterophyes*; (D) *Metagonimus yokogawai*. Note that the eggs in panels C and D are shown at a higher magnification to demonstrate very minor differences; the operculum of *H. heterophyes* is less pronounced than that of *Clonorchis sinensis* (see chapter 19), and the operculum outline of *M. yokogawai* is the least obvious of the three small trematode eggs that are often confused (*C. sinensis*, *H. heterophyes*, and *M. yokogawai*). doi:10.1128/9781555819002.ch18.f4

F. buski is the largest of the intestinal trematodes and attaches to the duodenal and jejunal walls (Fig. 18.6). The adult worms are fleshy, somewhat pale, and elongate-ovoid and have no cephalic cone structures like that seen in the liver fluke, *Fasciola hepatica*. The large egg tends to be yellowish brown, has a clear, thin shell with a small operculum but no opercular shoulders, and is nearly identical to that of *F. hepatica* and *F. gigantica*. The less mature the egg, the more difficult it is to see the operculum "breaks" in the shell outline.

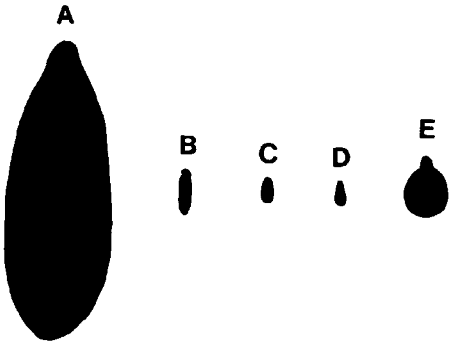

Figure 18.5 Outline of the sizes of adult intestinal trematodes. (A) *Fasciolopsis buski*; (B) *Echinostoma ilocanum*; (C) *Heterophyes heterophyes*; (D) *Metagonimus yokogawai*; (E) *Gastrodiscoides hominis*. doi:10.1128/9781555819002.ch18.f5

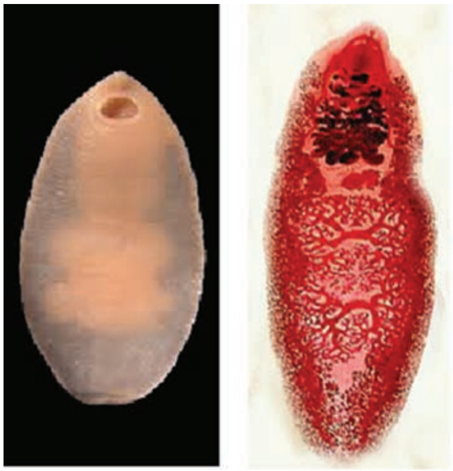
Clinical Disease

Regarding intestinal fluke infections, school-age children were found to be at the highest risk of infection and infection intensity, as documented previously for *F. buski* (4). In light infections, the adult worms inhabit the duodenum and jejunum; in heavy infections, they may be found in the stomach and most of the intestinal tract. The attachment of worms to the mucosal wall produces local inflammation with hypersecretion of mucus, hemorrhage, ulceration, and possible abscess formation. In heavy infections, the worms may cause bowel obstruction, acute ileus, and absorption of toxic or allergic worm metabolites, producing general edema and ascites. Edema of the face may occur as a result of hypoalbuminemia secondary to malabsorption or protein-losing enteropathy. Occasionally, vitamin B_{12} absorption is impaired, with resulting low vitamin B_{12} levels. A marked eosinophilia and leukocytosis are commonly seen. Few symptoms are associated with light infections, but in heavier infections, the patient may experience abdominal pain and diarrhea. In heavy infections, the stools are profuse and yellow-green and contain increased amounts of undigested food, suggesting a malabsorption process. The symptoms may be confused with those of giardiasis or peptic ulcer or with other causes of bowel obstruction. Depending on the worm burden, the infection can be associated with severe cachexia and prostration and can lead to death (5).

Figure 18.6 *Fasciolopsis buski* adult worms. (Left) Unpreserved adult worm: fleshy, pale, elongate-ovoid with no cephalic cone as seen in *F. hepatica*; the adult *F. buski* worms measure 20 to 75 mm in length by 8 to 20 mm in width, and 0.5 to 3 mm in thickness. (Right) Stained and flattened adult worm: from anterior to posterior characterized by a large ventral sucker, coiled uterus, branched ovary, and two branched testes filling most of the posterior section of the worm; the lateral fields are filled with vitellaria. doi:10.1128/9781555819002.ch18.f6



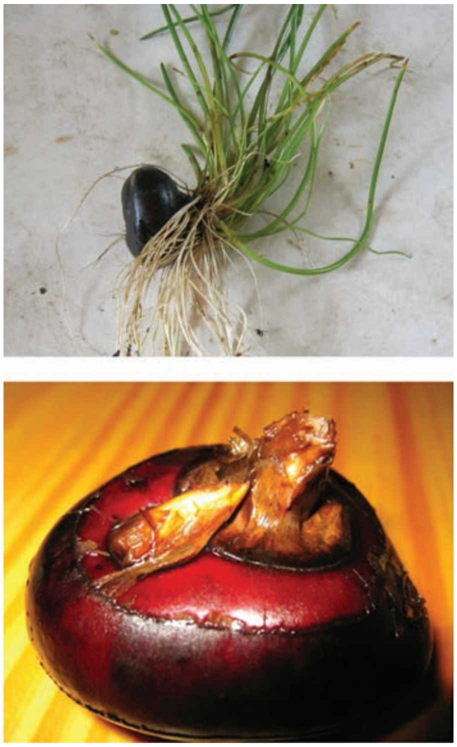


Figure 18.7 *Eleocharis dulcis*, water chestnut. (Upper) Plant structure (courtesy of Mass Spectrum Botanicals). (Lower) Chestnut (courtesy of Joscha Feth at the German Wikipedia project—released into the public domain). doi:10.1128/9781555819002.ch18.f7

Diagnosis

The diagnosis is suggested by the clinical features in areas where infections are endemic and is confirmed by detecting the eggs in the stool. The zinc sulfate flotation concentration is not recommended for concentrating trematode eggs because of the operculum and the fragility of the eggshell. The high specific gravity of the zinc sulfate causes the operculum to "pop" open, the eggshell fills with fluid, and the egg sinks to the bottom of the tube, where it may appear to be very distorted. Therefore, when this concentration procedure is used, both the upper flotation layer and the sediment must be examined. The formalin-ethyl acetate sedimentation concentration is recommended for routine fecal concentration. The sedimented material can be examined with or without iodine. The eggs of *Echinostoma ilocanum*, *Fasciola hepatica*, *F. buski*, and *Gastrodiscoides hominis* are similar in size and shape; therefore, an exact identification cannot be made from examining the eggs. It is possible to detect adult worms in the stool in heavy infections when they lose their ability to remain attached to the intestinal mucosa.

Other methods available include Kato-Katz thick smears or Stoll's dilution egg count method. Also, excellent results have been reported with the FLOTAC technique, a multivalent fecal egg count technique (6). It is important to remember that trematode species-specific diagnosis on the basis of egg morphology is difficult.

KEY POINTS—LABORATORY DIAGNOSIS

Fasciolopsis buski

1. The eggs are found in the stool; rarely, adult worms are found during heavy infections.
2. The eggs of *F. buski*, *E. ilocanum*, *G. hominis*, *F. hepatica*, and *F. gigantica* appear almost identical and are very difficult to differentiate from one another. When passed, the eggs do not contain mature larvae but instead contain undifferentiated embryos.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the "breaks" in the shell may be difficult to identify. This egg has no opercular shoulders; therefore, it is difficult to see where the operculum "breaks" in the shell actually occur.

Treatment

Although different drugs have been used for therapy, the drug of choice is praziquantel, an isoquinoline derivative that is administered orally (7). The drug is well tolerated; however, there may be some side effects, including abdominal pain, headache, dizziness, nausea, drowsiness, pruritus, and myalgia. These side effects usually disappear within 48 h but may be more pronounced in heavily infected individuals. The drug is administered as a single 15-mg/kg dose after the evening meal or before going to bed. A second regimen consists of 75 mg/kg/day in three doses for 1 day. Apparently, children tend to tolerate the drug better than adults. Contraindications for use include ocular cysticercosis, cerebral paragonimiasis, pregnancy, and physically demanding tasks where dizziness or drowsiness might put the patient at risk.

An alternative drug is niclosamide (Niclocide), a salicylamide derivative; alcohol should be avoided during treatment. The drug may be given for 1 or 2 days at 40 mg/kg/day (up to a maximum of 4 g) (8). This drug is minimally absorbed from the gastrointestinal tract, and side effects include nausea, vomiting, diarrhea, and abdominal pain.

Epidemiology and Prevention

F. buski reservoir hosts include dogs, pigs, and rabbits. The infection is commonly found in Bangladesh, Cambodia, central and southern China, India, Indonesia, Laos, Malaysia, Pakistan, Taiwan, Thailand, and Vietnam; it has also been reported from Japan. Drainage of farm waste, use of manure for cultivation, and defecation in or near ponds or lakes that contain snails from the family *Planorbidae* (*Gyraulus*, *Polypylis*, *Segmentina*, or *Hippeutis* spp.), with water plants acting as vectors, allow the life cycle of the worm to continue. Metacercariae encyst on freshwater vegetation, such as water chestnuts, bamboo shoots, or water caltrops, and the infection is acquired when these infested plants are consumed raw or the outer coat is peeled off the nut with the teeth, resulting in accidental ingestion.

To prevent the infection, plants should be cooked or immersed in boiling water for a few seconds before they are eaten or peeled. In areas of endemicity, the use of unsterilized night soil for fertilizer should be prohibited. If these safeguards were used, the risk of infection would be considerably decreased.

Fasciolopsiasis remains a public health problem despite changes in eating habits, agricultural practices, health education, industrialization, and environmental approaches. The disease occurs focally and is most prevalent in school-age children. In areas of endemicity, the prevalence of infection in children ranges from 57% in mainland China to 25% in Taiwan and from 50% in Bangladesh and 60% in India to 10% in Thailand. Control programs are not fully successful because of long-standing traditions of eating raw aquatic plants and using untreated water. Control measures are also impacted by social and economic factors, an expanding free-food market, a lack of sufficient food inspection and sanitation, and declining economic conditions (9, 10).

Echinostoma ilocanum

A number of species of echinostomes have been reported to infect humans, including *E. hortense*, *E. ilocanum*, *E. macrorchis*, *E. perforiatum*, and *E. revolutum*. Most of the species are found in Asian countries; *E. ilocanum* is the most important species. The infection was first noted by Garrison in 1907 (8). *Echinostoma* flukes are distinguishable from other trematodes by their distinctive horseshoe-shaped collar of spines on the lateral and dorsal sides of their oral sucker.

Life Cycle and Morphology

Adult worms are attached to the mucosal wall of the small intestine and lay eggs, which are passed from the intestinal lumen in the feces. The eggs are immature, ellipsoidal, yellow-brown, and operculated. They measure 86 to 116 μm by 58 to 69 μm (Table 18.1; Fig. 18.4). The miracidia take 1 to 2 weeks to mature in the environment before they hatch from the eggs and infect the snail intermediate host. Two or more generations of rediae are produced before cercariae develop. These cercariae encyst in freshwater mollusks, and humans are infected by eating these mollusks raw rather than cooked. The metacercariae hatch in the intestine, attach to the mucosal wall, and develop into mature adult worms.

The adults are less than 1 cm long and 0.2 cm wide and are reddish gray (Fig. 18.5). The anterior end of the adult worm has a circumoral disk with a crown of spines surrounding the oral sucker (Fig. 18.8).

Clinical Disease

With light infections, the patient may be asymptomatic and the adult worms cause only minor problems other than localized inflammation. In heavy infections, the worms can produce catarrhal inflammation and mild ulceration and the patient may experience diarrhea and abdominal pain.

Diagnosis

Eggs of *E. ilocanum* can be detected in the stool. They are the same size (some strains) and shape as the eggs of *F. hepatica* and *F. buski*. Because of the overlap in size range, exact identification cannot be made from the eggs; therefore, the diagnosis may have to be made on the basis of patient history or clinical findings.

KEY POINTS—LABORATORY DIAGNOSIS

Echinostoma ilocanum

1. The eggs are found in the stool; rarely, adult worms are found during heavy infections.
2. The eggs of *E. ilocanum*, *G. hominis*, *F. buski*, *F. hepatica*, and *F. gigantica* appear almost identical and are very difficult to differentiate from one another. When passed, the eggs do not contain mature larvae but instead contain undifferentiated embryos.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the "breaks" in the shell may be difficult to identify. This egg has no opercular shoulders; therefore, it is difficult to see where the operculum "breaks" in the shell actually occur.

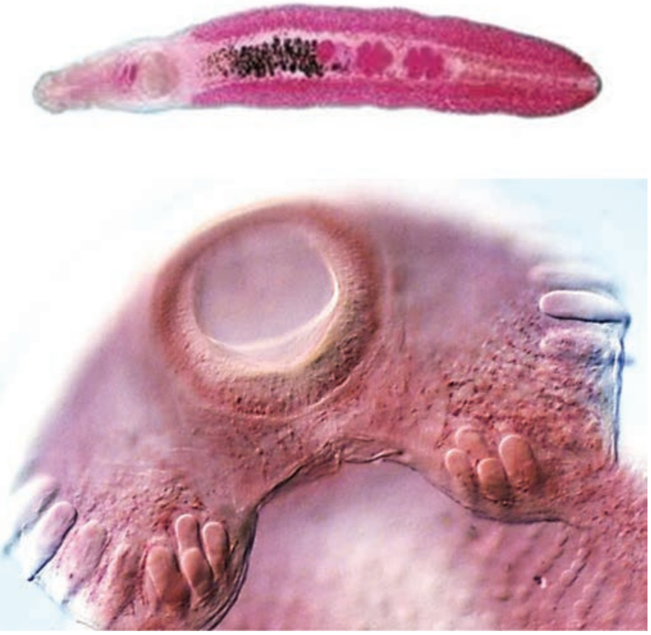
Treatment

Praziquantel is the drug of choice and can be given in a single dose of 40 mg/kg at bedtime. Another option would be albendazole at 400 mg twice a day for 3 days.

Epidemiology and Prevention

Information concerning *E. ilocanum* infections and epidemiology is limited. Both rats and dogs have been found to be infected in areas where infections are endemic. The infection has been reported from the Celebes, China, India, Indonesia, Japan, Korea, Malaysia, the Philippines, Russia, Taiwan, and Thailand. In some areas in northeastern Thailand, the infection rate may be as high as 50%. In areas of the Philippines with high levels of endemic infection (Luzon, Mindanao, and Leyte), local infection rates from 1 to 44% have been reported

Figure 18.8 *Echinostoma ilocanum* adult worms. (Upper) Stained adult worm characterized by having a circumoral disk with a crown of spines surrounding the small oral sucker. (Lower) Enlarged image of the crown of spines (surrounding the oral sucker) and the large ventral sucker. The living worm is reddish gray and measures 2.5 to 6.5 mm in length by 1 to 1.35 mm in width. (Courtesy of www.k-state.edu.) doi:10.1128/9781555819002.ch18.f8



(8). In China, the infection appears to be limited to dogs, with an infection rate of 14% being reported. The miracidia must infect a susceptible species of snail from the family *Planorbidae* (*Gyraulus* or *Hippeutis* spp.). The cercariae can encyst in a number of freshwater mollusks, particularly snails, which, if eaten raw, will allow the metacercariae to excyst in the intestinal tract and develop to adult worms. The infection can be prevented in areas of endemicity by restricting the use of night soil for fertilizer and eating cooked rather than raw mollusks. The disease is most prevalent in those areas where snails, fish, and other possible intermediate hosts are eaten raw.

Human infections with other echinostome species have been reported; however, actual infection rates are unknown or estimated. Some of these species have been identified and are listed in Table 18.2. For a number of these species, the food source is often fish rather than mollusks.

Heterophyes heterophyes

H. heterophyes is one of the smallest trematodes to infect humans and is acquired through the ingestion of pickled or uncooked fish. The heterophyids are capable of parasitizing birds and mammals, and infection was first reported by Bilharz in 1851 (11, 12).

Life Cycle and Morphology

The adult worms measure 1.0 to 1.7 mm in length by 0.3 to 0.4 mm in width, are gray, and have a broadly rounded posterior end (Fig. 18.5 and 18.9). They lay embryonated eggs in the intestinal lumen, and the eggs are discharged into the environment via the feces. The eggs are small, brownish yellow, and operculate, and they possess very subtle opercular shoulders. They measure 27 to 30 μm by 15 to 17 μm (Table 18.1; Fig. 18.4). The eggs are ingested by the snail intermediate host before the miracidium hatches. A sporocyst and one or two redia generations develop in the snail before the production and release of cercariae. The cercariae encyst under the scales or in the flesh of freshwater fish. Humans become infected by eating raw, pickled, or poorly cooked fish containing the metacercariae (10). The metacercariae excyst in the intestinal tract, attach to the walls of the small intestine, and grow to maturity. The adult worm, in addition to an oral and ventral sucker, contains a third sucker, the genital sucker, surrounding the genital pore. The eggs tend to appear in the feces approximately 2 to 3 weeks after infection.

Clinical Disease

Following ingestion of metacercariae, the prepatent period is approximately 9 days. The adult worms cause little damage

TABLE 18.2 Other echinostome infections reported from humans[a]

Trematode	Location	Host	No. and location of spines	Infection acquired
Echinostoma malayanum	Northeastern and northern Thailand	Rats, dogs	43, crown	Freshwater snails, usually cooked
Echinostoma revolutum	Taiwan (3–7% infection rate)	Ducks, geese, rats	37, circumoral	Raw mollusks
Echinostoma lindoense	Indonesia (Lindu Valley; infection may no longer be present in this area); found in Brazil	Rats, mice	37, collar	Raw mollusks
Hypoderaeum conoideum	Northeastern Thailand	Ducks, other fowl, rats, humans	Two rows of 45–53	Salted or raw snails or clams
Echinostoma cinetorchis, *Psilorchis hominis*[b]	Japan, Taiwan			Tadpoles, frogs
Euparyphium melis, *E. beaveri*	Romania, China; may also be in Douglas Lake, Michigan (not studied)		27, crown	Tadpoles
Hypoderaeum cibiuduyn	Northeast Thailand (55% infection rate)	Ducks, geese, fowl		Raw snails
Artyfechinostomum mehrai	India (two cases)	Pig	39–42, collar	Raw snails
Echinostoma recurvatum	Taiwan, Indonesia, Egypt	Rats	45, crown	Tadpoles, frogs
Echinoparyphium paraulum[c]	Former USSR	Ducks, geese, swans, doves		
Himasthla muehlensi	New York City		32, circumoral	Raw clams
Echinochasmus perfoliatus	Hungary, Italy, Romania, former USSR, Far East	Dogs, cats, pigs, foxes	24, circumoral	Raw freshwater fish

[a] Data from reference 3.
[b] May or may not be an echinostome; specimens may have lost crown spines.
[c] May be the same as *Echinostoma revolutum*.

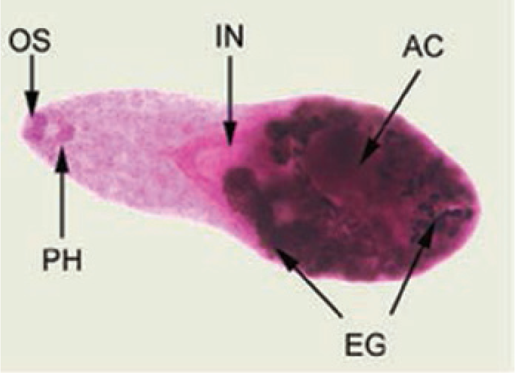


Figure 18.9 *Heterophyes heterophyes* adult worm, stained with carmine. These worms tend to have a broadly rounded posterior end, measure approximately 1 to 1.7 mm in length by 0.3 to 0.4 mm in width, and tend to be gray. In this figure, the following structures are labeled: oral sucker (OS), pharynx (PH), intestine (IN), ventral sucker or acetabulum (AC), and eggs within the uterus (EG). (Courtesy of CDC Public Health Image Library.) doi:10.1128/9781555819002.ch18.f9

to the intestinal tract mucosa except for a mild inflammatory reaction. In heavy infections, the worms cause abdominal pain, mucous diarrhea, and ulceration of the intestinal wall. Because of the small size of the eggs and the fact that the adult may attach itself deeply into the intestinal wall, some of the eggs may end up in the general circulation of the host. The eggs may provoke pathologic lesions, particularly in the heart and brain (13, 14). In the Philippines, 15% of fatal heart disease may be a result of heterophyid myocarditis. Neurologic manifestations due to adult worms or eggs in the brain have been reported (5).

Diagnosis

The diagnosis is suggested by detecting the eggs in the stool. Because the eggs of *H. heterophyes* are similar in shape and size to those of *Metagonimus yokogawai* and *Clonorchis sinensis*, differentiation must be made on the basis of patient history, clinical findings, or recovery of adult worms in the stool.

In Kobe, Japan, *H. katsuradai*, a closely related species that is broader and more rounded, with a very large ventral sucker and smaller eggs (25 to 26 μm by 14 to 15 μm), has been recovered after therapy in patients with diarrhea. Apparently, infection is acquired from the ingestion of raw mullet.

KEY POINTS—LABORATORY DIAGNOSIS

Heterophyes heterophyes

1. The eggs are found in the stool; rarely, adult worms are found in patients with heavy infections after therapy or at autopsy.
2. The eggs of *H. heterophyes*, *M. yokogawai*, and *C. sinensis* appear almost identical and are very difficult to differentiate from one another. When passed, each egg contains a miracidium larva, but the eggs are ingested by the snail before they hatch.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The eggs have very inconspicuous opercular shoulders and, unlike *C. sinensis*, lack the "seated" operculum and knob at the abopercular end. *H. heterophyes* eggs are some of the smallest trematode eggs seen and may be missed using the low power of the microscope (10× oculars and 10× objective); high dry power may be required for identification (10× oculars and 40× objective).

Treatment

Praziquantel is the drug of choice and can be given in a single dose of 15 to 25 mg/kg at bedtime.

Epidemiology and Prevention

Numerous fish-eating mammals, including dogs, cats, and birds, act as reservoirs (11). The infection is found in China, Greece, Egypt, India, Iran, Italy, Israel, Japan, Korea, the Philippines, Sudan, Taiwan, Tunisia, and Turkey. Snails serving as the first intermediate host include *Pironella* and *Cerithidea* spp., and a variety of freshwater fish can serve as the second intermediate hosts (15, 16).

Humans become infected by ingestion of parasitized fish that is raw, inadequately cooked, or improperly pickled or salted. Metacercariae can survive for up to 7 days in salted fish. Off the coast of Israel a brackish-water fish, *Mugil capito*, can be heavily infected with *H. heterophyes*, with metacercariae numbering 2,300 to 6,000 per g of fish. The life cycle could be disrupted by improved sanitary conditions and educational information about proper sewage disposal away from ponds or lakes where the intermediate hosts reside.

Metagonimus yokogawai

M. yokogawai was first discovered by Katsurada in 1911 in an infected human (17). The infection is found most often in the Far East and clinically resembles that of *H. heterophyes*. *M. yokogawai* is the most common intestinal fluke infecting humans in the Far East.

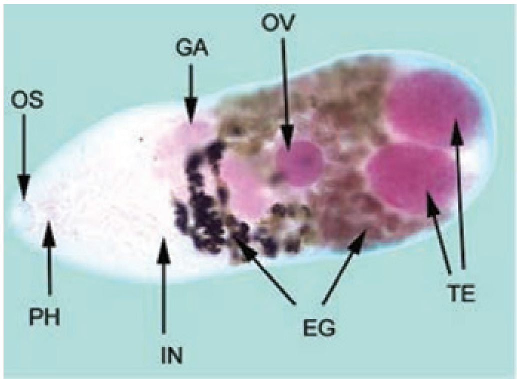

Figure 18.10 *Metagonimus yokogawai* adult worm, stained with carmine. These worms are quite small, like *Heterophyes*, and measure 1 to 2.5 mm by 0.4 to 0.75 mm. The ventral sucker is deflected to the right of the midline and is visible in this image. In this figure, the following structures are labeled: oral sucker (OS), pharynx (PH), intestine (IN), genitoacetabulum (GA), ovary (OV), the large, paired testes (TE), and eggs within the uterus (EG). (Courtesy of CDC Public Health Image Library; image courtesy of Conchology, Inc., Mactan Island, Philippines.) doi:10.1128/9781555819002.ch18.f10

Life Cycle and Morphology

The adult worm measures 1.0 to 2.5 mm by 0.4 to 0.8 mm, attaches to the mucosal wall of the small intestine, and lays embryonated eggs that are passed out with the feces into the environment (Fig. 18.10). The egg is small, brownish yellow, and operculate, with minimal opercular shoulders; it measures 26 to 28 μm by 15 to 17 μm (Table 18.1). The eggs are ingested by the snail intermediate host, *Semisulcospira*, before the miracidium is liberated. On infection of the snail, a sporocyst generation and two redia generations develop before cercariae are liberated. Cercariae encyst under the scales or in the flesh of freshwater or brackish-water fish, which are eaten uncooked or pickled by humans. The metacercariae excyst in the intestinal tract, attach to the mucosal wall, and develop to mature worms. A *Metagonimus* adult is slightly larger than a *Heterophyes* adult and has a ventral sucker that is deflected to the right of the midline axis. The genital pore is attached to the outer rim of the ventral sucker.

Clinical Disease

Symptoms and pathologic changes are similar to those produced by *H. heterophyes* and depend largely on the worm burden of the host. Clinical symptoms are generally mild and transient unless the patient is heavily infected or immunocompromised.These symptoms can include intermittent diarrhea, nausea, and abdominal pain; there may also be eosinophilia in the early stages of infection. Eggs may infiltrate into the intestinal capillaries and lymphatics and be carried to the myocardium, brain, spinal cord, and other tissues, where emboli or granulomatous reactions may occur. In these cases, serious sequelae can occur and include seizures, neurologic deficits, and cardiac insufficiency.

Major histopathological findings include villous atrophy and crypt hyperplasia, with variable degrees of inflammatory reactions. The infected mucosa shows blunting and fusion of the villi, edema of the villus tips, congestion and inflammatory cell infiltrations in the villous stroma, and decreased villus/crypt height ratios.

Diagnosis

The diagnosis is based on recovery of the eggs in the feces. Because the eggs of *M. yokogawai* are similar in shape and size to those of *H. heterophyes* and *C. sinensis*, the definitive diagnosis must be made on the basis of clinical findings, patient history, or recovery of adult worms after therapy or at autopsy. It is documented that *M. yokogawai* adults tend to burrow into the intestinal mucosa, while *H. heterophyes* tends not to invade the intestinal mucosa unless it is a heavy infection. Based on these differences, if a patient presents eggs in the stool *and* demonstrates extraintestinal signs, it is more likely, but not definitive, that the individual is infected with *M. yokogawai*.

KEY POINTS—LABORATORY DIAGNOSIS

Metagonimus yokogawai

1. The eggs are found in the stool; rarely, adult worms are found in patients with heavy infections after therapy or at autopsy.
2. The eggs of *M. yokogawai*, *H. heterophyes*, and *C. sinensis* appear almost identical and are very difficult to differentiate from one another. When passed, each egg contains a miracidium larva, but the eggs are ingested by the snail before they hatch.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The eggs have inconspicuous opercular shoulders but a more obvious operculum than *H. heterophyes* eggs and are some of the smallest trematode eggs seen. *M. yokogawai* eggs do not really have the "seated" operculum and knob at the abopercular end like those seen in *C. sinensis* eggs. They may be missed using the low power of the microscope (10× oculars and 10× objective), and high dry power may be required for identification (10× oculars and 40× objective).

Treatment

Praziquantel is the drug of choice and can be given in a single dose of 15 to 25 mg/kg at bedtime, with a 95 to 100% cure rate.

Epidemiology and Prevention

Reservoir hosts are similar to those of *H. heterophyes*. The infection is found in China, Indonesia, Israel, Japan, Korea, Russia, Siberia, Spain, Taiwan, and the Balkans. *M. yokogawai* is considered the most common intestinal fluke infection in the Far East; the prevalence tends to be high in Japan, Korea, and Taiwan, with rates of 2 to 50% being reported from Japan. Freshwater snails (*Semisulcospira* spp.) act as the first intermediate hosts, and a variety of freshwater fish act as the second intermediate hosts.

Preventive measures are similar to those proposed for *H. heterophyes*. Improved education and sanitary standards would greatly reduce the risk of infections.

Other heterophyid species have been found in areas of Asia where people eat raw or poorly cooked freshwater fish. A list of these trematodes can be found in Table 18.3.

Aquaculture. Aquaculture of fish has increased dramatically from 5.3% in 1970 to 32.2% in 2000 (10). Freshwater production has increased greatly and now accounts for 45.1% of the total aquaculture production. The production of grass carp, an important species that serves as an intermediate host for foodborne trematodes, has increased from 10,000 tons in 1950 to 3 million tons in 2002. This growth must be monitored for potential problems related to increased disease in which infection is transmitted through the ingestion of raw or poorly cooked fish. It is estimated that by 2030, at least half of the globally consumed fish will come from aquaculture.

TABLE 18.3 Other heterophyid infections reported in humans[a]

Organism[b]	Comments
Centrocestus formosanus, *Centrocestus* spp.	Reservoir hosts are fish-eating birds and mammals; reported from Taiwan and mainland China
Haplorchis pumilio, *H. yokogawai*, *Haplorchis* spp.	Reservoir hosts are fish-eating birds and mammals; reported from Taiwan, the Philippines, Indonesia, and Thailand
Metagonimus minutus, *Diorchitrema formosanum*, *D. amplicaecale*, *Metagonimus* spp.	Reservoir hosts are fish-eating birds and mammals; reported from Taiwan
Stellantchasmus falcatus, *Stellantchasmus* spp.	Reservoir hosts are fish-eating birds and mammals; reported from Hawaii (from eating raw mullet), Japan, the Philippines, Palestine, Vietnam, Korea, and Thailand
Pygidiopsis summa	Reservoir hosts are fish-eating birds and mammals; reported from Korea (up to 4,000 worms have been recovered from patients)

[a] Intestinal lesions are similar to those produced by *H. heterophyes* and *M. yokogawai*. Eggs of *H. yokogawai*, *H. pumilio*, and *H. taichui* have been found in cardiac lesions but rarely cause complications such as vascular occlusion. Treatment with praziquantel in a single dose of 15 to 25 mg/kg is effective.

[b] From Chai JY et al, *Korean J Parasitol* **47**:S69–S102, 2009.

Freshwater fish aquaculture has increased from an annual production of 136,000 tons in 1952 to 16.6 million tons 50 years later in China, the Republic of Korea, and Vietnam. Most (97.6%, 16.2 million tons) of this fish is produced in China (18). The farmed fish population has increased 100-fold globally in 60 years: from 320,000 tons in 1950, aquaculture fish production reached 32,000,000 tons in 2007.

Suitable conditions for the transmission of foodborne trematodes occur in different ecosystems (waste-fed, traditional, or wild aquaculture systems) and depend on environmental and climatic conditions, the presence of reservoir hosts, and the contamination of water bodies from human defecation and animal feces, among others (19).

Gastrodiscoides hominis

Gastrodiscoides hominis was first recovered in the late 1800s by Lewis and McConnell from an Indian patient suffering from diarrhea (3). The infection is commonly found in Assam, India. Although gastrodiscoidiasis was initially supposed to be restricted to Asian countries, this infection is now being reported in African countries (4). As a common parasite of humans and pigs, it can be found in China, India, Kazakstan, Myanmar, Pakistan, the Philippines, Thailand, Vietnam, and the Volga Delta in Russia, and in Indian immigrants in Guyana.

Life Cycle and Morphology

The complete life cycle is unknown but is probably similar to that of other amphistome trematodes; aquatic plants, crustaceans, and amphibians are thought to be involved. The adult worm is bright pink, can be found attached to the cecum and ascending colon in humans, and may produce a mucous diarrhea. In India, the planorbid snail *Helicorbis coenosus* serves as an intermediate host for this infection.

The eggs of *G. hominis* are passed in feces unfertilized, usually into some kind of water source where they are ingested by the snail intermediate host. The eggs hatch and release miracidia which develop into the sporocyst stage followed by one or more generations of redia. Finally, the redia transform into the cercarial stage. This entire process occurs in approximately 20 days. The cercaria search and penetrate a second intermediate host, such as a fish, where they encyst as metacercaria. These metacercaria can attach to vegetation as another option. The human ingests the metacercaria (approximately 30 to 150 days after being in the snail) either in the infected fish or on contaminated vegetation.

The living worm measures approximately 4 to 5 mm by 8 to 14 mm, is usually bright pink, and is pyriform in outline with a conical anterior (Fig. 18.5 and 18.11). The anterior portion measures about 2 mm. The ventral surface has a prominent acetabulum at the posterior end that bears a characteristic notch. The eggs are greenish brown, operculated, and immature when laid; they measure 60 to 70 µm by 150 µm.

Clinical Disease

The adult worms live in the cecum and ascending colon; symptoms are related to the overall worm burden. In light infections the patient may be asymptomatic, while in heavier infections there may be a mucous diarrhea; lymphocytes, plasma cells, and eosinophils infiltrate the mucosa and submucosa (8). At the attachment site, papular lesions with surface desquamation may lead to necrosis.

Diagnosis

The diagnosis is based on recovery of eggs in the feces. They resemble the eggs of *F. buski* but tend to be more slender. A definitive diagnosis could be made on the basis of clinical findings, patient history, geographic area, or recovery of adult worms after therapy or at autopsy.

KEY POINTS—LABORATORY DIAGNOSIS

Gastrodiscoides hominis

1. The eggs are found in the stool; rarely, adult worms are found after therapy or at autopsy in patients with heavy infections.
2. The eggs of *G. hominis*, *F. buski*, *E. ilocanum*, *F. hepatica*, and *F. gigantica* appear very much alike and can be difficult to differentiate from one another. When passed, these eggs do not contain mature larvae but instead contain undifferentiated embryos. The egg of *G. hominis* tends to be a bit smaller and more slender than that of *F. buski*, but they are very similar.
3. The formalin-ethyl acetate sedimentation concentration is recommended for egg recovery; operculated eggs do not float in the zinc sulfate flotation concentration method.
4. The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the "breaks" in the shell may be difficult to identify. This egg has no opercular shoulders, and so it is difficult to see where the operculum "breaks" in the shell actually occur.

Treatment

Praziquantel is the drug of choice and is administered as a single 15-mg/kg dose after the evening meal or at bedtime. A second regimen consists of 75 mg/kg/day in three doses for 1 day. Apparently, children tend to tolerate the drug better than adults.

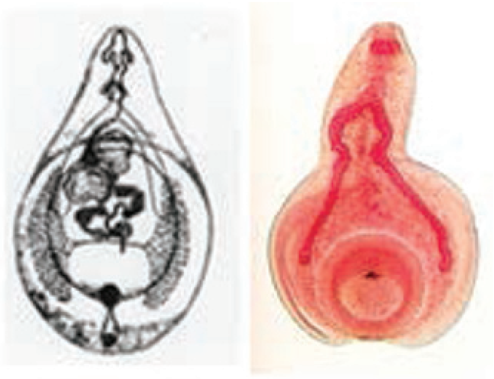

Figure 18.11 *Gastrodiscoides hominis* adult worms. Note the pyriform shape and the deep concavity on the ventral surface, which contains a large sucker. The adult worms measure 8 to 14 mm in length by 4 to 5 mm in width and are usually bright pink. (Illustration by Sharon Belkin. Adapted from references 3 and 8.) (Right image courtesy of http://www.med.cmu.ac.th/dept/parasite/trematodes/GhAd.htm.)
doi:10.1128/9781555819002.ch18.f11

Epidemiology and Prevention

G. hominis is commonly found in Asia and has been reported from Assan, Bihar, and Orissa in India, as well as from China, Kazakhstan, Myanmar, the Philippines, Thailand, Vietnam, and Guyana. One study in India found a 41% prevalence rate in which pigs were the reservoir host. Other reservoir hosts include deer mice in Malaysia and rats in Indonesia, Japan, and Thailand. Prevention of this disease is not difficult when simple sanitary measures are taken. Night soil should never be used as a fertilizer because it could contain any number of parasites, including the eggs of *G. hominis* in endemic areas. All fish should be thoroughly cooked and/or potentially contaminated vegetation should be thoroughly washed before ingestion.

Liver and Lung Trematodes

Liver Flukes

Clonorchis sinensis

Opisthorchis viverrini

Opisthorchis felineus

Fasciola hepatica

Fasciola gigantica

Less Common Liver Flukes

Dicrocoelium dendriticum, *Dicrocoelium hospes*, and *Eurytrema pancreaticum*

Lung Flukes

Paragonimus westermani

Paragonimus kellicotti

Clonorchis, *Opisthorchis*, and *Fasciola* spp. are trematodes that parasitize the biliary ducts of humans. *Clonorchis* and *Opisthorchis* spp. are narrow, elongate worms that localize in the more distal, smaller ducts of the biliary tree. *Fasciola hepatica*, because of its much larger size, resides in the larger bile ducts and gallbladder.

Paragonimus spp., also known as lung flukes, cause paragonimiasis in humans. The adults encapsulate in the lungs and are occasionally found in other body sites.

The infections caused by the liver and lung trematodes are food borne and have considerable economic and public health impact. It is estimated that more than 50 million people have acquired foodborne trematode infections. It is estimated that 601 million, 293 million, 91 million, and 80 million people are at risk of infection with *Clonorchis sinensis*, *Paragonimus* spp., *Fasciola* spp., and *Opisthorchis* spp., respectively (1). Of great public health concern is cholangiocarcinoma associated with *Clonorchis* and *Opisthorchis* infections, severe liver disease associated with *Fasciola* infections, and the misdiagnosis of tuberculosis in those infected with *Paragonimus* spp.

Liver Flukes

Clonorchis sinensis

McConnell was the first to describe the adult worms and pathologic changes caused by *C. sinensis*, in a Chinese patient who died in Calcutta, India. The complete life cycle was developed in a number of publications by Iijima in 1887, Saito in 1898, Kobayashi in 1914, and Muto in 1918 (2). *C. sinensis* is also known as the Chinese or oriental liver fluke (Table 19.1).

Life Cycle and Morphology

The definitive hosts of *C. sinensis* are humans, dogs, hogs, cats, martens, badgers, mink, weasels, and rats. Adult worms deposit eggs in the bile ducts, and the eggs are discharged with the bile fluid into the feces and passed out into the environment (Fig. 19.1). An adult fluke can produce 1,000 to 4,000 eggs/day for at least 6 months. The eggs are fully embryonated when laid and measure 28 to 35 µm by 12 to 19 µm (Fig. 19.2). The eggs are ovoid, with a thick, pale

doi:10.1128/9781555819002.ch19

TABLE 19.1 Characteristics of liver and lung trematodes

Species	Distribution	Agent of infection	Reservoir host	Egg		
				Size (µm)	Morphology	Comments
Clonorchis sinensis	Far East	Uncooked fish	Dogs, cats, other fish-eating mammals	28–35 by 12–19	Embryonated, operculated	Very prominent opercular shoulders; has a "seated" operculum and knob at the abopercular end.
Opisthorchis viverrini	Northern Thailand, Laos	Uncooked fish	Dogs, cats, other fish-eating mammals	19–29 by 12–17	Embryonated, operculated	Prominent opercular shoulders; has a "seated" operculum and may or may not have a knob at the abopercular end; eggs tend to be broader with less prominent shoulders than *C. sinensis* eggs.
Opisthorchis felineus	Poland, Germany, Russian Federation, Kazakhstan, western Siberia	Uncooked fish	Dogs, cats, other fish-eating mammals	28–30 by 11–16	Embryonated, operculated	Prominent opercular shoulders; has a "seated" operculum and may or may not have a knob at the abopercular end; eggs tend to be broader with less prominent shoulders than *C. sinensis* eggs.
Fasciola hepatica	Worldwide; mixed *F. hepatica* and *F. gigantica* infections have been reported from Pakistan	Uncooked water plants	Herbivores	130–150 by 63–90	Unembryonated, operculated	The less mature the egg, the more difficult it may be to see the actual operculum—it blends into the shell outline, and the "breaks" in the shell may be difficult to identify. This egg has no opercular shoulders, and so it is difficult to see where the operculum breaks in the shell actually occur. Eggs resemble those of *F. buski*, *E. ilocanum*, *F. gigantica*, and *G. hominis*; eggs may have thickening at the abopercular end of the shell (unlike eggs of *F. buski*).
Fasciola gigantica	Africa, southern Europe, southern United States, Hawaii, former Soviet Union, Middle East, Southeast Asia	Uncooked water plants	Herbivores	160–190 by 70–90; egg is larger than *F. hepatica*	Unembryonated, operculated	The egg is larger than that of *F. hepatica*; both *F. hepatica* and *F. gigantica* worms have been found in ectopic sites.
Dicrocoelium dendriticum, *D. hospes*, *Eurytrema pancreaticum*	Europe, Turkey, northern Africa, Far East, China, Japan, North and South America	Ants, grasshoppers, crickets	Cattle, sheep, deer, water buffalo	38–45 by 22–30; dark brown	Embryonated, operculated, thick shell	Eggs have a thick, dark brown shell and essentially no opercular shoulders; they cannot be differentiated from each other.
Paragonimus westermani	Far East, Africa	Crabs, crayfish	Dogs, cats, tigers, lions	80–120 by 45–65	Unembryonated, operculated	Eggs have a moderately thick, dark golden-brown shell, a prominent operculum, opercular shoulders, and a thickened abopercular end; may be confused with *D. latum* eggs (smaller, abopercular knob).
P. kellicotti	North America	Crayfish	Dogs, cats, bobcats, raccoons, foxes, skunks, minks, coyotes	75–118 by 48–68	Unembryonated, operculated	Eggs have a moderately thick, dark golden-brown shell, a prominent operculum, opercular shoulders, and a slightly thickened abopercular end; tapers more sharply than *P. westermani*; may be confused with *D. latum* eggs (smaller, abopercular knob).
P. mexicanus	Central and South America	Crabs	Opossum, cats, dogs	60–70 by 42–56	Unembryonated, operculated	Thin, irregular undulations on outer shell; eggs have a prominent operculum, opercular shoulders, and a thickened abopercular end; may be confused with *D. latum* eggs (smaller, abopercular knob); eggs smaller than *P. westermani;* also golden-brown shell.

brownish yellow shell and an operculum. There are distinct opercular shoulders surrounding the operculum. Frequently, the eggs contain a comma-shaped appendage at the abopercular end. Eggs are ingested by the snail host, at which time the miracidium hatches to infect the snail; *Parafossarulus* and *Bithynia* are the most suitable hosts. More than 100 species of snails can serve as an intermediate host for *C. sinensis*. The snails generally live in ponds used for commercial fish raising, lakes, and slow-moving water, and the overall infection rate is relatively low (3). Sporocyst and redia generations are produced in about 4 to 5 weeks before cercariae are released to encyst in the skin or flesh of freshwater fish. Numerous species of freshwater fish, mostly belonging to the family Cyprinidae, serve as the second intermediate host. After a few days in the fish muscle, the cercariae become encysted and form metacercariae. Humans become infected by ingesting the metacercariae in raw or incompletely cooked fish.

Metacercariae excyst in the duodenum, enter the common bile duct, and travel to the distal bile capillaries, where the worms mature over a period of about a month (Fig. 19.3 and 19.4). The life cycle takes approximately 3 months to complete in humans. Reservoir hosts include dogs, cats, pigs, mink, rats, and other fish-eating mammals.

The adult worm is a small trematode with an elliptical shape and an average length of 10 to 25 mm. The trematode is a true hermaphrodite and has a life span of 20 to 25 years, which explains the persistent infection for a long duration.

Clinical Disease

Most patients with mild infections of fewer than 100 flukes have few symptoms, which may include general malaise, abdominal discomfort, and diarrhea. In 10 to 40% of patients, peripheral eosinophilia occurs with fluctuating obstructive jaundice. Moderate infections with fewer than 1,000 worms include symptoms of fever and chills, fatigue, anorexia, diarrhea, weight loss, discomfort, and abdominal distention. In severe disease with up to 20,000 flukes, an additional symptom may include acute right upper quadrant pain. In the late stage of severe cases, jaundice, diarrhea, portal hypertension, hepatosplenomegaly, ascites, and edema can occur.

In general, the complications of clonorchiasis are the result of biliary obstruction. As the worms mature in the

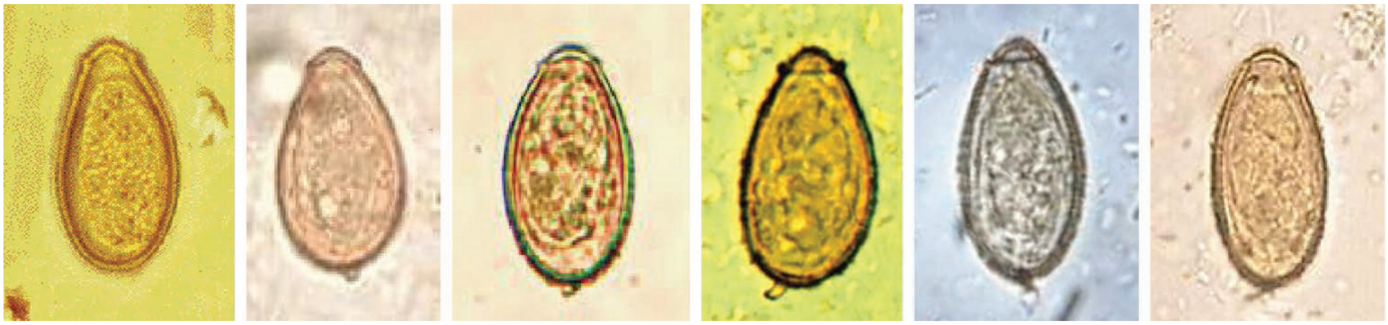

Figure 19.2 Eggs of *Clonorchis sinensis*. Note the range of sizes and shapes. doi:10.1128/9781555819002.ch19.f2

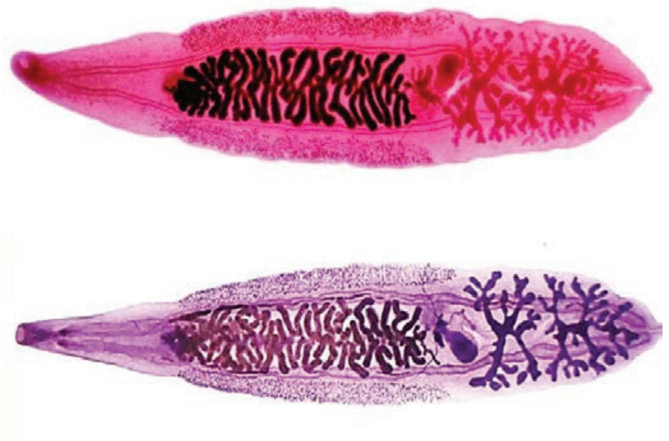

Figure 19.3 *Clonorchis sinensis* adults (10 to 25 mm long by 3 to 5 mm wide). (Upper, Armed Forces Institute of Pathology photograph; lower, CDC Public Health Image Library.) doi:10.1128/9781555819002.ch19.f3

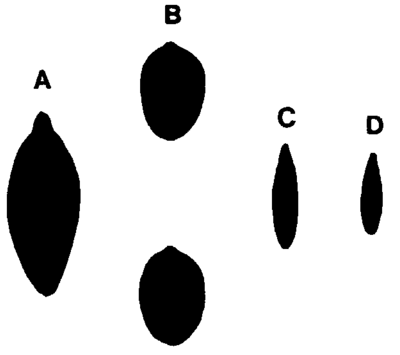
distal bile ducts, an inflammatory response is seen in the biliary epithelium. The extent of pathologic changes is related to the intensity and duration of infection (Algorithm 19.1). The lesions are confined mainly to the biliary system and are the result of mechanical irritation and toxins produced by the worms. In light infections, there appears to be little or no change in liver parenchyma, whereas heavy infections cause thickening and localized dilations of the bile ducts with hyperplasia of the mucinous glands. As a result, the biliary tract may become obstructed, causing bile retention, infiltration of lymphocytes and eosinophils, and fibrosis (Fig. 19.5). The adenomatous changes may persist for many years in patients with light infections. The infections have been associated with obstructive jaundice, which may be aggravated by biliary stones and liver abscesses. Many patients infected with *C. sinensis* have recurrent pyogenic cholangitis. There is no direct evidence that infection with *C. sinensis* causes chronic bacterial infection. Acute pancreatitis, cholecystitis, and cholelithiasis may be the result of worm invasion. Cirrhosis is probably related to malnutrition rather than parasitic infections. Evaluation by computed tomography (CT) has shown that in the presence of diffuse mild intrahepatic bile duct dilation, enlargement of the body or tail (or both) of the pancreas, with a cluster of small cystic changes within the pancreatic parenchyma, provides strong evidence of *C. sinensis* pancreatitis (4).

Figure 19.4 Adult liver and lung trematodes. (A) *Fasciola hepatica*; (B) *Paragonimus westermani*; (C) *Clonorchis sinensis*; (D) *Opisthorchis viverrini* and *O. felineus*. doi:10.1128/9781555819002.ch19.f4



In light infections, the patient generally experiences no symptoms. In heavier infections acquired over time, the patient may experience dull pain and abdominal discomfort that may last for 1 to 2 h, often in the afternoon. As the disease progresses, the duration of pain lengthens and the pain may become so severe that the patient is unable to work. Patients who have had the disease for a long time show liver enlargement with some degree of functional impairment that is secondary to biliary obstruction. Acute infections caused by ingestion of large numbers of metacercariae cause fever, chills, diarrhea, epigastric pain, enlarged tender liver, and possibly jaundice within a month of ingestion. The acute symptoms last for about 1 month and subside at about the time when eggs are detected in the stool. In chronic infections, cholangitis, cholelithiasis, pancreatitis, and cholangiocarcinoma are common complications and can lead to death (5, 6).

Cholangiocarcinoma. Liver flukes play a major role in East Asia, while exposure to chemical compounds, such as naphthenic acids, has been postulated as a source of the rate increase of cholangiocarcinoma in Western countries. *C. sinensis* has been linked to neoplasms of the bile duct and to cholangiocarcinoma (5, 7), which is most frequently observed in areas where clonorchiasis is endemic. Cholangiocarcinoma is a malignant tumor that arises from the bile duct epithelium and is the second most prevalent liver cancer after hepatocellular carcinoma. The tumor usually occurs in patients 60 to 80 years of age and rarely in patients younger than 40 years. There appears to be no direct link between infection and carcinoma, although one of the first steps in malignant transformation may be induced by the biliary tract hyperplasia caused by the worms. Patients with primary sclerosing cholangitis (PSC) have a substantial predisposition for bile duct carcinoma. Although the exact mechanisms are not well defined, longstanding inflammation can lead to cholangiocarcinoma in patients with chronic *C. sinensis* infection. PSC is an uncommon disease, characterized by stricturing, fibrosis, and inflammation of the biliary tree, which is closely associated with chronic inflammatory bowel disease, particularly ulcerative colitis. The only effective treatment for PSC is

orthotopic liver transplantation, which in the absence of cholangiocarcinoma has a 5-year survival rate of 89%. However, patients with cholangiocarcinoma who undergo liver transplantation have a high risk of recurrence and poor survival statistics. Between 10 and 20% of patients with PSC will go on to develop a cholangiocarcinoma (9). Therefore, identification of patients with deteriorating liver function prior to the development of cholangiocarcinoma remains an important goal in the management of PSC, particularly in areas where *C. sinensis* infection is endemic (10). It is also probable that cofactors play a role; liver flukes are promoters and not initiators of cholangiocarcinoma (7). It has been suggested that regular biliary cytologic sampling to detect dysplasia can predict the development of cholangiocarcinoma; however, this approach is unlikely to be widely used. In the Far East, forms of chronic inflammation associated with cholangiocarcinoma include infestation with either of the liver flukes, *C. sinensis* or *Opisthorchis viverrini*.

The interaction of interleukin-6 (IL-6), transforming growth factor beta (TGF-β), tumor necrosis factor alpha (TNF-α), and platelet-derived growth factor (PDGF) are at the basis of the proliferation of biliary epithelial cells or cholangiocytes. Additional steps for the final development of cholangiocarcinoma probably also involve an increase of the mutation rate of tumor suppressor genes, such as TP53, and the evasion of apoptosis (11).

Diagnosis

Fecal Examination. Individuals who have lived in areas where infections are endemic, have a history of eating raw freshwater fish, and have symptoms of upper abdominal pain, indigestion, diarrhea, and hepatomegaly may be suspected of having liver trematode infection. Eggs can be detected in the feces by direct microscopy or by examination of fecal concentrates. Sedimentation concentration is recommended since these eggs have opercula and do not float in the zinc sulfate flotation concentration method. Sedimented material can be examined using saline or D'Antoni's iodine or both. It is important not to add too much iodine; if the eggs stain too darkly, they may resemble debris. In light infections, egg counts may be low and so multiple specimens may be required to confirm their presence. The eggs of *C. sinensis* (Fig. 19.2) and *O. viverrini* are similar in size and shape to those of *Heterophyes heterophyes* and *Metagonimus yokogawai* and cannot be readily differentiated from them. If a patient has not resided in or recently visited areas where infections are endemic, the infection is probably due to *C. sinensis* or *O. viverrini*. The infection may be confirmed by detecting eggs in the bile fluid (duodenal aspirate), by recovering adult worms, or from the clinical history. Some strains of *C. sinensis* produce eggs that have a comma-shaped appendage at the abopercular end. Multiple egg measurements are usually required to determine size differences; however,

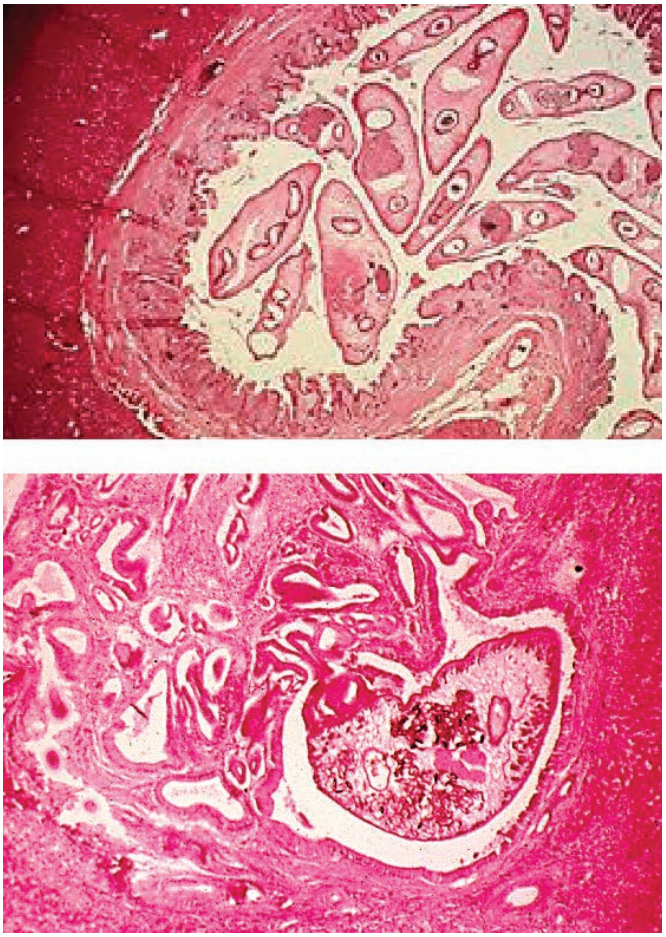

Figure 19.5 *Clonorchis sinensis* adult in a biliary duct (cross section). (Upper, http://usmlepathslides.tumblr.com/post/21383019000/common-bile-duct-with-clonorchis; lower, from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch19.f5

absolute identification among the small trematode eggs can be very difficult. Eggs can also be seen in duodenal drainage material or, if the Entero-Test capsule is used, in the mucus removed from the string. Definitive identification usually requires examination of adult worms recovered after therapy or during surgery or autopsy.

Eggs are generally not found in stool specimens from patients with biliary obstruction. Consequently, needle aspiration, surgery, or autopsy specimens may be required to confirm their presence. In these patients, biliary obstruction must be differentiated from enlarged gallbladder, cholangitis with jaundice, liver carcinoma, and cholangiocarcinoma.

Serologic Methods. IgE and *C. sinensis*-specific IgE levels in serum are elevated in infected individuals. In patients with acute infections, there is an increase in IgM levels in serum followed by increases in IgA and IgG levels. In patients with chronic infections, the IgA level returns to normal while the IgG and IgM levels remain elevated. The intradermal test is no longer used due to its very low specificity. An enzyme-linked immunosorbent assay (ELISA) for the detection of antibodies against *C. sinensis* has also been used (12). A recombinant propeptide of cathepsin L proteinase (rCsCatL-propeptide) used in an ELISA appears to be a valuable candidate for specific IgG4 detection in sera from clonorchiasis patients. This ELISA has minimal cross-reactions and acceptable sensitivity. In addition, specific IgG4 detection can be used to evaluate the level of infection and therapeutic effect in clonorchiasis patients (13). A multiplex PCR approach has proven to be species specific, sensitive, and rapid in the accurate diagnosis of clonorchiasis and/or opisthorchiasis. This test can be used for the detection of metacercariae in infected fish or adult worms or eggs from patients in areas of endemic infection (14).

Radiological Screening. Cholangiography, ultrasonography, and liver scans may reveal lesions consistent with liver fluke infection. Clonorchiasis is often diagnosed incidentally during abdominal ultrasonography, since symptoms tend to be nonspecific. However, none of these methods is any more sensitive than fecal examination because of their limited sensitivity and specificity (15). According to a study carried out in an endemic area, the sensitivity of ultrasonography was 52% and its specificity was 51%. The low sensitivity was due to false-negative cases with mild infection, and the low specificity was due to false-positive cases with residual pathology after cure (16). This low specificity becomes more of an issue as the number of patients cured continues to increase due to extended control measures and changes in the ecological environment. Thus, ultrasonography becomes less helpful in the differentiation between cured and active infections. The pathological changes in the bile ducts may persist for years after cure and may not indicate the presence of the viable worms. CT results are essentially the same as those observed by ultrasonography, with mild, uniform dilatation of the peripheral intrahepatic bile ducts without a focal obstructing lesion.

Peripheral cholangiocarcinoma is usually seen as a large, well-defined hepatic mass with lobulated margins. CT and magnetic resonance imaging (MRI) reveal band-like peripheral contrast enhancement of variable thickness around the tumor during the early phase, with progressive filling of contrast material in the later stages. This appearance occurs through slow diffusion of contrast materials into the interstitial spaces of the tumor. Fibrosis within this type of cholangiocarcinoma also contributes to the delayed contrast enhancement of the tumor. Additional findings in peripheral cholangiocarcinoma include capsular retraction and dilatation of the peripheral intrahepatic ducts (17).

Most hilar and extrahepatic cholangiocarcinomas cause a focal stricture of the bile duct, whereas papillary carcinoma is occasionally found in the form of a polypoid mass within the duct. By thin-section CT, this tumor type can be seen as an ill-defined focal wall thickening. Using ultrasonography, the tumor can appear as a thickening or encircling mass along the bile duct wall. In a number of cases, the infiltrating tumor is seen by either ultrasonography or CT as a simple nonunion of the dilated right and left hepatic ducts without any identifiable mass. Cholangiography shows a focal or diffuse stricture or complete obstruction of the bile ducts; from this image the extent of the disease can be determined (17).

Radiological findings are regarded as pathognomonic for clonorchiasis because they demonstrate the unique pathological changes of this disease. Due to remarkable advances in imaging technology, individual flukes can now be seen using noninvasive radiological techniques.

KEY POINTS—LABORATORY DIAGNOSIS

Clonorchis sinensis

1. Multiple stool specimens may be required to find the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 30 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *C. sinensis* can resemble those of many other intestinal and liver trematodes.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. Some strains of *C. sinensis* and *O. viverrini* produce eggs that have a comma-shaped appendage at the abopercular end; this finding generally differentiates the liver fluke eggs from those of the intestinal flukes *Heterophyes heterophyes* and *Metagonimus yokogawai*.
8. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
9. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Praziquantel is the drug of choice for treatment of *C. sinensis* infections. It has very few or limited side effects but is not recommended for use during pregnancy. The recommended dose is 75 mg/kg after meals three times a day for 1 or 2 days (18, 19). These regimens yielded 85 and 100% cure rates, respectively. The majority of patients do well, with the exception of those who have pyogenic cholangitis, obstructive jaundice, or cholangiocarcinoma. Common reactions are usually mild and include abdominal pain, diarrhea, dizziness, sleepiness, and headache. It is recommended that praziquantel be given before sleep at night. However, in rare instances, praziquantel may cause allergic, anaphylactic, or hypersensitivity reactions in some individuals. Albendazole may be used as an alternative drug. Once cholangiocarcinoma is diagnosed, complete resection with negative histologic margins provides the greatest chance for long-term survival. Unfortunately, cholangiocarcinoma responds poorly to chemotherapy.

Epidemiology and Prevention

Humans, dogs, cats, and other fish-eating mammals are reservoir hosts and, in some areas, the sole cause of continual transmission. Recent estimates of the number of cases of this infection in parts of Asia were as follows: China (12.5 million), Hong Kong (333,000), Japan (only occasional cases), Korea (1.17 million), Macao (21,000), Taiwan (89,000), and Vietnam (1 million), for a total of approximately 15 million (3, 20). Infections have also been documented in Russia, Malaysia, other parts of Asia, Europe, North America, South America, Australia, and Africa, but it is no longer endemic in Japan. Natives of Hawaii also harbor the infection, which is contracted through the ingestion of frozen, pickled, or dried fish imported from areas of endemicity. Human infections result from the widely prevalent practice of consumption of metacercaria-infested freshwater fish eaten uncooked, pickled, smoked, salted, or dried. The traditional eating habits which are a part of a cultural heritage are very difficult to change. In the past few years, clonorchiasis has often been found in refugee immigrants from areas of endemic infection who are resident in the United States, Canada, France, or Australia. Participants in laboratory proficiency testing programs have improved their ability to identify these eggs in challenge stool samples, thus increasing the probability that patients who are infected with *C. sinensis* will be diagnosed. In 2009, it was also estimated that about 681 million people worldwide are at risk of infection and more than 46 million people are infected with liver flukes (*C. sinensis* and *Opisthorchis* sp.) (21).

The life cycle is perpetuated by humans or reservoir hosts defecating in or near freshwater sources containing suitable species of snails. In areas where fish cultivation is of economic importance, toilets have been built over ponds to provide a source of fish food. Operculate snails noted to be infected are *Parafossarulus*, *Bulinus*, *Semisulcospira*, *Alocinma*, and *Melanoides* spp. Metacercariae can encyst in numerous species of freshwater fish.

Aquaculture. Fish aquaculture as a proportion of global fish production has increased dramatically from 5.3% in 1970 to 32.2% in 2000 (1). Freshwater fish production has increased dramatically and now accounts for 45.1% of the total aquaculture production. The production of grass carp, an important species that serves as an intermediate host for food-borne trematodes, has increased from >10,000 tons in 1950 to >3 million tons in 2002. Growth of this industry must be monitored for potential problems related to an increased incidence of disease in which infection is transmitted through the ingestion of raw or poorly cooked fish. Freshwater fish aquaculture has increased from an annual production of 136,000 tons in 1952 to 16.6 million tons 50 years later in China, the Republic of Korea, and Vietnam. Most (97.6%, 16.2 million tons) of this fish is produced in China (1). The farmed fish population has increased 100-fold globally in 60 years: from 320,000 tons in 1950, aquaculture fish production reached 32,000,000 tons in 2007. It is estimated that by 2030, at least half of the fish consumed globally will come from aquaculture farming.

In one study of fish farms in Vietnam, the prevalence of fish-borne zoonotic trematodes in fish increased by 11 percentage points during a 1-year culture period. It was also emphasized that the young fish were already highly infected when stocked into the grow-out systems (22).

Prevention. The life cycle can be broken and infection can be prevented in humans by thorough cooking of all freshwater fish. Although cultural habits are difficult to change, public health education can be used to modify them. Night soil used for fertilizer without disinfection should not be applied in lakes or ponds containing susceptible snails. It has been suggested that night soil should be stored prior to use; eggs of *C. sinensis* die within 2 days when stored at 26°C.

Opisthorchis viverrini

Liver fluke infections with *Opisthorchis viverrini*, *Opisthorchis felineus*, and *Clonorchis sinensis* continue to be a major public health problem in many areas within Asia and Eastern Europe. *O. viverrini* has been reported to infect a significant portion of the population in northern Thailand and Laos. In some areas, the prevalence was 100% for age groups older than 10 years, and it is estimated that 10 million people are infected (23) (Table 19.1). Although the overall prevalence rate has been reported to be 35%, there are some areas where it is greater than 90%. There is an association between infection with *O. viverrini* and carcinoma of the bile duct epithelium (cholangiocarcinoma) (24, 25).

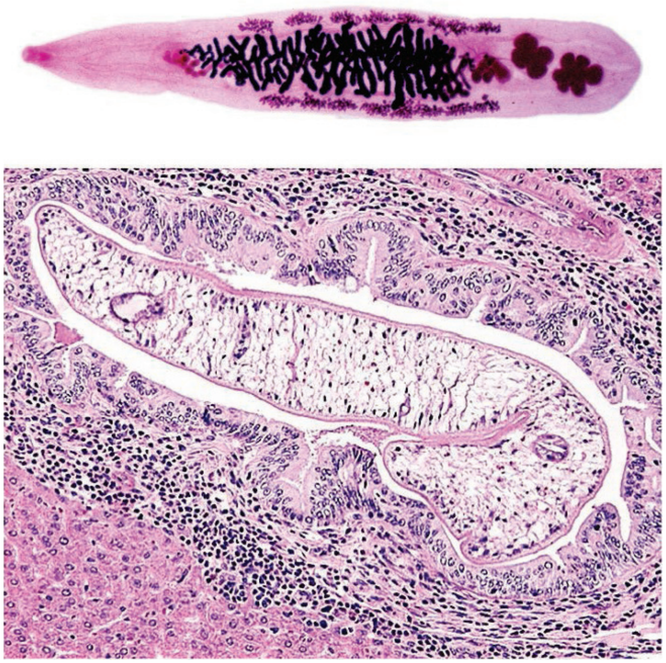
Life Cycle and Morphology

Adult worms in distal bile ducts produce eggs that are carried by the bile to the intestinal lumen and to the outside environment in the feces (Fig. 19.1, 19.4, and 19.6). The eggs are brownish yellow, oval, and operculated; they have opercular shoulders and may have a comma-shaped appendage at the abopercular end. The egg size averages 27 by 15 μm. The life cycle is similar to that of *C. sinensis*, requiring developmental periods in susceptible snails and finally in freshwater fish, in which the metacercariae encyst. Metacercariae excyst in the duodenum of the mammalian host and migrate to the intrahepatic bile ducts, where they develop to mature adults. The adult worms are transparent and leaf-shaped and measure approximately 8 to 12 mm long (Fig. 19.4). The length-to-width ratio is similar to that of *C. sinensis*; therefore, the two can be confused. The life span of *O. viverrini* can exceed 20 years.

Clinical Disease

Individuals who have lived in areas where infections are endemic, who have a history of eating raw fish, and have

Figure 19.6 *Opisthorchis viverrini*. (Upper) Adult trematode (courtesy of CDC Public Health Image Library). (Lower) Adult trematode in bile duct of experimentally infected hamster (from Sripa B, *PLoS Negl Trop Dis* **2**:e232, 2008, doi:10.1371/journal.pntd.0000232). doi:10.1128/9781555819002.ch19.f6



symptoms of right upper abdominal pain, indigestion, diarrhea, and hepatomegaly may be suspected of having liver trematode infection. Pain usually appears in the late afternoon and lasts several hours. This infection is associated with a number of hepatobiliary abnormalities, including cholangitis, obstructive jaundice, hepatomegaly, periductal fibrosis, cholecystitis, and cholelithiasis. As with *C. sinensis*, the pathologic changes are confined mainly to the biliary tract system and morbidity is significantly associated with the worm burden of the host. Intensity of infection is correlated with clinical signs of abdominal pain, flatulence, weakness, hepatomegaly, cholangitis, chronic cholecystitis, cholelithiasis, and obstructive jaundice. Patients with heavy worm burdens may have severe cirrhosis, ascites, pedal edema, and acute abdominal pain. There may be severe jaundice, secondary infection of the biliary system (as seen with *C. sinensis*), cholangitis, and hepatomegaly. The bilirubin transaminase level tends to be elevated, while the serum albumin is low.

Cholangiocarcinoma. The association between cholangiocarcinoma and liver flukes has been documented for approximately 60 years. Apparently, chronic *O. viverrini* infection and the development of cholangiocarcinoma is the strongest association between a parasitic infection and cancer and is even stronger than the link between *Schistosoma haematobium* infection and squamous cell carcinoma. A large number of individuals with *O. viverrini* infection have cholangiocarcinomas, which were confirmed at autopsy. The biliary epithelium may be highly susceptible to malignant transformation because of chronic proliferation due to *O. viverrini* infection. There is a significant relationship between the intensity of infection and cholangiocarcinoma, and there is a high prevalence of the disease among males (7, 24, 25). There is a definite relationship between a high risk of liver cancer and infestation with *O. viverrini* in northeastern Thailand. However, in other areas of the country where the prevalence of liver cancer is high, there is little to no exposure to *O. viverrini* infection. Case-control studies suggest that exposure to exogenous and possibly endogenous nitrosamines in food, tobacco, and betel nut may play a role in the development of hepatocellular carcinoma, while infestation with *O. viverrini* and chemical interaction of nitrosamines may also be etiologic factors in the development of cholangiocarcinoma (26). Carcinomas of the biliary tract are rare cancers developing from the epithelial or blast-like cells lining the bile ducts. A variety of known predisposing factors, including infection with *O. viverrini*, have been identified. Chronic inflammatory processes, generation of active oxygen radicals, altered cellular detoxification mechanisms, activation of oncogenes, functional loss of tumor suppressor genes, and dysregulation of cell proliferation and apoptotic mechanisms have been identified as important contributors to the development of cholangiocarcinomas (25, 27). Approximately 20,000 worms have been recovered from a single individual at autopsy.

As the flukes feed on the biliary epithelium, they cause damage from mechanical injury and the inflammatory response to this process. Excretory-secretory proteins are released from the tegument and excretory pore of the worms into the bile, some of which are highly immunogenic. These proteins have been associated with cancers; they include proteases of different mechanistic classes and are similar to mammalian growth factors and antiapoptotic proteins. A cysteine protease inhibitor has also been identified which, in other helminth pathogens, induces nitric oxide production by macrophages and may contribute to malignant transformation of inflamed cells (28).

Diagnosis

Fecal Examination. Eggs can be detected in the feces by direct microscopy or by examination of fecal concentrates. Sedimentation concentration is recommended since these eggs have opercula and do not float in the zinc sulfate flotation concentration method. Sedimented material can be examined using saline or D'Antoni's iodine or both. It is important not to add too much iodine; if the eggs stain too darkly, they may resemble debris. In light infections, egg counts may be low and so multiple specimens may be required to confirm their presence. The eggs of *O. viverrini* and *C. sinensis* are similar in size and shape to those of *H. heterophyes* and *M. yokogawai* and cannot be readily differentiated from them. If a patient has not resided in or recently visited areas where infections are endemic, the infection is probably due to *O. viverrini* or *C. sinensis*. The diagnosis can be confirmed by detecting eggs in the bile fluid (duodenal aspirate), by recovering adult worms, or from the clinical history. Like *C. sinensis*, some strains of *O. viverrini* produce eggs that have a comma-shaped appendage at the abopercular end. Differentiation is difficult without a patient history. Multiple egg measurements are usually required to determine size differences; however, absolute identification among the small trematode eggs can be very difficult. Eggs can also be seen in duodenal drainage material or if the Entero-Test capsule is used. Definitive identification usually requires examination of adult worms recovered after therapy or during surgery or autopsy.

Eggs are not found in stool specimens from patients with biliary obstruction, so needle aspiration, surgery, or autopsy specimens may be required to confirm their presence. In these patients, biliary obstruction must be differentiated from enlarged gallbladder, cholangitis with jaundice, liver carcinoma, and cholangiocarcinoma.

Serologic Methods. Elevated IgE levels in serum of up to three or four times normal can be detected in infected patients (29). There is an early rise in the serum levels of IgM followed by elevations of IgA and IgG. In chronic infections, the IgG and IgM levels remain elevated whereas the IgA levels return to normal (30). DNA hybridization and detection of antigen have been used to detect infections in stool (31). DNA hybridization and antigen detection methods have not been extensively tested in areas where infections are endemic but may be slightly better than classical methods of detection (32). Although serologic diagnostic tests for detection of antibodies have been developed, they are not widely available, are not standardized, and give false-positive results due to cross-reactivity with other parasitic diseases (33).

Radiological Screening. Cholangiography, ultrasonography, and liver scans may reveal lesions consistent with liver fluke infection. However, over 75% of patients with this infection tend to have normal ultrasonograms.

Molecular Methods. A single-step duplex real-time fluorescence resonance energy transfer (FRET) PCR merged with melting curve analysis has been developed for the fast detection and differentiation of *C. sinensis* and *O. viverrini* eggs in human fecal samples. *C. sinensis* and *O. viverrini* eggs in infected human fecal samples were detected and differentiated with high (100%) sensitivity and specificity. The detection limit was as little as a single *C. sinensis* egg and two *O. viverrini* eggs in 100 mg of fecal sample. The assay could distinguish the DNA of these two flukes from the DNA of negative fecal samples, fecal samples containing other parasites, and the DNA of human leukocytes. This test would be helpful in determining the accurate range of endemic areas and/or to confirm the co-endemic areas of *C. sinensis* and *O. viverrini* in Asia. This approach also would be valuable for the differential diagnosis of the suspected cases of liver fluke infections among travelers who had visited the endemic countries of these parasites (34). Although this is not the only molecular test, these methods are generally not routinely available, even in endemic areas.

KEY POINTS—LABORATORY DIAGNOSIS

Opisthorchis viverrini

1. Multiple stool specimens may be required to find the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 30 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *O. viverrini* can resemble those of many other intestinal and liver trematodes.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. Some strains of *O. viverrini* and *C. sinensis* produce eggs that have a comma-shaped appendage at the abopercular end; this finding differentiates the liver fluke eggs from those of the intestinal flukes *Heterophyes heterophyes* and *Metagonimus yokogawai*.
8. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
9. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

In patients with asymptomatic and mild to moderate cases, 75 mg of praziquantel per kg given three times after meals in a single day, or a single dose of 40 mg/kg, is 100 and 90% effective, respectively (18, 19). In those with heavy infections, a single dose of 50 mg/kg produces a cure rate of 97% (3). No eggs are recovered in the stool after about a week; however, clinical symptoms and gallbladder dysfunction may take several months to resolve. Any side effects can be minimized by administration of the single-dose regimen at bedtime.

Mebendazole has also been given at 30 mg/kg/day for 3 or 4 weeks, with cure rates of 89 and 94%, respectively. No adult worms were recovered after therapy (3).

It is important to remember that only 5 to 10% of cases are relieved with praziquantel alone and that relapsing cholangitis and obstructive jaundice may require the use of antimicrobials. For complicated cases, surgery may also be required. Unfortunately, cholangiocarcinoma associated with *O. viverrini* infection carries a poor prognosis.

Epidemiology and Prevention

Dogs, cats, and other fish-eating mammals including humans are reservoir hosts. The infection has been reported to occur in Cambodia, Laos, and Thailand. In Southeast Asia, close to 70% of the population may be infected in some villages. Human infections result from the widely prevalent practice of consumption of metacercaria-infested freshwater fish eaten uncooked, pickled, smoked, salted, or dried. *Bithynia* snails are the first intermediate hosts, and freshwater fish are the second intermediate hosts. The metacercarial cysts are somewhat less resistant to pickling than those of *C. sinensis*; however, thorough cooking of fish is the only guaranteed method of prevention.

It is important to remember that growth of the aquaculture industry must continue to be monitored for problems related to an increased incidence of disease in which infection is transmitted through the ingestion of raw or poorly cooked fish. Freshwater fish aquaculture has increased from an annual production of 136,000 tons in 1952 to 16.6 million tons 50 years later in China, the Republic of Korea, and Vietnam.

Public health education should be used to advise the at-risk population in areas of endemicity about the hazards of eating uncooked fish. This approach has not met with much success because of the difficulty in disrupting established cultural and dietary traditions. Also, defecation in or near ponds or lakes should be prevented, as should the application of night soil where the intermediate hosts are abundant. Community-based therapy of opisthorchiasis will significantly decrease the prevalence of infection; however, therapy alone will not solve the problem because of the high rates of reinfection due to cultural habits. Mass treatment can be undertaken with praziquantel as a single dose of 40 to 50 mg/kg at bedtime.

Opisthorchis felineus

C. sinensis, *O. felineus*, and *O. viverrini* are the three most important liver flukes involved in human health, infecting more than 45 million people. *C. sinensis* and *O. viverrini*, and possibly *O. felineus*, can induce human cholangiocarcinoma as well as inducing other hepatobiliary pathology. Although the three have similar life cycles, only that of *O. felineus* in Europe is predominantly zoonotic, while *O. felineus* in Asia and *C. sinensis* have a mixture of zoonotic and anthroponotic components. Over 680 million people are estimated to be at risk for these infections. *O. felineus* (Siberian liver fluke) infections in humans have been reported from Germany, Kazakhstan, Poland, and the Russian Federation, with the largest area of endemicity being found in western Siberia. Prevalence of human infection with this fluke ranges from 80% in certain regions of Siberia to sporadic cases in the Central and Southern Europe. *O. felineus* infection has been documented in humans and/or animals in 13 countries of the European Union. Over 1.5 million people are infected, with some prevalence rates reaching 95%. The first report of a human infection was in 1892.

Life Cycle and Morphology

The life cycle can be seen in Fig. 19.1. The eggs are elongate and ovoid, with an operculum that resembles that seen in *O. viverrini*. They are generally light yellowish brown and measure approximately 30 by 11 μm. Like the eggs of some strains of *C. sinensis* and *O. viverrini*, some eggs have a small tubercular thickening ("comma") at the abopercular end. Although the miracidium larva is fully developed when the egg is laid, hatching occurs only after ingestion by the snail intermediate host. Apparently, the only known molluscan host is the snail *Bithynia*, in which the first- and second-generation sporocysts and rediae develop. The cercariae leave the snail host and then encyst within the tissues of freshwater fish in the carp family. More than 20 species from 17 genera of freshwater fish serve as second intermediate hosts. Humans, cats, and other reservoir hosts become infected after ingestion of raw or poorly cooked fish. The metacercariae excyst in the duodenum, migrate to the distal bile passages, attach, and begin egg production within 3 to 4 weeks. The adult worm lives attached in the biliary and pancreatic ducts of the host. The adult worm is lancet-shaped and measures 7 to 12 mm in length, which is larger than the adult worms of *O. viverrini* (Fig. 19.4 and 19.7).

Clinical Disease

Although this infection tends to have an incubation period of several weeks, symptoms may appear at the end of the first week. Like infections with other liver flukes, the degree of clinical involvement depends on the extent and duration of the infection. With a low worm burden (up to 50 or 60 worms), there may be localized damage in the distal bile ducts but the liver function remains normal. With a worm count up to 1,000, there may be hepatomegaly and jaundice; the pancreas may also be involved, which can result in digestive problems. Like some of the other liver trematode infections, it is quite likely that chronic infection will lead to cholangiocarcinoma. Overall, the symptoms and clinical sequelae are similar to those seen with *O. viverrini* infection. Acute symptoms can include abdominal pain, urticaria, dizziness, and fever.

In one Italian outbreak with mild infections, the clinical pattern was unclear, and laboratory parameters such as eosinophilia, gamma-glutamyl transpeptidase (GGT), and transaminases often returned to normal or close to normal even when adult worms were still alive in the bile duct and shedding eggs. In this particular outbreak, 21 people with a normal eosinophil count, 16 people with normal GGT values, and 25 people with normal transaminase values shed *O. felineus* eggs 4 to 5 months postinfection. The only laboratory feature that allowed a correct diagnosis was the detection of anti-*Opisthorchis* IgG in the serum, which is detectable for a long period of time and decreases very slowly only after successful treatment (35). Unfortunately, in this situation, the diagnosis was made 5 months after infection, thus confirming that physicians are generally unfamiliar with this disease and may not consider the possibility in the differential diagnosis. In areas where they are not endemic, poor awareness of these liver fluke infections may definitely delay diagnosis and therapy.

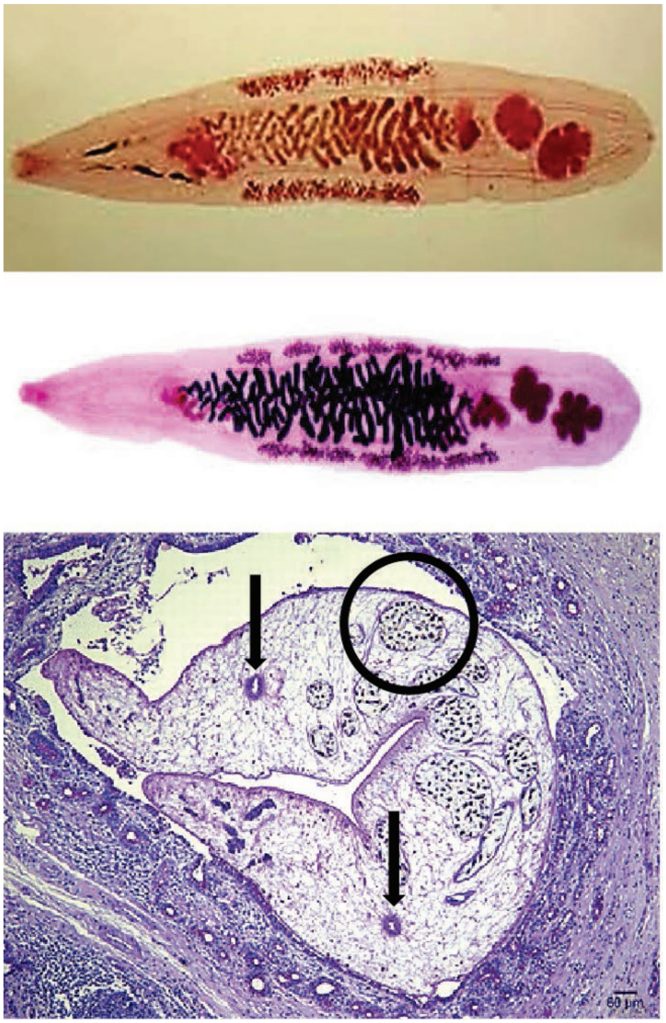


Figure 19.7 *Opisthorchis felineus*. (Top and middle) Adult trematodes (courtesy of the CDC Public Health Image Library). (Bottom) Close-up of *O. felineus*. Multiple branches of the egg-filled uterus are visible (circle), flanked by the paired ceca (arrows) on this cross section through the midbody fluke. Eggs measure 32 by 14 µm on average (length:width ratio of 2.28) and are thus consistent with *O. felineus*. Sparse vitellaria are found on the lateral extremes of the parasite on this section. Slight chronic inflammation of the host's lamina propria without marked eosinophilic infiltrate can be seen. Periodic acid-Schiff stain, original magnification ×100 (courtesy of www.ajtmh.org).
doi:10.1128/9781555819002.ch19.f7

Diagnosis

Fecal Examination. The infection is diagnosed by finding the eggs in the stool; however, they resemble eggs of the other liver trematodes such as *C. sinensis* and *O. viverrini*. Although detection of fluke eggs in stools represents the best way to confirm the diagnosis of opisthorchiasis, it is unreliable in cases with a low worm burden. The eggs have been described as being slightly more narrow (30 by 12 µm) than *C. sinensis* eggs and are more regularly ovoid without a clear shoulder at the operculum. Eggs can also be seen in duodenal drainage material or if the Entero-Test capsule is used.

Serologic Methods. Serology has been performed using an ELISA in accordance with a standard protocol using excretory/secretory (E/S) antigens from adult worms of *O. felineus* maintained *in vitro* (35).

KEY POINTS—LABORATORY DIAGNOSIS

Opisthorchis felineus

1. Multiple stool specimens may be required to find the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 30 µm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *O. felineus* can resemble those of many other intestinal and liver trematodes; however, they tend to be somewhat more narrow than the other eggs.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. Like some strains of *C. sinensis* and *O. viverrini*, *O. felineus* usually produces eggs that have a comma-shaped appendage at the abopercular end; this finding generally differentiates the liver fluke eggs from those of the intestinal flukes *Heterophyes heterophyes* and *Metagonimus yokogawai*.
8. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
9. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

A single praziquantel dose of 40 mg/kg after a meal has been recommended. Although side effects are usually mild, they tend to occur in a number of patients and include abdominal pain, vomiting, diarrhea, lassitude, myalgia, headache, and rashes. Any side effects can be minimized by administration of the single-dose regimen at bedtime.

Epidemiology and Prevention

In central, eastern, and southeastern Europe, the Russian Federation, and Kazakhstan, the dog and cat, the red, silver, and polar foxes, domestic and wild swine, rabbit, Norway rat, water rat, beaver, wolverine, marten, polecat, Caspian seal, bearded seal, and lion (in captivity) are infected (33). In some areas of the Ukraine, there is an 82% infection rate, primarily from eating fish on the first day of salting. There is a 15 to 68% infection rate in the middle Urals, with an 84% infection rate in cats. There has been as high as 90% infection with metacercariae in carp in the Tyumen Region of western Siberia (30). Cats are an important reservoir host, with a 43% infection rate being reported from the Ukraine.

Certain factors need to be remembered in understanding this infection and appropriate control measures. Even a single consumption of raw fish dishes can lead to infection. Unfortunately the initial symptoms can disappear quickly, and laboratory test results rapidly return to normal. Symptoms can be nonspecific, and infected individuals can continue to harbor adult worms, often developing serious sequelae years later. Diagnosis is difficult due to a general lack of awareness on the part of physicians, and serologic diagnostic kits are generally not available. Another fact that may be overlooked is that proper freezing of fish to be consumed raw is not always used for the protection of the public (35).

Fasciola hepatica

Fascioliasis (sheep liver fluke disease) is primarily a zoonotic disease that causes liver infections with adult flukes. Over 2.4 million people are infected with this parasite worldwide, including Europe, the Americas, northern Asia, Oceania, Africa, New Zealand, Tasmania, Great Britain, Iceland, Cyprus, Corsica, Sardinia, Sicily, Japan, Papua New Guinea, the Philippines, and the Caribbean. This infection has been recognized by the World Health Organization as an important health problem, particularly in the Andean countries of Peru, Bolivia, and Chile (36). *F. hepatica* was the first trematode to be described and the first for which the entire life cycle was defined; it is interesting that approximately 500 years passed between the description of the parasite and the clarification of its life cycle. The first recorded information on *F. hepatica* infections was provided by de Brie in 1379, when he described the effects of certain types of water plants on sheep that had eaten them. The complete life cycle was established by the investigations of Leuckart and Thomas in 1883, independently of one another (2). The most common definitive hosts are sheep; however, other herbivores such as goats, cattle, horses, camels, hogs, vicuna, rabbits, and deer are often infected as well. In sheep, the migratory phase produces such extensive liver parenchyma damage that the disease is known as liver rot.

Although the disease has a cosmopolitan distribution, at least three cases of autochthonous infection in humans in the United States have been reported (37, 38) (Table 19.1). Two of the patients had eaten watercress at the same time; both had eosinophilia and liver lesions on imaging. The diagnosis was based on serology and both were successfully treated with triclabendazole (38).

Life Cycle and Morphology

Adult worms, which may live for many years in the bile ducts, produce eggs that are carried by the bile fluid into the intestinal lumen and passed into the environment with the feces (Fig. 19.1, 19.4, and 19.8). The eggs are unembryonated, operculated, large, ovoid, and brownish yellow and measure 130 to 150 µm by 63 to 90 µm (Fig. 19.8). The miracidium develops within 1 to 2 weeks in water from 22 to 26°C and escapes from the egg to infect the snail intermediate host, *Lymnaea* sp. These snails are amphibious. Within 4 to 7 weeks, cercariae are liberated from the snail after the production of a sporocyst generation and two or three redia generations. Cercariae encyst on water vegetation, e.g., watercress. Humans are infected by ingestion of uncooked aquatic vegetation on which metacercariae are encysted. Metacercariae excyst in the duodenum and migrate through the intestinal wall into the peritoneal cavity. The larvae enter the liver by penetrating the capsule (Glisson's capsule) and wander through the liver parenchyma for up to 9 weeks. The larvae finally enter the bile ducts, where they mature and produce eggs, which are passed out in the feces. The adult worms can attain a length of 30 mm and a width of about 13 mm and can live for more than 10 years (Fig. 19.4 and 19.8).

Clinical Disease

Acute. The incubation period for fascioliasis can range from a few days to a few months. The patient's symptoms reflect the phase of the infection, as well as the number of parasites present in the host. In the acute phase, symptoms may be present over a period of weeks to months and include dyspepsia, fever, right upper quadrant pain, anorexia, hepatomegaly, splenomegaly, ascites, urticaria, respiratory symptoms, and jaundice. Metacercarial larvae do not cause significant pathologic damage until they begin to migrate through the liver parenchyma. The amount of damage depends on the worm burden of the host. Linear lesions of 1 cm or greater can be found. Hyperplasia of the bile ducts occurs, possibly as a result of toxins produced by the larvae. Symptoms associated with this migratory phase have included fever, epigastric and right upper quadrant pain, intestinal complaints, and urticaria, although other patients remain asymptomatic. Asymptomatic infections appear to be more common in Peru (3). Other symptoms include loss of appetite, flatulence, nausea, diarrhea, and a nonproductive cough. Patients may also have hepatomegaly, splenomegaly, ascites, chest signs, and jaundice. Leukocytosis, eosinophilia, and mild to moderate anemia are found in many patients. Levels of IgG, IgM, and IgE in serum are usually elevated.

Chronic. In the more chronic phases of the disease, the patient generally has few to no symptoms once the flukes have lodged in the biliary passages (Fig. 19.9). However, there may be some epigastric and right upper quadrant pain, diarrhea, nausea, vomiting, hepatomegaly, and jaundice. If the flukes are found in the extrahepatic biliary ducts, symptoms may mimic those seen in cholelithiasis. In the chronic phase, there tend to be some liver function

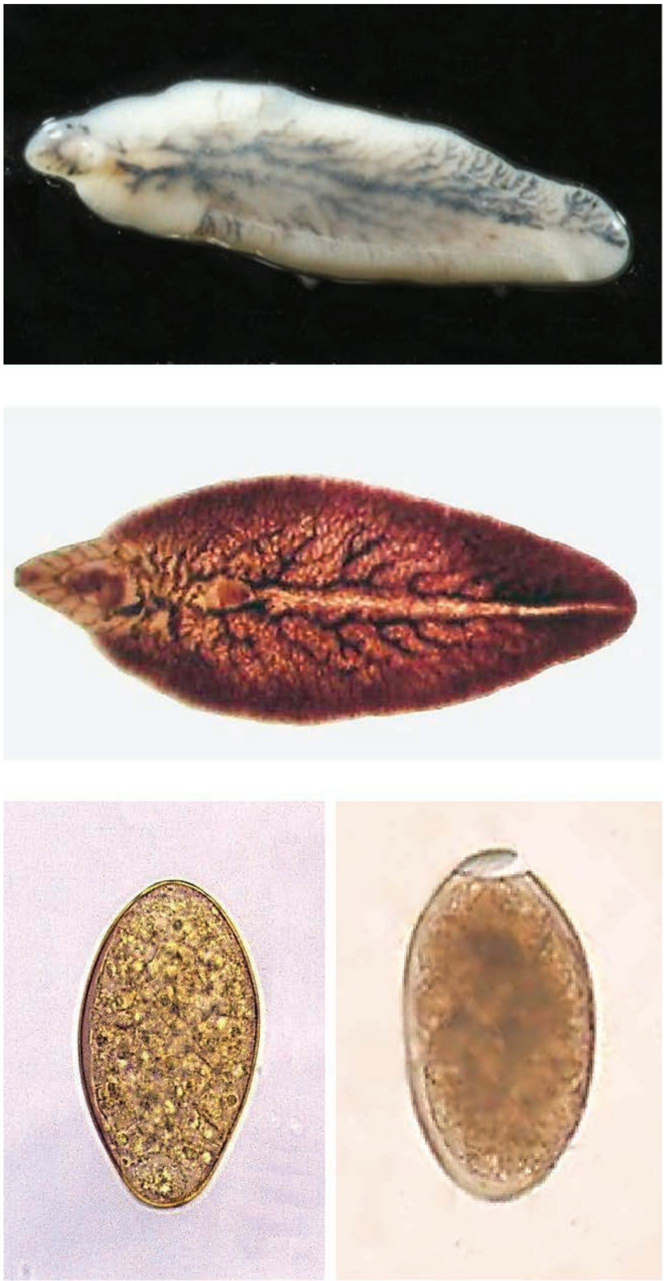

Figure 19.8 *Fasciola hepatica*. (Top) Adult worm, fresh specimen. (Middle) Adult worm, stained. (Bottom) Eggs; note the open operculum on the egg on the right. The operculum can be difficult to see; this egg resembles that of *F. buski* (intestinal trematodes) and *F. gigantica* (liver trematodes), although the egg of *F. gigantica* is larger. The *F. hepatica* adult worm is 20 to 30 mm long by 8 to 13 mm wide. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch19.f8

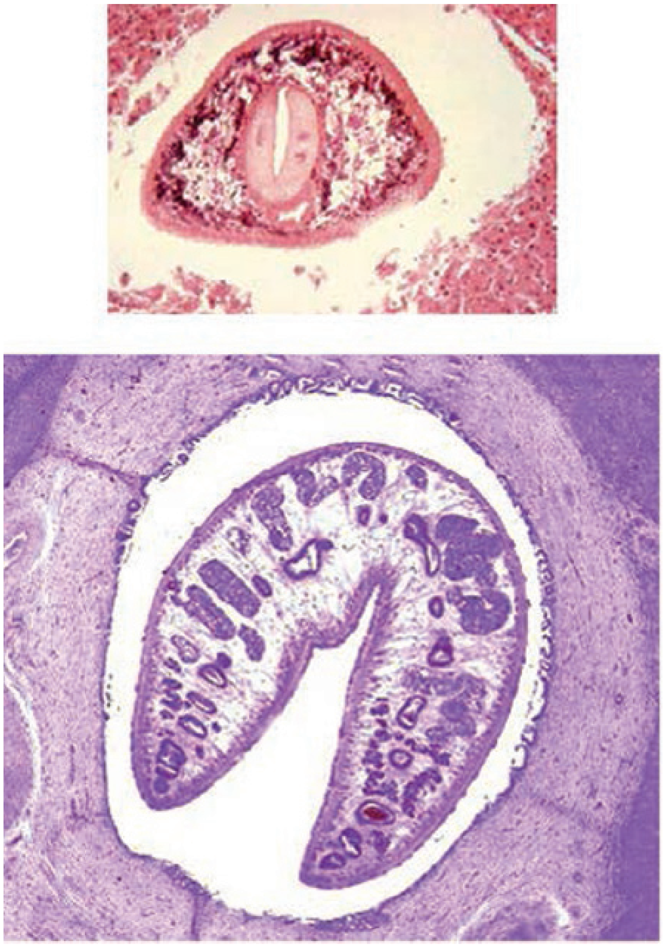

Figure 19.9 *Fasciola hepatica*. (Upper) Adult worm in a bile duct; note the U-shaped worm within the bile duct with surrounding tissues. (Lower) Higher magnification: adult worm in the liver; note the U-shaped worm with surrounding hepatic tissue, with a cellular response seen around the worm. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch19.f9

abnormalities, as well as eosinophilia (Fig. 19.9). Larvae may be found in ectopic foci after penetrating the peritoneal cavity. Worms in human infections have been discovered in many areas of the body other than the liver. Other body sites include the intestinal wall, lungs, heart, brain, and skin. Symptoms mimic those seen with visceral larva migrans and include vague abdominal pain. Unfortunately, surgery may be required to determine the exact cause of the symptoms.

Late. Once the worms have established themselves in the bile ducts and matured, they cause considerable damage from mechanical irritation and metabolic by-products as well as obstruction. The degree of pathologic change depends on the number of flukes penetrating the liver. The infection produces hyperplasia of the biliary epithelium and fibrosis of the ducts with portal or total biliary obstruction. The gallbladder undergoes similar pathologic changes and may even harbor adult worms. Adult worms may reinvade the liver parenchyma, producing abscesses. Symptoms and signs of infection during the late stages after egg production has begun are those associated with biliary obstruction and cholangitis. Acute epigastric pain, fever, pruritus, jaundice, hepatomegaly, and eosinophilia are common.

Halzoun Syndrome. In areas of endemicity where uncooked goat and sheep livers may be eaten, such as Lebanon, adult worms may attach to the pharyngeal mucosa, causing suffocation (halzoun syndrome). This condition is temporary, although it may cause considerable discomfort. The adult worms may lodge on the pharyngeal mucosa, causing edema and congestion of the soft palate, pharynx, larynx, nasal fossae, and eustachian tube. The symptoms include dyspnea, dysphagia, deafness, and occasionally suffocation. It has also been suggested that a number of these cases may be caused by infection with larval linguatulids rather than adult worms of *F. hepatica*.

Diagnosis

Stool examinations and ELISA are recommended for presumptive diagnosis, while radiographic techniques and MRI are used for confirmation and follow-up. Although they may be helpful, invasive techniques such as percutaneous cholangiography, endoscopic retrograde cholangiography, and liver biopsy are not always essential (6). However, liver biopsy may be very important in diagnosing fascioliasis, particularly for asymptomatic disease (3).

Fecal Examination. Several diagnostic methods are available, such as direct fecal smears, Kato-Katz thick smears, Stoll's dilution egg count method, or the formalin-ethyl-acetate technique. The most widely used techniques are the Kato-Katz and formalin-ethyl-acetate techniques, because these two methods have a reasonably high sensitivity at the level of moderate and heavy infections and allow the quantification of infection intensity. The eggs of *F. hepatica*, *Fasciolopsis buski*, *Echinostoma ilocanum*, and *Gastrodiscoides hominis* are similar in size and shape. Differentiation may be difficult without a patient history. Patients may be symptomatic during the first weeks of infection, but no eggs are found in the stool until the worms mature, which takes 8 weeks (39). Multiple stool examinations may be needed to detect light infections.

Spurious Infection. Eggs may be detected in the stools of individuals who have eaten *F. hepatica*-infected liver, thereby yielding an erroneous laboratory result (not a true human infection, but what is called a "spurious" infection). True infection and spurious infection can be differentiated by maintaining the patient on a liver-free diet for at least 3 days. If the patient continues to pass eggs in the stool, the infection is probably genuine.

Serologic Methods. Serologic diagnosis with *F. hepatica* excretion-secretion antigens has been used in areas of endemicity to detect patient antibodies (39). This approach includes ELISA, counterelectrophoresis, and enzyme-linked immunoelectrotransfer blots. Serologic tests can be used to monitor treated patients to ensure successful therapy (40). Serologic cross-reactions have been noted in patients infected with schistosomiasis. Serologic assays are the tests of choice for the diagnosis of acute and chronic fascioliasis when few eggs can be found in the stool or when large populations are to be screened (41).

Radiologic Screening. Imaging methods include ultrasound, CT, MRI, and tissue harmonic imaging. These imaging devices are able to reveal the pathology of the bile ducts. Ultrasound can detect biliary stones, dilatation, and fibrosis due to liver fluke infections, while CT and MRI can determine the lumen diameter of bile ducts, fibrosis, calcification, and epithelial hyperplasia. Tissue harmonic imaging is useful for the observation of bile duct wall trauma and stones.

Molecular Techniques. Various PCR-based methods have been developed and improved to detect egg trematode DNA in stool samples or metacercariae in the second intermediate host. These tests offer high sensitivity and specificity, even in light infections, compared to routine fecal and indirect immunological tests. However, PCR diagnosis is unlikely to become a tool for routine diagnosis in resource-poor areas but remains useful in research.

While research is ongoing in terms of metabolic profiling and biomarkers, it may be years before new diagnostic tests are routinely available. Other considerations include potential sensitivity and specificity, as well as cost and applicability in endemic areas.

KEY POINTS—LABORATORY DIAGNOSIS

Fasciola hepatica

1. Multiple stool specimens may be required to find the trematode eggs. In a very light infection, eggs may not be recovered; however, the patient might be asymptomatic.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen using this magnification.
5. Eggs of *F. hepatica* can resemble those *Fasciola gigantica* (liver fluke) and *Fasciolopsis buski* (intestinal fluke).
6. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.

Treatment

Although praziquantel is sometimes effective at a dose of 25 mg/kg taken after each meal for 2 days, it does not appear to be effective in treating patients in Egypt. Treatment with biothionol at 30 to 50 mg/kg on alternate days for 10 to 15 doses is recommended. Triclabendazole at 10 mg/kg as a single dose is also recommended, but this dose may not be as easily obtained. If a single dose has failed, the use of triclabendazole at 20 mg/kg is recommended (16); the drug is given orally in single or multiple doses and has few side effects (40). It acts by inhibiting protein synthesis in *F. hepatica* and will probably become the drug of choice; however, it is not currently available in the United States unless possibly through a compounding pharmacy (18).

Combination therapy in animal models may also lead to other treatment options (21). Artemether and tribendimidine disrupt the tegument of adult trematodes as can be seen via scanning electron microscopy in Fig. 19.10. Prominent morphological features observed following the treatment of rodents with artemisinins included sloughing, blebbing, and roughening of the tegument (Fig. 19.10B and D), while closure of the oral sucker was seen in *O. viverrini* (Fig. 19.10F).

Epidemiology and Prevention

Fascioliasis is a cosmopolitan disease that is found where there is close association of livestock, humans, and snails. The largest numbers of infections have been reported from Bolivia, Ecuador, Egypt, France, Iran, Peru, and Portugal. Although animal fascioliasis is endemic throughout the Americas, human infections are rare in most countries (43). Reservoir hosts include herbivores such as cattle, goats, and sheep. Animal fascioliasis is a major veterinary problem in Europe. The infection is contracted by the ingestion of metacercariae encysted on uncooked water plants, such as watercress. Watercress is the main source of infection; however, in many countries, wild watercress is touted as a healthy natural food. In many areas of the world, animal manure is used as the primary fertilizer for cultivation of watercress.

In surveying potential risk factors in the Northern Peruvian Altiplano, the principal exposure factor for *F. hepatica* infection was drinking alfalfa juice. Human fascioliasis should be suspected when a patient from an area in Peru where livestock is raised presents with recurrent episodes of jaundice and has a history of alfalfa juice or aquatic-plant ingestion or has eosinophilia (44).

Prevention may be accomplished by public health education in areas where infections are endemic, stressing the dangers of eating watercress grown in the wild where animals and snails are abundant. Other measures have included killing snails, treating infected animals, and draining pasture lands.

Fasciola gigantica

Fasciola gigantica is closely related to *F. hepatica*. It is also a common parasite of cattle, camels, and other herbivores in Africa and of herbivores in some Pacific islands. Human infections have been reported in a number of areas of endemicity. Generally, *F. hepatica* is found in temperate zones and is the predominant species in Europe, the Americas, and Oceania, while *F. gigantica* is better adapted to tropical and aquatic environments and is the predominant species in Africa.

Life Cycle and Morphology

Although *F. hepatica* and *F. gigantica* have different geographic distributions, both species essentially share the same life cycle. However, the snail hosts of *F. gigantica* are aquatic rather than amphibious like the first intermediate host for *F. hepatica*. Humans become infected through ingestion of water plants which carry the infective metacercariae. Apparently, developmental stages of *F. gigantica* grow more slowly, survive longer at high temperatures, and are more susceptible to drying than those of *F. hepatica*. The adult worm resembles *F. hepatica* but is somewhat more lanceolate, with a less distinct cephalic cone (Fig. 19.11). The eggs

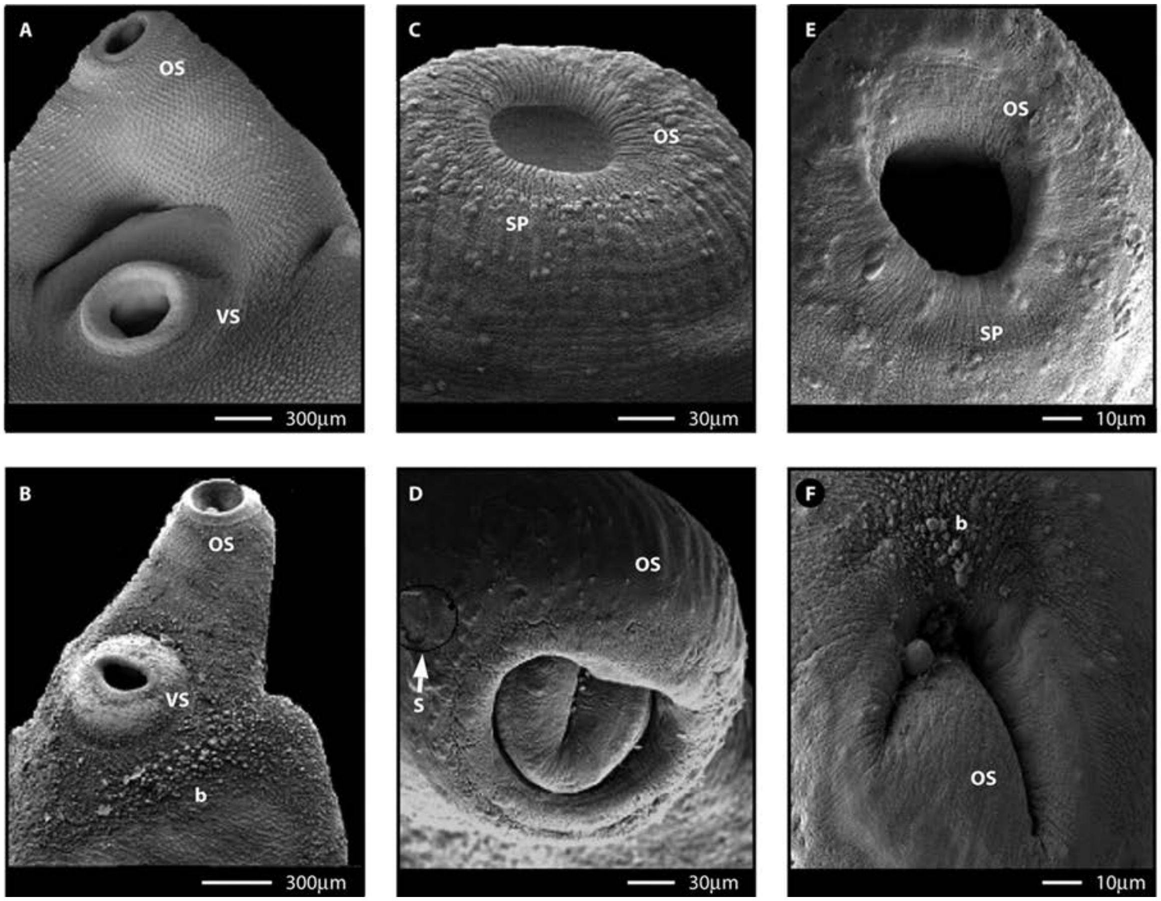

Figure 19.10 (A) Scanning electron microscope observations of the anterior part of an untreated *Fasciola hepatica* depicting the oral sucker (OS) and ventral sucker (VS). (B) A *Fasciola* fluke revealing blebbing (b) near the oral sucker and ventral sucker after administration of a single oral dose of 200 mg/kg artemether. (C) The oral sucker region of a *Clonorchis sinensis* fluke with sensory papillae (SP) visible. (D) Sloughing (s) seen on the oral sucker of an artemether-treated *C. sinensis* fluke. (E) Oral sucker region of an *Opisthorchis viverrini* fluke with sensory papillae. (F) Blebbing and closure of oral sucker observed on an *O. viverrini* fluke treated with a single oral dose of 400 mg/kg tribendimidine. (Courtesy of Keiser J, Utzinger J, *Clin Microbiol Rev* **22**:466–483, 2009.) doi:10.1128/9781555819002.ch19.f10

are very difficult to differentiate from those of *F. hepatica* or *Fasciolopsis buski*; however, they tend to be larger (160 to 190 µm by 70 to 90 µm) (Fig. 19.11).

Clinical Disease

The clinical symptoms of *F. gigantica* infection are very similar to those of *F. hepatica* infection and depend on the worm burden. The prepatent period between infection and the presence of adult worms in the bile ducts is 9 to 12 weeks. Patients may experience fever, nausea, vomiting, abdominal pain, hepatomegaly, hepatic tenderness, and eosinophilia. As in many light trematode infections, there may be vague symptoms or the patient may remain asymptomatic. Abscess or tumor-like reactions have also been reported to occur in subcutaneous tissues or in the liver (3).

Diagnosis

The eggs can be found in the stool; however, they may be absent more often than in infections with *F. hepatica*, so that multiple stool examinations may be required to demonstrate the eggs. Although these eggs are larger than those of *F. hepatica* or *F. buski*, they are very similar in shape. Recovery of adult flukes at surgery would confirm the diagnosis. Other diagnostic options discussed for *F. hepatica* are also recommended for this infection.

KEY POINTS—LABORATORY DIAGNOSIS

Fasciola gigantica

1. Multiple stool specimens may be required to find the trematode eggs. In a very light infection, eggs may not be recovered; however, the patient might be asymptomatic.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen under this magnification.
5. Eggs of *F. gigantica* can resemble those *F. hepatica* (liver fluke) and *F. buski* (intestinal fluke); however, they are somewhat larger and could probably be differentiated by careful measurement. Unfortunately, many people might not consider this particular species and thus might not even measure the eggs.
6. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.
7. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Praziquantel is sometimes effective at a dose of 25 mg/kg taken after each meal for 2 days. Treatment with biothionol at 30 to 50 mg/kg on alternate days for 10 to 15 doses is recommended. Triclabendazole at 10 mg/kg as a single dose is recommended, but this drug may not be as easily obtained. If a single dose has failed, the use of triclabendazole at 20 mg/kg is recommended (45). Triclabendazole is not currently available in the United States unless possibly through a compounding pharmacy (18).

Epidemiology and Prevention

Like *F. hepatica*, infection can occur in a wide range of herbivorous mammals when they ingest infected water plants or drink water contaminated with metacercariae. In some areas, the rate of infection in these animal hosts is quite high: in China, the rates are 50% for cattle, 45% for goats, and 33% for water buffalo; in Iraq, the rates are 71% for water buffalo and 27% for cattle; in northeastern Thailand, the rate is 60% for cattle (3). In various surveys, the occurrence of infections in cattle in Zambia was approximately 61%; in Tanzania, the incidence in cattle in traditional, large-scale dairy, and small-scale dairy herds, respectively, was 63, 46.2, and 28.4% (46, 47). Studies in Australia testing a commercially available ELISA for antibody detection have been reported; the results indicate this test will be very valuable in screening cattle and sheep for infections with *F. hepatica* and probably also *F. gigantica* (48).

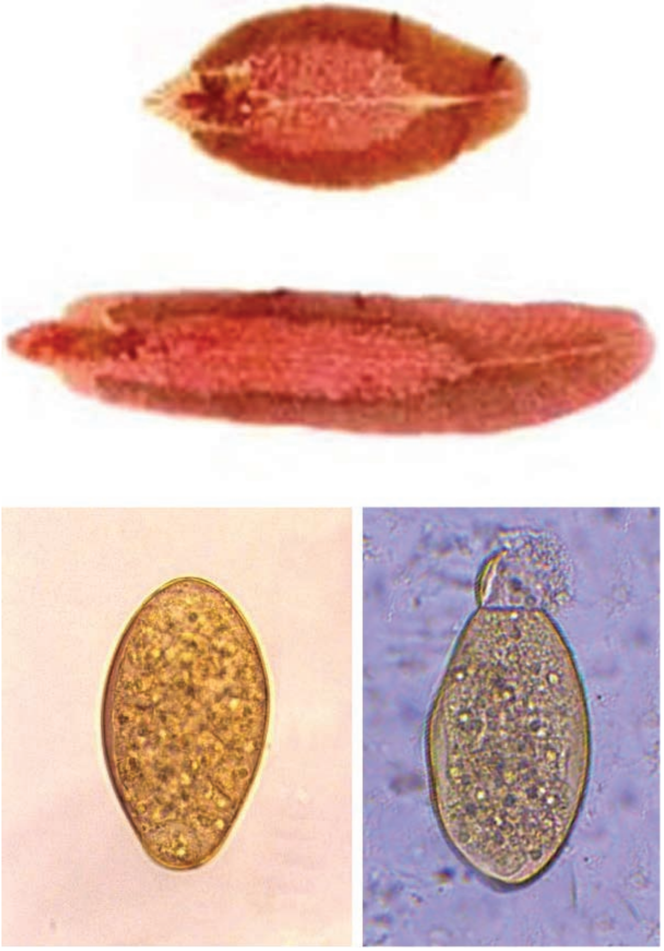

Figure 19.11 *Fasciola hepatica* adult worm (top), *Fasciola gigantica* adult worm (middle), and *F. gigantica* eggs (bottom). The operculum can be difficult to see; this egg resembles that of *F. buski* (intestinal trematodes) and *F. hepatica* (liver trematodes), although the egg of *F. gigantica* is larger (160 to 190 µm by 70 to 90 µm). The *F. gigantica* adult worm is 25 to 75 mm long by 12 mm wide. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch19.f11

Human infections have also been reported in specific areas where animal infection is relatively uncommon; these include Iraq, Hawaii, Uganda, Vietnam, Zimbabwe, Tashkent (Uzbekistan), and some areas within Thailand.

Less Common Liver Flukes

Dicrocoelium dendriticum, *Dicrocoelium hospes*, and *Eurytrema pancreaticum*

Dicrocoelium dendriticum (lancet fluke, lanceolate fluke) is commonly found in the biliary passages of sheep, deer, and other herbivores and omnivores in parts of Europe (e.g., Poland), Turkey, northern Africa, northern Asia, Turkistan (Kazakhstan), parts of the Far East, and North and South America; as an example, in southern Poland, 80% of the sheep are reported to be infected. Although many human infections have been reported, most are probably spurious infections acquired from eating infected raw sheep liver, often causing halzoun syndrome in Lebanon (49). However, true human infections have been reported from Europe, Egypt, Iran, Nigeria, Ivory Coast, and China. Approximately 30 cases of human infection with *D. hospes* have been reported from Democratic Republic of Congo, Ghana, Nigeria, and Sierra Leone. Although *D. hospes* has been thought to be a polymorph of *D. dendriticum*, ultrastructural studies can now distinguish *D. hospes* from other species in the family *Dicrocoeliidae* (50).

Eurytrema pancreaticum is usually found in the pancreatic ducts of hogs in southern China and of herbivores such as cattle, sheep, goats, monkeys, and camels in Asia and Brazil. True infection in humans has been reported in China and Japan.

Life Cycle and Morphology

The life cycle is similar to that of the other liver trematodes. However, in this case, the snail intermediate host is a land snail. The cercariae are released from the snail after rains following a long period of dry weather. They are released from the snail's respiratory chamber as slime balls that are left behind on grass as the snail crawls along the ground or on plants. The ant (*Formica fusca*) is the required second intermediate host for *D. dendriticum* within the United States, while other ants serve this function in other areas. The second intermediate hosts for *E. pancreaticum* are either tree crickets or grasshoppers. Human infection is acquired through accidental ingestion of ants, primarily on fresh herbs or plants used for human consumption. Accidental ingestion of infected crickets or grasshoppers can also result in human infection. The metacercariae excyst and migrate to the biliary passage (for *D. dendriticum*) or the pancreatic ducts (for *E. pancreaticum*), where they then become adult flukes.

The adult worms of *D. dendriticum* are lancet-shaped, flat, and transparent and measure 5 to 15 mm long by 1.5 to 2.5 mm wide (Fig. 19.12). The eggs are thick-shelled, operculate, and deep golden brown and measure 38 to 45 µm by 22 to 30 µm; the eggs of the two flukes cannot be differentiated (Fig. 19.12). The eggs are embryonated when passed and are resistant to drying. The adult worm of *E. pancreaticum* is 8 to 16 mm long by 5 to 9 mm wide and tends to be more ovate and broader than that of *D. dendriticum* (Fig. 19.13).

Clinical Disease

Although the life cycle is similar to that of *F. hepatica*, the pathogenic effects are less severe and patients may report mild symptoms. Symptoms include chronic constipation and flatulent dyspepsia. In patients with heavy infections, there may be jaundice with an enlarged liver. There may also be vomiting and diarrhea, as well as systemic toxemia. Eosinophilia tends to be absent in this infection.

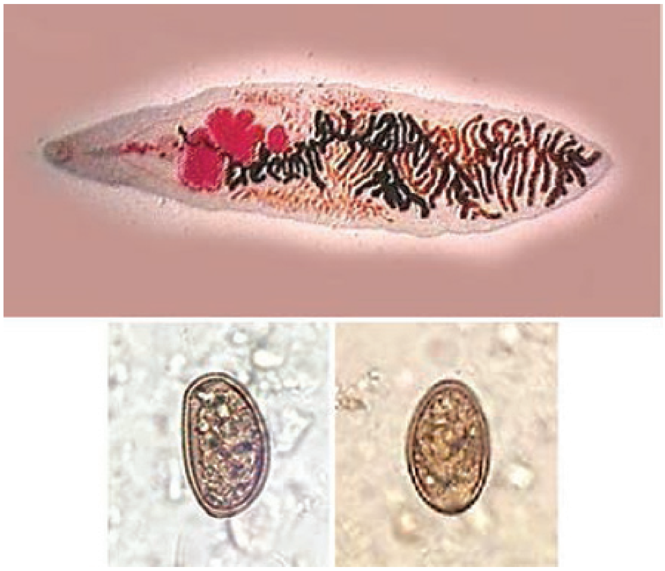

Figure 19.12 *Dicrocoelium dendriticum* adult worm (upper) and eggs (lower). (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch19.f12

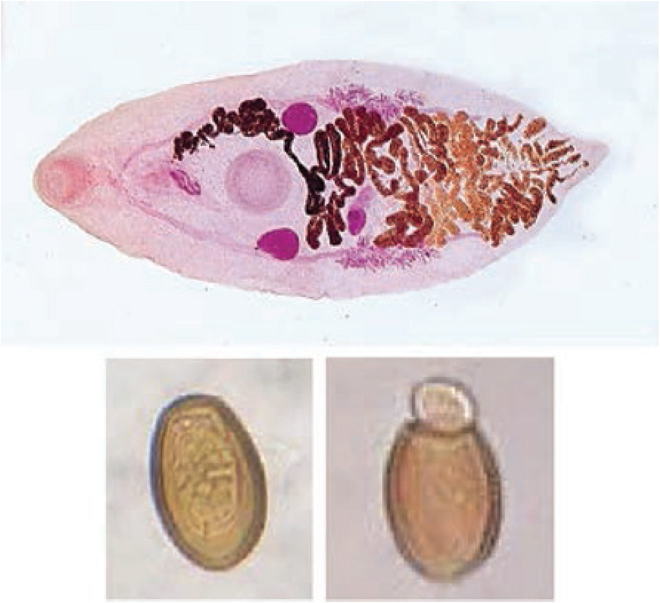
Figure 19.13 *Eurytrema pancreaticum* adult worm (upper) and eggs (lower). (Courtesy of http://www.ym.edu.tw/par/html/ParPic/Helminthes/Trematode/Eurytrema_pancreaticum/Eur-pan.htm.) doi:10.1128/9781555819002.ch19.f13



Diagnosis

Diagnosis is based on recovery of the eggs in the stool, bile, or duodenal drainage specimens. It is important to remember that any presumptive true infection must be differentiated from spurious infections acquired from the ingestion of infected raw animal liver. True infection can be distinguished from spurious infection by maintaining the patient on a liver-free diet for at least 3 days. If the patient continues to pass eggs in the stool, the infection is probably genuine. Definitive diagnosis would require the recovery of adult worms at surgery or autopsy.

KEY POINTS—LABORATORY DIAGNOSIS

Dicrocoelium dendriticum*, *Dicrocoelium hospes*, and *Eurytrema pancreaticum

1. Multiple stool specimens may be required to find the eggs; bile and duodenal specimens can also be examined for the eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the small eggs will stain very darkly and resemble debris.
4. Although the wet preparation can be examined using the 10× (low-power) objective, these eggs measure approximately 40 μm and can be easily missed. It is recommended that the 40× (high dry) objective be used for the wet preparation examination.
5. Eggs of *D. dendriticum*, *D. hospes*, and *E. pancreaticum* can resemble those of many other small intestinal and liver trematodes such as *C. sinensis*, *O. viverrini*, *H. heterophyes*, and *M. yokogawai*.
6. The wet preparation should not be so thick that the small eggs are obscured by normal stool debris.
7. If duodenal sampling is performed (drainage or the Entero-Test), eggs may be found in this material.
8. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

Praziquantel is the drug of choice, and the same dosage is recommended as that used for infection with *Opisthorchis* infection. Triclabendazole, an imidazole derivative, may also be effective.

Epidemiology and Prevention

Because infection in humans is usually accidental, few preventive measures are effective. Use of wild herbs and grasses as food should be avoided unless they are carefully washed. Crickets or grasshoppers could also be accidentally ingested if they were within plant material that had not been carefully washed.

Lung Flukes

Paragonimus westermani

Paragonimiasis is a disease of humans and carnivores in which adult flukes of the genus *Paragonimus* are found in the lungs. Naterer first detected the lung fluke in 1828; however, Kerbert detected flukes in the lungs of a Bengal tiger in 1878 and named the worms *Distoma westermani*, after the director of the Amsterdam Zoo, Westerman. Both Manson and von Baelz in 1880 reported finding eggs in the sputum of humans, and Yokogawa in 1915 and Nakagawai in 1916 completely described the life cycle. Since 1899, the name *Paragonimus westermani* has been used (Table 19.1). *Paragonimus mexicanus* is an important human pathogen in Central and South America, while *Paragonimus kellicotti* infections are found in North and South America. Most paragonimiasis infections are caused by *P. westermani*, which is the focus of this section (Table 19.2) (51).

Depending on the endemic area, a number of *Paragonimus* species are confirmed or thought to infect humans. These include *P. bangkokensis*, *P. harinasutai*, *P. heterotremus*, *P. hueitungensis* (may be included with *P. skrjabini*), *P. kellicotti*, *P. macrorchis*, *P. mexicanus*, *P. proliferus*, *P. pseudoheterotremus*, *P. siamensis*, *P. skrjabini*, *P. vietnamensis*, and *P. westermani*. As molecular testing expands, the species designations may be changed.

Life Cycle and Morphology

The life cycle is shown in Fig. 19.1. The adult worm is a plump, ovoid, reddish-brown fluke found encapsulated in the lung. Eggs deposited by the worms are ovoid, brownish yellow, unembryonated, and thick-shelled, with an operculum at one end and opercular shoulders. The eggs measure 80 to 120 μm by 45 to 65 μm (Fig. 19.14). *P. westermani* eggs are often confused with *Diphyllobothrium* eggs because they are operculated, unembryonated, and somewhat similar in size. However, unlike *Diphyllobothrium* eggs, *P. westermani* eggs have opercular shoulders and a thickened shell at the abopercular end (Fig. 19.15). Eggs escape from the encapsulated tissue through the bronchioles, are coughed up and voided in the sputum, or are swallowed and passed out in the feces. The eggs hatch in the water in 2 to 3 weeks, releasing a miracidium to infect a susceptible snail host. Cercariae are released after sporocyst and redia generations. Crabs and crayfish are infected by cercariae via the gill chamber or on ingestion of an infected snail. Cercariae encyst in the gill vessels and muscles. Humans are infected by ingesting uncooked crabs or crayfish containing metacercariae (Fig. 19.16). The metacercariae excyst in the duodenum and migrate through the intestinal wall into the abdominal cavity. The larvae migrate around or through the diaphragm into the pleural

TABLE 19.2 Human paragonimiasis

Species	Geographic distribution	Disease (mode of transmission)	Mean egg size (µm) and characteristics
P. westermani[a]	Asia, India, Philippines, New Guinea	Pulmonary (crabs, crayfish, freshwater shrimp)	85–100 by 47; abopercular thickening; oval with barrel-shaped center, operculum with opercular shoulders
P. heterotremus[a]	China, Laos, Thailand	Pulmonary (crabs, raw shrimp salad in Thailand)	86 by 48, uniform thickness
P. mexicanus[a] (*P. peruvianus, P. ecuadoriensis, P. caliensis*)	Mexico, Central and South America	Pulmonary (crabs)	79 by 48; eggshell thin, irregularly undulated
P. africanus	Cameroon, Congo, Nigeria, Liberia, Guinea, The Gambia, and Côte d'Ivoire	Pulmonary (crabs)	90 by 50; tend to be more narrow, abopercular thickening
P. kellicotti	North and South America	Pulmonary (crabs, crayfish)	75–118 by 48–68; shell 2–3 µm thick; abopercular thickening; tapers more sharply than *P. westermani*
P. miyazakii[b]	Japan	Pleural; high frequency of pleural effusion, pleural exudate, marked eosinophilia (crabs, raw juice of crabs, crayfish)	75 by 43; shell very thin; thinner at abopercular end
P. westermani filipinus (*P. philippinensis*)	Philippines	Pulmonary (crabs)	79 by 50; abopercular thickening
P. skrjabini (*P. szechuanensis*)[b]	China	Pleural, subcutaneous nodules (crabs)	75 by 46; egg slightly asymmetrical, small knob at abopercular end
P. hueitungensis	China	Migratory, subcutaneous nodules (crabs); high leukocytosis, elevated eosinophilia	75 by 46; widest part of egg slightly anterior to middle; thin shell, visible opercular shoulders; small knob at abopercular end
P. uterobilateralis	Cameroon, Guinea, Liberia, Nigeria, The Gambia, Gabon, Sudan, Côte d'Ivoire, and southern Africa	Pulmonary (crabs)	70 by 45; abopercular thickening of shell

[a] Pathogenic organisms most frequently isolated from humans; synonyms are given in parentheses.

[b] It has been suggested that in some areas in China and Japan, *P. skrjabini* and *P. miyazakii* should be referred to as *P. skrjabini miyazakii*. Some workers regard the following as synonyms of *P. skrjabini*: *P. miyazakii*, *P. szechuanensis*, and *P. hueitungensis*. Examination of specimens and reclassification studies are under way (51).

cavity and the lungs; they mature to adults in the vicinity of the bronchioles, where they discharge their eggs into the bronchial secretions. Although these worms are hermaphroditic, two worms are usually required for fertilization to occur. The worms can live as long as 20 years, but most die after about 6 years.

Although we generally think of infected raw crabs or crayfish as the most common sources of infection, a number of other foods and cultural practices can be implicated as well, including the ingestion of metacercariae in the flesh of paratenic hosts (Table 19.3).

Clinical Disease

Migration of the larval forms through the intestinal wall into the abdominal cavity is generally not associated with any significant pathologic changes or symptoms. If the larvae remain in the abdomen, some patients may have abdominal pain, intra-abdominal masses, tenderness, fever, diarrhea, nausea, vomiting, and eosinophilia. Once the larvae have reached the peritoneal cavity, they begin to migrate through organs and tissues, producing localized hemorrhage and leukocytic infiltrates.

Pulmonary Disease. When the worms finally reach the lungs and mature, a pronounced tissue reaction occurs, with infiltration of eosinophils and neutrophils. A fibrotic capsule forms around the worm. The cysts contain purulent fluid with flecks or "iron filings" composed of brownish yellow eggs. Many of the cysts perforate into the bronchioles, releasing their contents of eggs, necrotic debris, metabolic by-products, and blood into the respiratory tract. The eggs may also enter the pulmonary tissue, or they may be carried by the circulatory system to other body sites, where they cause a granulomatous reaction (Fig. 19.17, Fig. 19.18).

Symptoms of paragonimiasis depend largely on the worm burden of the host and are usually insidious in onset and mild in patients with chronic infections. Light infections may be asymptomatic, although peripheral blood eosinophilia and lung lesions may be noted on X-ray exam-

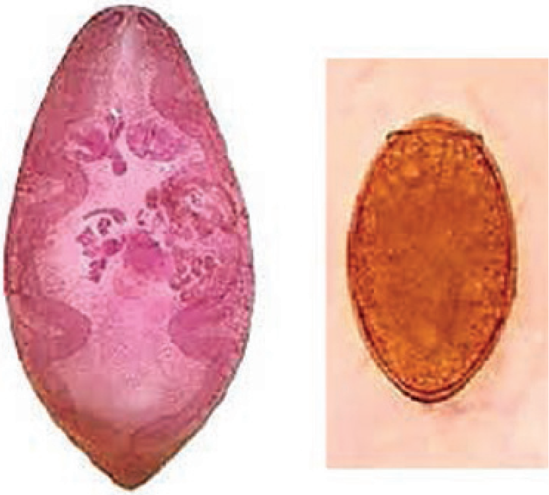


Figure 19.14 *Paragonimus westermani* adult worm (left) and egg (right). The opercular shoulders are clearly visible at the top of the egg, as is the thickened abopercular end. (Left, courtesy of CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch19.f14

ination. As the cysts rupture, a cough develops, with increased production of viscous blood-tinged sputum (rusty sputum, which may have a foul fish odor) and increasing chest pain. The patient may experience increasing dyspnea with chronic bronchitis and be misdiagnosed as having tuberculosis or bronchial asthma (52). The individual generally has a moderately high peripheral blood eosinophilia and leukocytosis, with elevated levels of IgG and IgE in serum. Although some patients exhibit symptoms continuously, others may remain asymptomatic for weeks to months between periods of hemoptysis.

doi:10.1128/9781555819002.ch19.f16

Cerebral Disease. Larval forms may end up in many ectopic sites other than the lungs; ectopic infections are generally associated with *P. heterotremus*, *P. mexicanus*, and occasion-

TABLE 19.3 Possible means of acquiring infection with *Paragonimus* spp.[a]

Geographic area	Food or cultural practice
Asia	Ingestion of raw or inadequately cooked crabs, crayfish, and shrimp
China	"Drunken crab" (immersion of live crabs in wine for 12 h); raw crab sauce or jam; crayfish curd
Thailand	Kung ten (raw shrimp salad); nam prik poo (crab sauce)
Philippines	Sinugba (roasted crab); kinilao (raw crab)
Korea	Ke jang (crab immersed in soy sauce)
Korea and Japan	Raw juice of crabs or crayfish used in traditional medicine (treatment of measles, diarrhea, and urticaria)
Japan	Ingestion of raw infected wild boar meat (paratenic host)
Africa	Ingestion of raw crustaceans to increase fertility
North America	Ingestion of raw crayfish; on a dare, survival foods, etc.
Central America, South America, Mexico	Several species of freshwater shellfish can harbor this parasite in Brazil; consumption of raw crab with lemon juice (ceviche)
Any of the above	Contaminated utensils, chopping blocks, and cloths used in food preparation

[a] Data from reference 3.

ally *P. westermani*. Cysts have been detected in the liver, intestinal wall, muscles, peritoneum, and brain (Fig. 19.19). The most serious consequences of paragonimiasis are the cerebral complications, which are commonly found in younger age groups. Unlike adult flukes in other extrapulmonary sites, worms found in the brain usually contain eggs. The worms probably migrate from ruptured lung cysts and travel through the soft tissues surrounding veins into the brain area. The worms eventually encapsulate, but before being walled off they cause necrosis within the brain tissue, as well as possible cerebral hemorrhage, edema, and meningitis.

Most patients with cerebral or other extrapulmonary lesions have an associated lung lesion or a history of lung disease. Symptoms include fever, headache, nausea, vomiting, visual disturbances, motor weakness, localized or generalized paralysis, and possibly death. More than half of these patients also exhibit personality changes, possible disorientation, and a general decline in cognitive function. Depending on the central nervous system location, symptoms may also include paraplegia, sensory loss, or vision problems. Specific sites can include the cerebral cortex, cerebellum, basal ganglia, medulla oblongata, and spinal cord (53). When a worm dies, the lesion cavity becomes filled with necrotic material. Cerebral paragonimiasis can be difficult to differentiate from brain disease caused by other parasites such as *Schistosoma japonicum*, *Gnathostoma spinigerum*, or *Angiostrongylus cantonensis*, as well as other infectious agents such as bacteria or viruses.

Paragonimiasis in Other Body Sites. Abdominal or subcutaneous masses are frequently seen in patients with infections caused by *P. skrjabini*, *P. heterotremus*, *P. hueitungensis*, or *P. mexicanus*. Migratory subcutaneous nodules occur in 20 to 60% of patients with *P. skrjabini* infection and approximately 10% of patients with *P. westermani* infection. The nodules

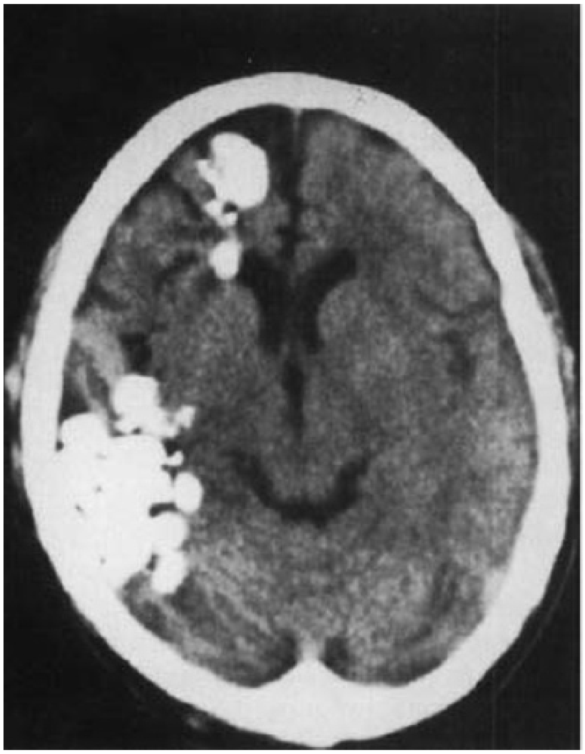

Figure 19.19 *Paragonimus westermani* brain image. CT showing multiple calcified densities in the right frontal and temporal areas. (Courtesy of http://synapse.koreamed.org/DOIx.php?id=10.3347/kjp.2000.38.3.167&vmode=PUBREADER#!po=58.3333.) doi:10.1128/9781555819002.ch19.f19

are firm, tender, a few millimeters to 10 cm, and somewhat irritating. They are often located in the lower abdomen, inguinal region, and thigh and are somewhat mobile. Ulcers or abscesses can also occur in the skin or subcutaneous tissue. Involvement of the mastoid area has been seen in *P. africanus* infections. The skin is one of the common sites for ectopic paragonimiasis which may be seen in children. The typical lesion is a migratory subcutaneous nodule that usually appears on the anterior chest wall, often migrating through the abdominal wall to the pelvic region or lower limbs without causing much discomfort to the patient except mild pain and itching. The abnormal migration is likely to occur in heavy infections in which the immature worm may invade any organ or tissue except bone. Other body sites that have been infected include the breast, lymph nodes, heart, pericardium, mediastinum, kidneys, adrenal gland, omentum, bone marrow, stomach wall, bladder, spleen, pancreas, and reproductive organs. While ectopic lesions are usually thought to be caused by worm migration, dissemination of eggs to other body sites can also be responsible for the pathology.

In China, *P. skrjabini* does not develop to the adult worm stage, but the disease is characterized by the presence of trematode larva migrans (3). These migratory subcutaneous nodules are associated with a high eosinophilia, as well as necrotic liver lesions. Brain involvement is common and is associated with subarachnoid hemorrhage.

Diagnosis

Laboratory Tests. Individuals with symptoms of chronic cough, vague chest pains, and hemoptysis who have resided in an area where infections are endemic and have a history of eating raw crayfish or crabs should be suspected of having paragonimiasis. *Paragonimus* eggs can be detected in the sputum and the stool, and concomitant examinations should be performed to improve the overall detection rate. In many individuals in whom the infection is eventually confirmed, small numbers of eggs are present intermittently in the sputum and feces. For patients with light infections, up to seven sputum examinations have been recommended. Frequently, pulmonary paragonimiasis is misdiagnosed as pulmonary tuberculosis. The Ziehl-Neelsen method for detecting mycobacteria destroys *Paragonimus* eggs (52). It is important to remember that the typical findings of cough, hemoptysis, and eggs in the feces or sputum may be absent in patients with ectopic or pleural *Paragonimus* infection.

Radiography and Scans. Skull radiographs generally reveal round or oval cystic calcifications; they have been described as looking like bubbles. CT scans reveal multilocular cysts with edema, migration tracks, peripheral density, bronchial wall thickening, and centrilobular nodules; ring enhancement may be visible after the use of contrast (Fig. 19.19). MRI demonstrates areas of granulomatous inflammation surrounding the lesions; MRI of the brain may reveal multiple conglomerated iso- or low-signal-intensity round nodules with peripheral rim enhancement. In the liver, CT and MR images may reveal a cluster of small cysts with rim enhancement in the subcapsular area. This finding seems to be characteristic for hepatic paragonimiasis. Solitary nodular lesions can often mimic lung cancer, tuberculosis, or fungal diseases. When a pulmonary mass lesion or empyema is detected in patients who live in areas where paragonimiasis is endemic, paragonimiasis should always be included in the differential diagnosis of lung diseases.

Immunodiagnostic Tests. The various immunological tests which have been evaluated are intradermal test, complement fixation test, immunodiffusion, indirect hemagglutination test, ELISA, dot-ELISA, and Western blot. Complement fixation has been used to diagnose active infections; however, the test becomes negative soon after the death of the worms. An immunoblot assay for the detection of antibodies to *P. westermani* by using adult worm homogenates is highly sensitive and specific (54). ELISA with adult excretory-secretory antigens is very sensitive for detecting parasite-specific IgG and

IgE (55). Pleural effusion fluid is more suitable than serum for detection of infections. The ELISA tests are most widely used for serological diagnosis of paragonimiasis due to their high sensitivity and specificity. However, ELISA tests are more expensive and time-consuming and require costly equipment and experienced persons; frequently, the reagents and antigens are not commercially available. Dot-ELISA has also been used to detect parasite-specific antigen in human sera (56). Monoclonal antibodies used to detect species-specific and stage-specific antigens are highly sensitive and specific for the detection of active infections (57). The serologic assays are available in areas of endemicity or in specialized diagnostic centers. Most of these assays involve nonstandardized reagents and have not been used in clinical trials. An intradermal test is also available for epidemiologic surveys in areas of endemicity; however, positive reactions persist for years after parasitologic cures.

Rapid Test. A dot-immunogold filtration assay (DIGFA) kit was developed in China for anti-*P. westermani* antibody detection. This test is simple and rapid and does not require any special devices and/or experienced technicians; results are obtained within 10 min. This kit was prepared using *P. westermani* antigen and reported in China to have sensitivity and specificity up to 99 and 92%, respectively (58).

KEY POINTS—LABORATORY DIAGNOSIS

Paragonimus spp.

1. *Paragonimus* eggs may be confused with *Diphyllobothrium latum* eggs because of similarities in their size and shape. However, most *Paragonimus* eggs have opercular shoulders and a marked thickening at the abopercular end, unlike *D. latum* eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen under this magnification.
5. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.
6. When looking at sputum specimens for eggs, it is necessary to carefully examine any blood-tinged flecks for eggs; the egg clusters have been described as looking like iron filings.
7. In light infections, multiple stool and sputum specimens may be needed before the eggs are detected.
8. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

The drug of choice is praziquantel at 25 mg/kg three times at 4-h intervals after meals for 3 days. Very few patients require retreatment; 100% cure is usually obtained except for certain patients with a heavy worm burden. There is dramatic improvement in symptoms, and they are usually gone within a few months. The dose required in cerebral paragonimiasis is generally higher and may have to be adjusted relative to the clinical outcome; convulsions and coma have been seen. These patients should be hospitalized for therapy and should be monitored closely; corticosteroids may also have to be given when treating patients with praziquantel. Bithionol is an alternative drug, which is available under an Investigational New Drug protocol from the Centers for Disease Control and Prevention Drug Service (18).

Triclabendazole at 10 mg/kg as a single dose or two doses is also recommended, but this dose may not be as easy to obtain. Patients should be examined at 3 months to determine the need for retreatment. If a single dose has failed, the use of triclabendazole at 20 mg/kg is recommended (59). Triclabendazole is not currently available in the United States unless possibly available through a compounding pharmacy (18).

Pulmonary paragonimiasis is rarely fatal; however, cerebral disease is characterized by chronic morbidity and symptoms including epilepsy, dementia, and other neurologic sequelae. About 5% of patients with cerebral disease die due to hemorrhage in the first 2 years of the disease (3).

Epidemiology and Prevention

There are approximately 200 million people at risk and 22 million people with paragonimiasis worldwide; a number of species are recognized as causing human disease (52) (Table 19.2). *P. westermani* is the most common human pathogen.

Reservoir hosts include dogs and cats in areas of endemic infection (the Far East and Africa). Eggs expectorated or passed in the feces in the vicinity of lakes or streams where the intermediate hosts live serve as the source of infection. Snail intermediate hosts include *Semisulcospira* and *Brotia* spp. In Ecuador, the intermediate host for *P. mexicanus* is *Aroapyrgus* sp., a freshwater snail belonging to the family *Hydrobiidae* (60). Humans contract the infection through ingestion of raw, undercooked, pickled, or wine-soaked crabs or crayfish; they may also become infected by the ingestion of uncooked meat from wild animals, such as wild boar. The migrating larvae in this meat may pass through the intestinal wall and continue their developmental cycle when eaten. Raw juice from crushed crayfish used as a home remedy for the treatment of measles has been a significant source of infection and may be a cause of cerebral paragonimiasis in children (30).

In most areas, the disease is primarily one of crab- or crayfish-eating mammals, with humans being incidental hosts. Measures devoted to public health education, warning people of the dangers of eating uncooked crabs or crayfish from areas of endemic infection, and sanitary care of utensils and fingers used to prepare food would reduce the risk of infection. Because the cycle depends on animals, the elimination of human paragonimiasis would have little effect on the overall prevalence of the disease.

Paragonimus kellicotti

In North America, paragonimiasis is caused by *P. kellicotti* flukes. Whether *P. kellicotti* extends into Central and South America has not been confirmed. All species of *Paragonimus* have a complex life cycle, requiring snail and crustacean intermediate hosts. Human infections are uncommon, with approximately 20 cases reported to date. However, paragonimiasis due to species not endemic to North America may also be contracted through the consumption of imported food that contains infective metacercariae. Henry Ward and D. S. Kellicott are credited with the independent, near-simultaneous discovery of the only North American *Paragonimus* species in 1894. Ward first described the infection in a cat from Michigan, whereas Kellicott later that year recognized an infection in a dog in Columbus, OH (8).

Life Cycle and Morphology

The life cycle is shown in Fig. 19.1. All species of *Paragonimus* have a complex life cycle, requiring snail and crustacean intermediate hosts. Definitive hosts excrete eggs in feces or sputum, which hatch in water to become ciliated miracidia. The eggs measure 75 to 118 μm by 48 to 68 μm (Fig. 19.20). The miracidia invade soft tissue of snails where they reproduce asexually. Cercariae released from snails invade the secondary intermediate host, a crustacean. Secondary intermediate hosts for *P. kellicotti* flukes are crayfish in the genera *Cambarus* and *Orconectes* (Fig. 19.16). Mammals acquire the infection when they ingest raw or undercooked crustaceans. *P. kellicotti* fluke infections have been found in cats, dogs, bobcats, raccoons, foxes, skunks, minks, and coyotes. Infected raw crayfish are the most common sources of infection.

Clinical Disease

Migration of the larval forms through the intestinal wall into the abdominal cavity is generally not associated with any significant pathologic changes or symptoms. If the larvae remain in the abdomen, some patients may have abdominal pain, intra-abdominal masses, tenderness, fever, diarrhea, nausea, vomiting, and eosinophilia. Once the larvae have reached the peritoneal cavity, they begin to migrate through organs and tissues, producing localized hemorrhage and leukocytic infiltrates. Symptoms include fever, cough, chest pain, dyspnea, night sweats, malaise, abdominal pain, and weight loss. In a series of nine patients, infections were characterized by the consumption of raw crayfish, with alcohol consumption at the time of crayfish consumption being common (61). The median time from symptom onset to the correct diagnosis was 12 weeks (range, 3 to 83 weeks). However, before the correct diagnosis was made, patients received multiple types of unnecessary treatment, some of which were associated with serious illness.

Approximately 75% of patients with this infection demonstrate eosinophilia (6.5 to 40%) and abnormal chest radiographic results. Pleural effusions are also common. Other chest radiographic findings included nodules, opacities, and infiltrates, while chest CT scans showed pleural thickening, pericardial thickening, pericardial effusions, and worm nodules (62). Although eosinophils and Charcot-Leyden crystals may be found in the respiratory secretions and stools of patients with paragonimiasis, these findings are nonspecific. However, these findings suggest an extensive search for fluke eggs should be performed.

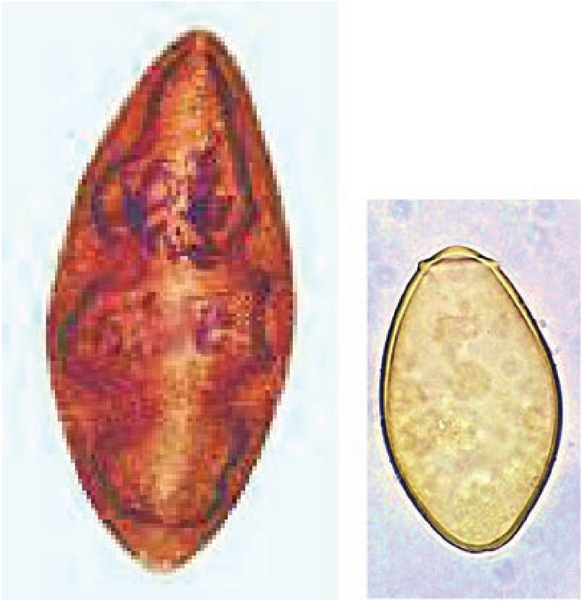

Figure 19.20 *Paragonimus kellicotti*: (left) adult worm; (right) egg. doi:10.1128/9781555819002.ch19.f20

Diagnosis

Laboratory Tests. Individuals with symptoms of chronic cough, vague chest pains, and hemoptysis who have resided in an area where infections are endemic and have a history of eating raw crayfish or crabs should be suspected of having paragonimiasis. *Paragonimus* eggs can be detected in the sputum and the stool, and concomitant examinations should be performed to improve the overall detection rate. In many individuals in whom the infection is eventually confirmed, small numbers of eggs are present intermittently in the sputum and feces. For patients with light infections, up to seven sputum examinations have been recommended. It is important to remember that the typical findings of cough, hemoptysis, and eggs in the feces or sputum may be absent in patients with ectopic or pleural *Paragonimus* infection.

An immunoblot for *P. westermani* flukes performed at the Centers for Disease Control and Prevention (Atlanta, GA) has been reported to be highly sensitive (96%) and specific (99%). However, this assay has not been validated for *P. kellicotti* flukes. In two patients with negative immunoblot results at the Centers for Disease Control and Prevention, these specimens were positive by Western blot with *P. kellicotti* fluke antigen at Washington University (Weil GJ et al., unpublished data). These patients had symptoms and abnormal laboratory test results suggestive of paragonimiasis after ingestion of raw crayfish (61).

Although molecular diagnostic assays of various types have been used for human diagnostic assays, they are not available commercially, nor do we know how they will compare with the traditional diagnostic methods. However, animal research studies are ongoing per the feasibility of using PCR-based methods as potential diagnostic tools for human infections.

KEY POINTS—LABORATORY DIAGNOSIS

***Paragonimus* spp.**

1. *Paragonimus* eggs may be confused with *Diphyllobothrium latum* eggs because of similarities in their size and shape. However, most *Paragonimus* eggs have opercular shoulders and a marked thickening at the abopercular end, unlike *D. latum* eggs.
2. The sedimentation concentration method should be used; because the eggs are operculated, they do not float in the zinc sulfate flotation concentration method.
3. It is important not to add too much iodine to the wet preparation, or the eggs will stain very darkly and resemble debris.
4. The wet preparation can be examined using the 10× (low-power) objective; these eggs are large enough that they can usually be seen under this magnification.
5. The wet preparation should not be so thick that the eggs are obscured by normal stool debris.
6. When looking at sputum specimens for eggs, it is necessary to carefully examine any blood-tinged flecks for eggs; the egg clusters have been described as looking like iron filings.
7. In light infections, multiple stool and sputum specimens may be needed before the eggs are detected.
8. If available, antigen or antibody detection may be helpful in confirming the infection.

Treatment

The drug of choice is praziquantel at 25 mg/kg three times at 4-h intervals after meals for 3 days. Very few patients require retreatment; 100% cure is usually obtained except for certain patients with a heavy worm burden. In general, symptoms, eosinophilia, and radiographic abnormalities should resolve within 1 to 3 months of treatment.

Epidemiology and Prevention

P. kellicotti flukes are believed to be widely distributed throughout the North America. Behavioral factors that may lead patients to eat raw or undercooked crayfish include alcohol consumption, dares, and demonstration of survival skills (42). Although crayfish are commonly regarded as food in survival situations, persons who learn or practice survival skills should be cautioned that eating raw or undercooked crayfish carries a risk for paragonimiasis. Owners and customers of campgrounds and canoe rental businesses should be alerted to thoroughly cook crayfish before eating. The Food and Drug Administration advises cooking shellfish to an internal temperature of 145°F (63°C). Success to date in substantially reducing infections in countries that traditionally have had high incidences of infection has been directly related to educational efforts. These efforts also apply to potential disease prevention within North America.

Blood Trematodes: Schistosomes

Schistosoma mansoni
Schistosoma japonicum
Schistosoma mekongi
Schistosoma malayensis
Schistosoma haematobium
Schistosoma intercalatum

Schistosomes belong to the phylum Platyhelminthes, family *Schistosomatidae*, and are a group of digenetic, dioecious trematodes requiring definitive and intermediate hosts to complete their life cycles. Four species are important agents of human disease: *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, and *Schistosoma haematobium*. *Schistosoma intercalatum* is of less epidemiologic importance. *Schistosoma malayensis* is a member of the *S. japonicum* complex and is found in Peninsular Malaysia; however, the number of cases is small (1). Schistosomiasis affects between 200 million and 300 million people in 77 countries throughout the world and is a significant cause of disease in areas of endemic infections. In Egypt, approximately 20% of the population is infected; prevalence rates in some villages have been estimated to be 85%. The number of infected individuals in China is estimated to be 1.52 million. Although only about 10% of infected people have serious disease, this represents 20 million to 30 million individuals worldwide. Approximately half of the remaining 180 million to 270 million infected individuals have symptoms.

The earliest known instance of schistosomiasis was found in Egyptian mummies of the predynastic period (3100 BCE), using enzyme-linked immunosorbent assay (ELISA) to detect circulating anodic antigen (2). Previously, eggs were detected in the kidneys of mummies from the Twentieth Dynasty (1250 BCE to 1000 BCE). Fujii in 1947 described schistosomiasis caused by *S. japonicum*, and Bilharz in 1951 noted *S. haematobium* infections in Cairo. Schistosome infections in the New World probably began with the African slave trade in the Americas during the 16th and 17th centuries.

Schistosomes are somewhat different from other human trematodes since they (i) have two sexes, (ii) live in the blood vessels, (iii) have nonoperculated eggs, and (iv) have no encysted metacercarial stage in the life cycle. The human is the definitive host for *S. mansoni*, *S. japonicum*, and *S. haematobium*; for *S. mekongi* and *S. malayensis* (both similar to *S. japonicum*); and for *S. intercalatum*. *Schistosoma mattheei*, which causes infections in sheep, cattle, and horses, also infects humans and can cause disease. Other schistosomes have been found in humans but do not tend to cause any pathology. Also, cercariae from birds and mammals can penetrate human skin but cannot complete the life cycle and tend to die without migrating or maturing; however, they do cause cercarial dermatitis.

doi:10.1128/9781555819002.ch20

Schistosoma mansoni

In one of the earliest reports on African schistosomiasis, Theodor Bilharz first noted the disease but mistakenly described two types of eggs, one with a lateral spine and one with a terminal spine, as occurring in the same adult worm. Manson was the first to note schistosomiasis in the New World, but it was Sambon who adequately described the differences between intestinal and urinary tract schistosomiasis and proposed the name *S. mansoni*. *S. mansoni* was probably established in the Western Hemisphere as a result of the African slave trade.

The prevalence of the hepatitis C virus (HCV) and *S. mansoni* ranges from 1% in Ethiopia to 50% in Egypt. In Egypt, HCV infection, along with *S. mansoni*, is the main cause of chronic liver disease and liver cirrhosis. HCV genotype 4a is highly prevalent in Egypt. Schistosomiasis, HCV, hepatitis B virus, and hepatitis G virus are all associated with liver disease. Coinfection with two or more of these infectious agents may potentiate the pathogenesis of the liver disease (3).

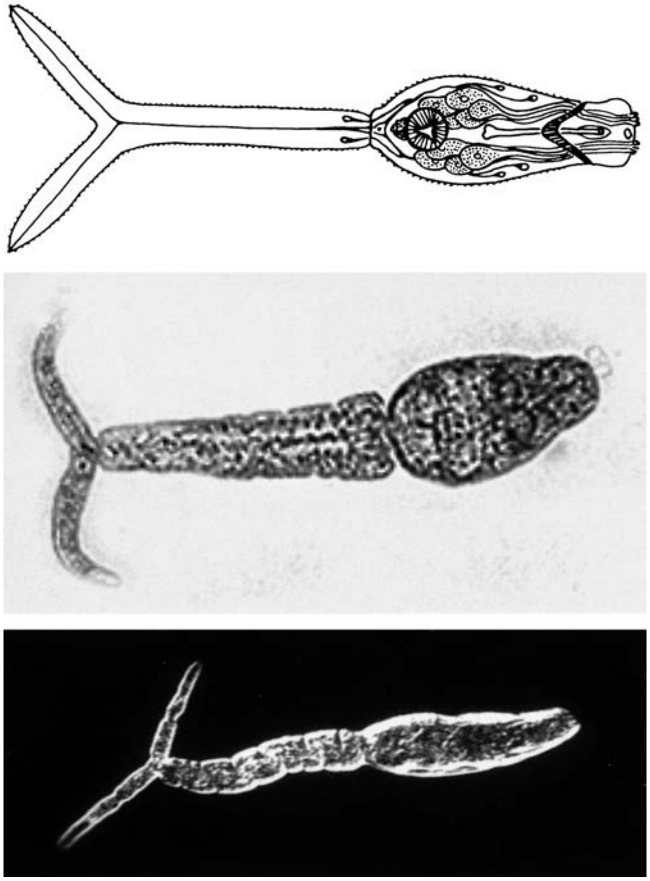

Figure 20.2 Schistosome cercariae. (Top, illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch20.f2

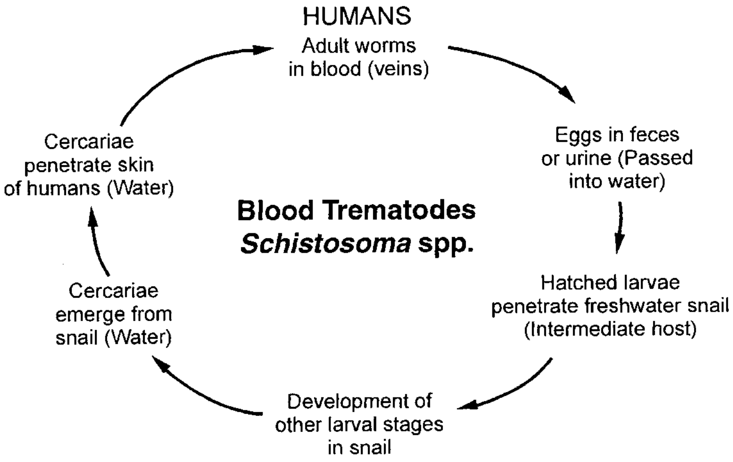
Life Cycle and Morphology

Humans become infected by penetration of cercariae through intact skin rather than by ingestion of metacercariae (Fig. 20.1); penetration can occur within as little as 5 min after initial skin contact. Cercariae consist of a body with glands containing a proteolytic enzyme (elastase), which is used to penetrate skin, and a bifurcated tail that is lost when the cercariae penetrate the skin (Fig. 20.2) (4). Once the cercariae have successfully entered the host, the organism is termed a schistosomulum. After about 48 h, the schistosomulum migrates through the tissues and finally invades a blood vessel. On entry into the blood vessels, the schistosomulum is carried to the lungs and then the liver. Once within the liver sinusoids, the worms begin to mature into adults. The adults of *S. mansoni* are found in the inferior mesenteric veins. The worms form pairs (male and female), with the female lying in the gynecophoral canal of the male (Fig. 20.3 and 20.4). Sexual maturity of female schistosomes depends on the presence of mature male worms. The female worm has selective gene expression in the reproductive tract in the presence of male worms, whereas females separated from male worms lose



HUMANS
Adult worms in blood (veins)
Eggs in feces or urine (Passed into water)
Hatched larvae penetrate freshwater snail (Intermediate host)
Development of other larval stages in snail
Cercariae emerge from snail (Water)
Cercariae penetrate skin of humans (Water)
Blood Trematodes
Schistosoma spp.

Figure 20.1 Life cycle of schistosomes. doi:10.1128/9781555819002.ch20.f1

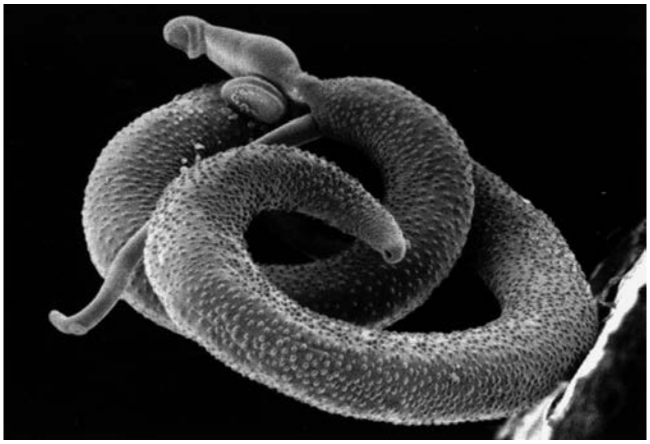


Figure 20.3 Scanning electron micrograph of male and female schistosome *in copula*. doi:10.1128/9781555819002.ch20.f3

this capability. Exploitation of these genetic differences may be of value in drug research and in attempts to reduce host morbidity. Prior to egg production, migration and maturation generally require about 4 to 6 weeks.

Humans are the only important definitive hosts of *S. mansoni* (Table 20.1). Fully embryonated eggs without an operculum (114 to 180 μm by 45 to 73 μm) are passed in the stool (Fig. 20.5 and 20.6). The eggs are light yellowish brown and elongate, and they possess a large lateral spine projecting from the side near one end of the egg. The eggshell is acid fast when stained by a modified Ziehl-Neelsen technique. On reaching water, the eggs hatch, liberating miracidia (Fig. 20.7) which must penetrate a suitable snail host (*Biomphalaria* spp.). Cercariae liberated from the infected snail infect humans when the latter come in contact with cercaria-infested water. A period of 4 weeks or more from the time of first infection with a miracidium is required before the snail sheds cercariae. On infection, the cercariae lose their tails, and the body (schistosomulum) migrates through the lungs to the liver, where it develops to a mature adult in the mesenteric veins of the large bowel. Some worms are also found in the superior mesenteric veins, vesical plexus, and intrahepatic portion of the portal veins.

The adult male and female can reach lengths of 1.2 and 1.6 cm, respectively. They have oral and ventral (acetabulum) suckers at the anterior end. The worm surface is a tegument containing a syncytium of cells. The male worm's body, which is flattened behind the ventral sucker, appears cylindrical as it curves to form the gynecophoral canal to clasp the female worm. The female worm is long, slender, and cylindrical in cross section (Fig. 20.4). While held in the gynecophoral canal of the male, the female ingests 10 times more red blood cells than does the male. The tegument of the male contains many prominent tuberculations, while the tegument of the female is devoid of the tuberculations (Fig. 20.3). The uterus of the female is short and usually contains only one egg at a time. After mating, the female leaves the male and migrates against the flow of blood to the small venules of the intestine. Initial egg production begins 4 to 7 weeks after infection. *S. mansoni* mature females produce 100 to 300 eggs per day.

The eggs are immature when first laid and take approximately 8 to 10 days to develop a mature miracidium. They are nonoperculate and contain a lateral spine. Egg deposition takes place intravascularly. Many of the eggs laid are swept away and become lodged in the microvasculature of the liver and other organs. About half of the eggs swept away by the bloodstream become embedded in the mesenteric venule wall. The presence of eggs in the tissues

Figure 20.4 *Schistosoma mansoni* male and female *in copula*. (Upper) Cross-section (indirect fluorescent antibody stain). (Courtesy of CDC Public Health Image Library/Marianna Wilson.) (Lower) Cross-section of adult worm pair in the mesenteric venule of a mouse; hematoxylin and eosin stain (courtesy of http://openi.nlm.nih.gov/detailedresult.php?img=2154383_pntd.0000032.g002&req=4). Note the female is seen within the male worm in both images (arrows). doi:10.1128/9781555819002.ch20.f4

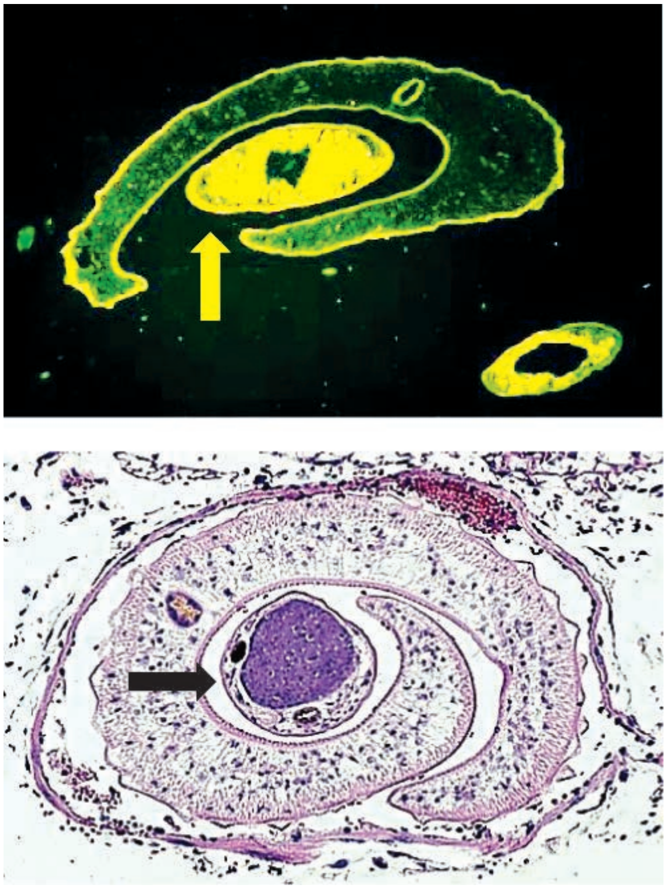

TABLE 20.1 Characteristics of blood trematodes

Species	Distribution	Reservoir hosts	Intermediate snail host genus	Diagnostic specimen or test	Egg		
					Size (µm)	Morphology	Comments
S. mansoni	Africa, Madagascar, West Indies, Suriname, Brazil, Venezuela	Humans, nonhuman primates	*Biomphalaria*	Stool, rectal biopsy, serology	114–180 by 45–73	Elongate, prominent lateral spine; acid-fast positive	In a wet preparation, egg may be turned so lateral spine is not visible; evidence of flame cell activity is proof of viability; can use hatching test (unpreserved specimens) to confirm; occasionally found in urine
S. japonicum	China, Indonesia, Japan, Philippines	Dogs, cats, cattle, water buffalo, pigs	*Oncomelania*	Stool, rectal biopsy, serology	70–100 by 50–65	Oval, minute lateral spine; acid-fast positive	Eggs can mimic debris in the wet preparation; small spine may be very hard to see; debris often clings to the surface of the egg; less likely to be found in urine, but possible
S. malayensis	Malaysia	Jungle rat	*Robertsiella*	Stool	50 by 28	Oval, lateral knob-like structure	Eggs found in liver granuloma; closely related to *S. mekongi*; eggs smaller than *S. mekongi*
S. mekongi	Mekong River basin	Humans, dogs, rodents	*Lithoglyphopsis*	Stool, rectal biopsy, serology	50–65 by 30–55	Subspherical, minute lateral spine	Looks very much like *S. japonicum* egg; lateral spine may be difficult to see
S. haematobium	Africa, Middle East, India, Portugal	Humans	*Bulinus*	Urine, stool (some cases), bladder biopsy, serology	112–170 by 40–70	Elongate, terminal spine; acid-fast negative	If present, usually easy to identify; however, urine sedimentation can be time-consuming; can use membrane filter approach as well; eggs occasionally found in stool; hatching test on urine (unpreserved) sediment is relevant
S. intercalatum	Central and western Africa	Humans	*Bulinus*	Stool, rectal biopsy, serology	140–240 by 50–85	Elongate, terminal spine; acid-fast positive	Egg resembles *S. haematobium* egg but is found in stool rather than urine

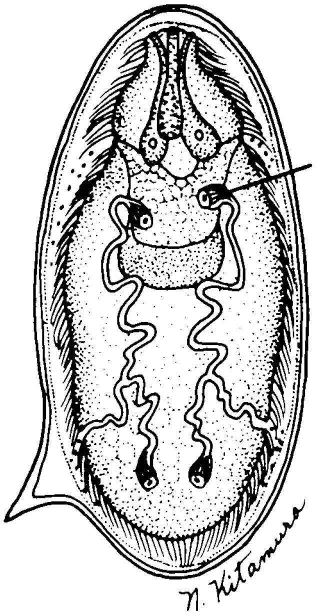

Figure 20.5 *Schistosoma mansoni* egg with a mature miracidium. (Illustration by Nobuko Kitamura; adapted from Beaver PC et al, *Clinical Parasitology*, 9th ed, Lea & Febiger, Philadelphia, PA, 1984.) doi:10.1128/9781555819002.ch20.f5

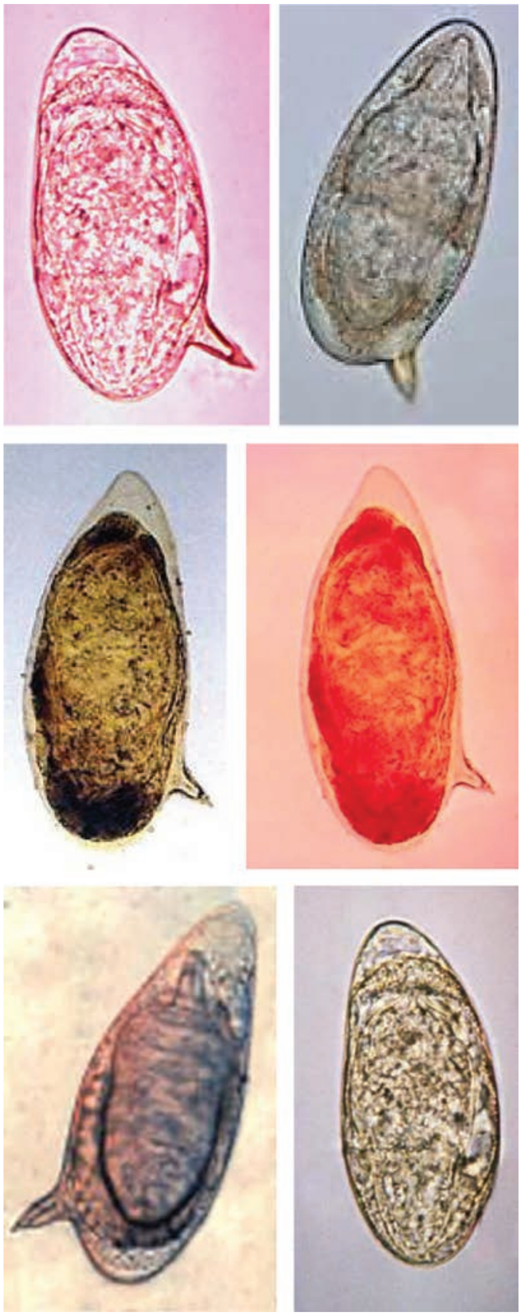

Figure 20.6 *Schistosoma mansoni* eggs. Note the large lateral spines. (Bottom) Note that the lateral spine may not be visible if the egg is turned the wrong way in the wet preparation. Tap on the coverslip to move the eggs into a different position. doi:10.1128/9781555819002.ch20.f6

stimulates granuloma formation; the eggs die, calcify, and are eventually absorbed by the host (Fig. 20.8 and 20.9).

The eggs that are not trapped in the tissues will continue the normal life cycle. The process of maturation and tissue penetration takes about 8 to 10 days; the eggs work their way through the tissues into the lumen of the intestine to be released from the body in the feces. Egg migration through the tissues is facilitated by the release of enzymes by the miracidium through the eggshell. These enzymes help digest the tissue. Eggs making their way through the tissues into the lumen contain a mature miracidium that is released when the eggs are in contact with water (Fig. 20.7). The actively swimming miracidium seeks a suitable snail host, which it penetrates. Within the snail, the miracidium develops into a mother sporocyst, which in turn produces daughter sporocysts. The daughter sporocysts develop in the hepatopancreas of the snail and produce cercariae (Fig. 20.2). The miracidium, which may be either female or male, gives rise to cercariae of the same sex. This portion of the cycle in the intermediate snail host takes approximately 3 to 5 weeks. The cercariae are released from the snail into freshwater, where they may infect humans by penetrating the skin. Stimuli for cercarial shedding of *S. mansoni* cercariae include bright, direct sunlight and water temperatures of 24 to 30°C, leading to higher transmission rates during the summer. *S. mansoni* cercariae move vertically, alternating between migrations toward the surface and sinking. The cercariae attach to the skin of the definitive host via their ventral or oral suckers. Approximately 40% of the cercariae that penetrate the skin will go on to become adult worms; if the cercariae do not find a suitable host, they usually die within 48 to 72 h.

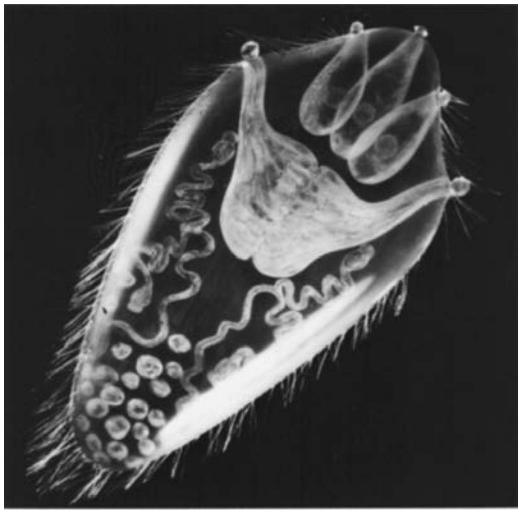

Figure 20.7 *Schistosoma* miracidium (Armed Forces Institute of Pathology photograph). doi:10.1128/9781555819002.ch20.f7

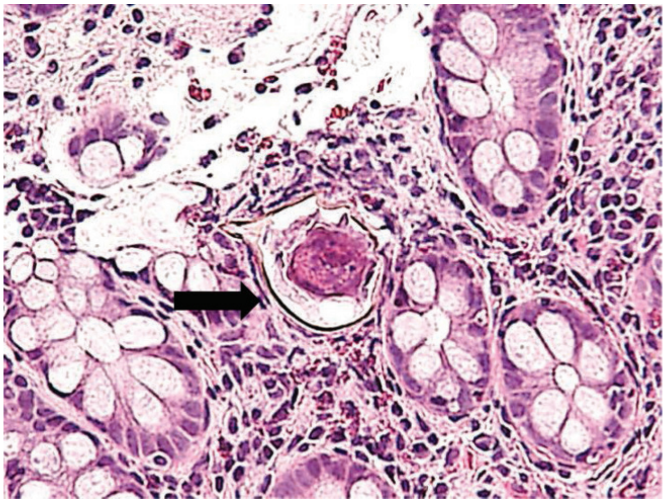
Clinical Disease

Disease syndromes associated with schistosomiasis are related to the stage of infection, previous host exposure, worm burden, and host response. Syndromes include cercarial dermatitis, acute schistosomiasis (Katayama syndrome), and related tissue changes resulting from egg deposition. It has been noted that schistosomiasis exerts disruptive influences on the nutritional reserves and growth of humans from middle childhood through adolescence.

Schistosome Cercarial Dermatitis. Cercarial dermatitis follows skin penetration by cercariae, and the reaction may be due partly to previous host sensitization. Few clinical manifestations are associated with primary exposure, but both humoral and cellular immune responses are elicited on subsequent exposure. After cercarial skin penetration, petechial hemorrhages with edema and pruritus occur. The subsequent maculopapular rash, which may become vesicular, may last 36 h or more. Cercarial dermatitis is common with *S. mansoni* infections. Dermatitis is a constant feature of human infection with avian schistosomes, with cercarial death occurring in the subcutaneous tissues and immediate hypersensitivity reactions occurring at the invasion sites. This condition is known as swimmer's itch. Avian schistosomiasis has been reported worldwide; typically, any bay region with freshwater or saltwater where infected snails are found can be linked to nonhuman cercarial dermatitis. Previous contact with cercariae will lead to a more immediate intense immune response. Schistosomiasis must be included in the list of differential diagnosis of skin lesions, especially in endemic areas, due to the potential sequelae in cases in which the diagnosis and treatment are delayed.

Figure 20.8 *Schistosoma mansoni* eggs in colon biopsy (arrow). (Courtesy of Jennifer Stumph, Spectrum Health; http://www.pathologyoutlines.com/topic/parasitologyschisto.html.) doi:10.1128/9781555819002.ch20.f8



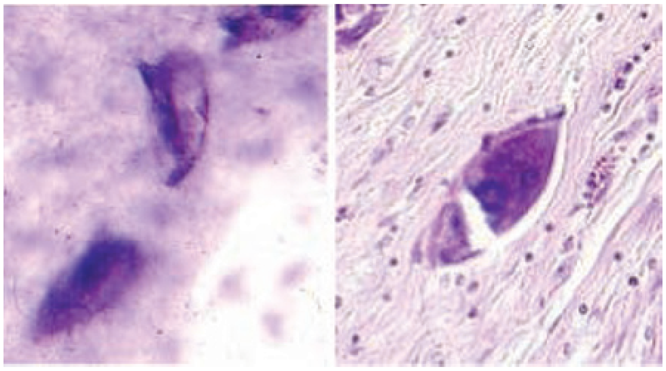


Figure 20.9 Schistosome eggs in tissue. (Left) *S. mansoni*; (right) *S. haematobium*. doi:10.1128/9781555819002.ch20.f9

Acute Disease: Katayama Syndrome. Acute schistosomiasis (Katayama syndrome) is an early clinical manifestation of schistosomiasis that occurs several weeks postinfection with *Schistosoma* spp. (trematode) worms and is associated with heavy primary infections and the initiation of egg production throughout areas of high transmission risk. Because of this time delay and its nonspecific presentation, it is most likely to be misdiagnosed by travel medicine physicians and infectious disease specialists in countries where the disease is not endemic. The signs and symptoms resemble those of serum sickness. Characteristic symptoms include high fever, hepatosplenomegaly, lymphadenopathy, eosinophilia, and dysentery. Diffuse pulmonary infiltrates are seen radiologically, and almost all patients have eosinophilia and a history of water contact 14 to 84 days before presentation of symptoms. This clinical syndrome occurs a few weeks after the primary infection, particularly with *S. mansoni*; however, it is infrequent in inhabitants of areas where infections are endemic. Although widely described, this syndrome does not appear to be as common as it once was, nor are its immunology and pathology well understood (5, 6).

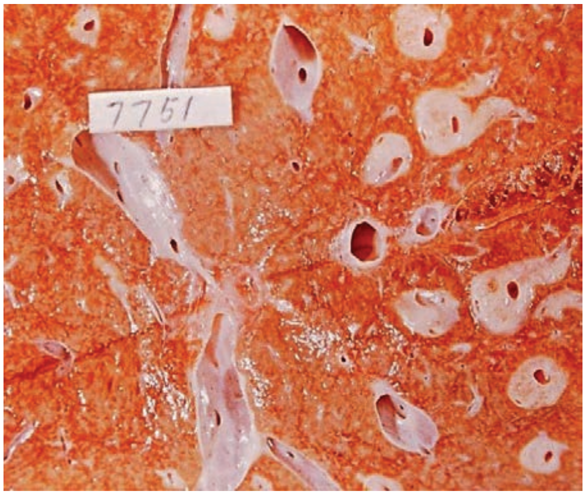
Immune Response. After infection and the transformation of cercariae to schistosomula, the schistosomulum expresses antigens on its surface that evoke a host immune response that provides some degree of resistance to reinfection. As the worms mature, they become less antigenic and more resistant to the immune system-mediated killing mechanisms of the host. The worms are able to incorporate host antigen onto their surface, thus preventing the host from recognizing these parasites as foreign. Because schistosomes are incapable of synthesizing fatty acids or cholesterol, they must bind low-density lipoproteins onto their surface. These bound low-density lipoproteins may be essential in allowing the parasite to evade the host immune response. The adult worms do not appear to cause any damage to the host, nor do they evoke much of an immune response. Immunoglobulin E (IgE) antibodies and eosinophilia appear to play a major role in the host immune response and resistance to reinfection (7). In infected individuals, there is a marked increase in the levels of IgE and IgG4 against various parasitic antigens (8). Individuals develop an age-acquired resistance as they are exposed to infection (9). These antibodies have also been associated with resistance to reinfection. In acute schistosomiasis, the levels of IgA and IgM correlate with the intensity of infection. The detection of IgA might be useful for the differentiation of acute and chronic schistosomiasis. High IgM levels can be detected in both acute and chronic disease.

Chronic Schistosomiasis. After production of eggs by the adult worms (Fig. 20.6), the eggs become trapped in the fine venules and are able to pass through the tissues, escaping into the intestine or, less commonly, the bladder. The eggs liberate a number of soluble antigens, evoking minute abscesses, which facilitate their passage into the lumen. The passage of eggs through the wall of the intestine or bladder leads to symptoms that correlate with the worm burden of the host, including fever, abdominal pain, liver tenderness, urticaria, and general malaise. In *S. mansoni* infection, blood and mucus are detected in the stools and the patient may have diarrhea or dysentery.

Intestinal disease. As eggs are deposited in the tissues, the antigenic substances released by the eggs invoke a host immune response that includes the formation of granulomas around the eggs trapped in the tissues. Many eggs are retained in the intestinal tissue. Cellular infiltrates include lymphocytes, eosinophils, macrophages, and fibroblasts. Granuloma aggregation in the intestinal tract wall is the major cause of pathologic change (Fig. 20.8). The intestinal wall becomes inflamed, thickened, and fibrotic, leading to mechanical obstruction. Apparently, adhesion molecules are important elements in schistosomal intestinal granuloma formation (10). Intestinal schistosomiasis is common in *S. mansoni* infections but can also occur in *S. haematobium* infections.

Hepatosplenic disease. Although many eggs remain where they are deposited, others are swept into the circulation and filtered out in the liver, leading to hepatosplenic schistosomiasis. Hepatosplenomegaly is common in patients with *S. mansoni* chronic infections. In some areas, *S. mansoni*, *S. japonicum*, and viral hepatitis are the most common causes of chronic liver disease. Patients with concomitant viral hepatitis may develop a more severe form of hepatosplenic schistosomiasis. In hepatic schistosomiasis, pathology occurs when schistosome eggs are trapped in the host liver, producing an interleukin 4 (IL-4)- and IL-13-mediated dominant $CD4^+$ Th2 immune response. This response leads to the development of granulomas and fibrosis, with eosinophils, neutrophils, macrophages, hepatic stellate cells, and lymphocytes all identified as major cellular contributors to these sequelae (11). Eggs deposited in the portal triads of the liver stimulate a granulomatous response, leading to continuous fibrosis of the periportal tissue. The fibrotic tissue is white and hard (Fig. 20.10); it has been referred to as Symmer's pipe-stem fibrosis but is now known as fibro-obstructive hepatic schistosomiasis (12). The liver increases in size as a result of the lesions induced by the eggs. The major effect

Figure 20.10 Pipe-stem fibrosis in the liver as a result of *Schistosoma mansoni*. (Original photograph by L. Millman; from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch20.f10



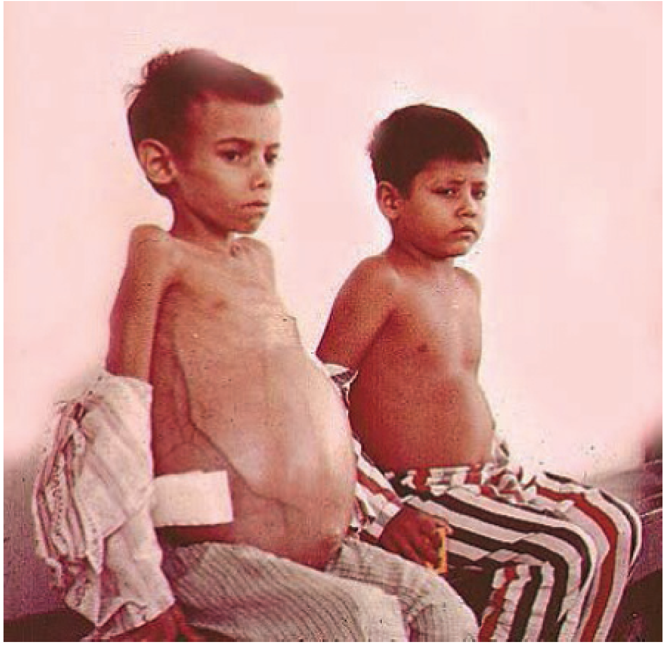


Figure 20.11 Schistosomiasis. Note the engorgement of collateral circulation of the abdomen. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch20.f11

of the liver changes is the blockage of portal blood flow, resulting in increased portal hypertension and the development of collateral circulation, such as esophageal varices (Fig. 20.11). Ascites may be evident, depending on the degree of liver obstruction. The spleen becomes congested and increases greatly in size (Fig. 20.12). The presence of large quantities of antigenic material in the spleen could suggest an important role for this organ in antigen clearance and might provide an additional explanation for the hepatosplenomegaly seen in *S. mansoni*-infected children.

Kidney disease. The level of circulating immune complexes appears to be correlated with the worm burden of the host. These immune complexes may be deposited on the basement membrane and glomerular capillaries, causing nephrosclerosis and kidney failure. The severity of kidney disease is associated with the worm burden and the degree and duration of hepatic fibrosis. The relationship between renal and hepatic disease may be the result of development of a collateral circulation, which would interfere with the normal clearance of circulating antigens and immune complexes by Kupffer cells.

Neuroschistosomiasis. Eggs trapped in the brain have caused focal and generalized seizures. Spinal cord schistosomiasis has been found in patients with *S. mansoni* infections; the myelopathy is probably the result of hypersensitization to the eggs. Myelopathies occur infrequently, and eggs are commonly found in the spinal cord of patients without eliciting symptoms. Neuroschistosomiasis is one of the most severe clinical outcomes associated with schistosome infection. Eggs within the central nervous system (CNS) induce a cell-mediated Th2-driven periovular granulomatous reaction. The mass effect of thousands of eggs and the large granulomas concentrated within the brain or spinal cord explain the signs and symptoms of increased intracranial pressure, myelopathy, radiculopathy, and subsequent clinical sequelae. Cerebral complications include encephalopathy with headache, visual impairment, delirium, seizures, motor deficits, and ataxia, whereas spinal symptoms include lumbar pain, lower limb radicular pain, muscle weakness, sensory loss, and bladder dysfunction (13).

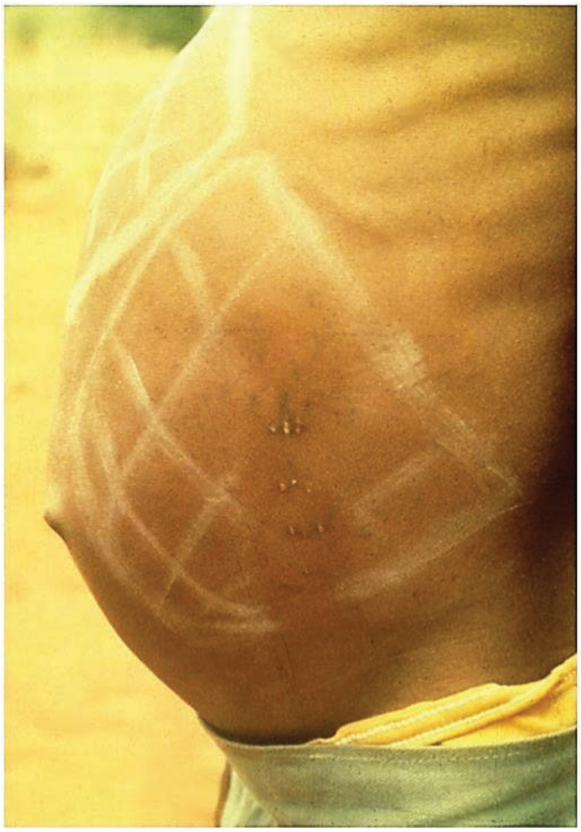

Figure 20.12 *Schistosoma mansoni* infection showing liver and splenic enlargement; 800 worms were removed from this patient. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. Goldsmith and B. H. Kean.) doi:10.1128/9781555819002.ch20.f12

Pulmonary disease. Although not frequently described, pulmonary involvement with *Schistosoma* can occur in acute cases and may be much more common than previously suspected. Dry cough is a frequent symptom in patients with Katayama syndrome, but shortness of breath, dyspnea, wheeze, and chest pain may also appear (14). Chest radiographs may reveal nodular lesions with ill-defined borders and less frequently pleural effusion or reticulonodular infiltrates. The most common findings on a chest CT scan are pulmonary nodules from 2 to 15 mm and ground-glass attenuation areas (15). Pulmonary involvement is seen with all forms of schistosomiasis in patients with heavy worm burdens. Schistosomiasis is one of the most common causes of pulmonary arterial hypertension worldwide. Schistosomal lung disease is usually seen only after the development of collateral circulation in infections with *S. mansoni* and *S. japonicum*. The subsequent development of pulmonary hypertension leads to cor pulmonale (right-sided heart failure). Signs of the disease include fatigue, cough with possible hemoptysis, palpitations, dyspnea on exertion, right ventricular hypertrophy, and pulmonary artery dilation.

Bacteremia. Chronic bacteremic infections with *Salmonella* spp. have been associated with *S. mansoni* infections. Common features of this association between *Salmonella* and *Schistosoma* infections include a long history of recurrent febrile illness, frequent isolation of *Salmonella* spp. from the blood, and chronic active schistosomiasis. The *Salmonella-Schistosoma* infection association is seen most frequently in males between the ages of 15 and 30 years. If the underlying schistosome infection is not treated, the *Salmonella* infection will continue to recur. It has also been shown that granulomas of *S. mansoni* in the liver are foci for colonization with *Staphylococcus aureus*, which in presence of staphylococcal bacteremia can form liver abscesses (16).

Diagnosis

We need more accurate, standardized, and sensitive diagnostic techniques for *Schistosoma* infection confirmation. Unfortunately, the development of new assays has evolved slowly, partially because of the current control approach that emphasizes preventive chemotherapy, which is the regular administration of drugs to at-risk populations without prior diagnosis. Another issue involves the perception of inadequate financial returns to the relevant companies that develop these diagnostic products.

Schistosomiasis should be suspected in individuals who have had significant contact with water in areas of endemic infection. Symptoms of acute schistosomiasis include fever, diarrhea, abdominal pain, weight loss, and eosinophilia. Symptoms of chronic disease include chronic diarrhea, abdominal pain, and hepatomegaly or hepatosplenomegaly.

Diagnostic Procedures. Specific diagnosis of schistosomiasis by detection of eggs in stool or urine specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with a low worm burden or old (chronic) infections may have very few eggs in the feces or urine, and the infections may not be confirmed due to insensitive diagnostic methods. Multiple stools and urine examinations should be performed for any individual suspected of having schistosomiasis. Occasionally, *S. mansoni* eggs are detected in the urine; adult worms may be found in vessels that are not their normal habitat, and this finding is known as "crossover."

S. mansoni eggs are yellowish brown and measure 114 to 180 μm long by 45 to 73 μm wide (Fig. 20.6; Table 20.1). The eggs are elongate and ovoid and have a large lateral spine projecting near one end. Direct detection or concentration techniques can be used to detect eggs in the stool or urine. Direct microscopic examination of stool smears is not very sensitive but may be useful for screening purposes. The Kato thick smear is a simple and sensitive quantitation technique that has been used successfully in the field. In one study, more than 50% of the eggs were missed by the sedimentation technique; the geometric mean egg count was 94 eggs/g when two Kato-Katz smears were used and 43 eggs/g when the sedimentation technique was used (17). However, no details of the centrifugation speed and time were given. Another study indicated that examination of fewer samples collected on different days was more effective than examination of more slides from one stool specimen for accurate estimation of the real infection status.

The zinc sulfate concentration technique is not recommended for schistosome eggs. The eggs rupture and do not float but instead are found in the sediment. The formalin-ethyl acetate technique is recommended for concentrating eggs; however, because it involves fixation, it cannot be used to detect egg viability.

In chronic infections in which the worm burden is light, hatching tests can be performed. Fresh stool specimens are diluted with nonchlorinated water in a sedimentation flask or a beaker. The sides of the flask or beaker are covered with aluminum foil to prevent light from passing through. A light source is used to project a perpendicular light beam through the water at the top. Miracidia that hatch from the live eggs will concentrate in the light and can be detected swimming around. This motility can easily be observed with a hand lens. Aliquots of the surface water can be transferred to a small petri dish and observed under a dissecting microscope for miracidia. Observation periods should be frequent because of the limited life span of the miracidia. Ideally, observations should be made every 30 min over a period of 4 h. The hatching test is designed to mimic the conditions in nature with spring water and sunlight (see chapter 4).

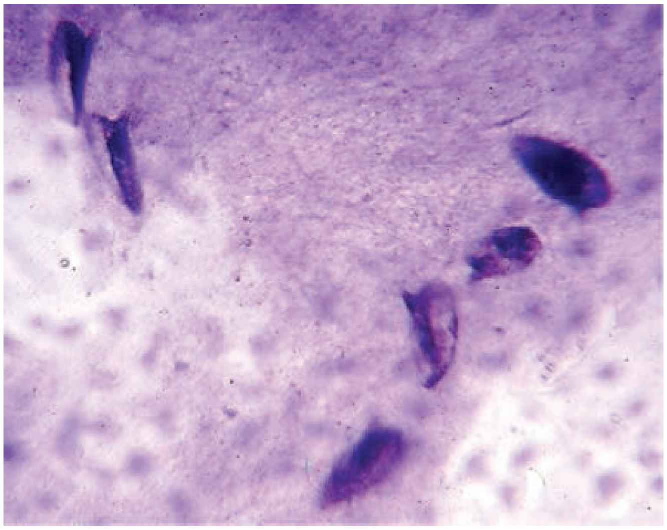

Figure 20.13 *Schistosoma mansoni* eggs in crushed rectal biopsy tissue. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch20.f13

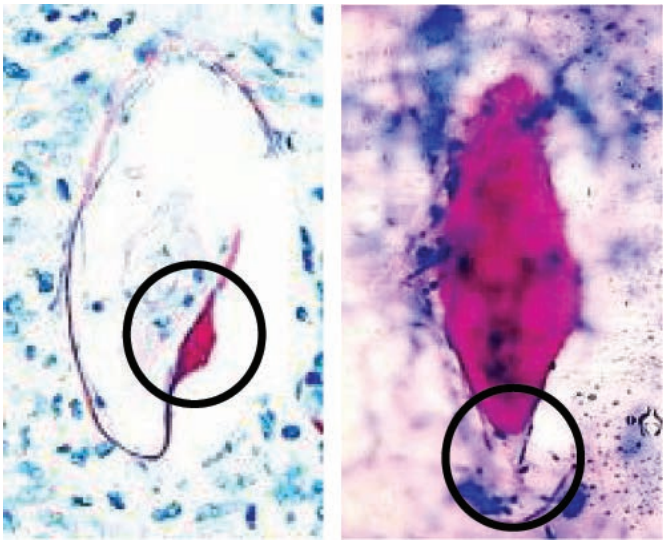

Figure 20.14 (Left) *Schistosoma mansoni* egg shell (acid-fast positive [circle]) (courtesy of http://www.ganfyd.org/index.php?title=Ziehl-Neelsen_staining). (Right) *Schistosoma haematobium* egg. Note the shell is acid-fast negative (circle), but the miracidium larva within the egg shell is acid-fast positive (courtesy of http://parasite.org.au/pugh-collection/Schistosoma%20haematobium%20%201%2022.jpg_Index.html). doi:10.1128/9781555819002.ch20.f14

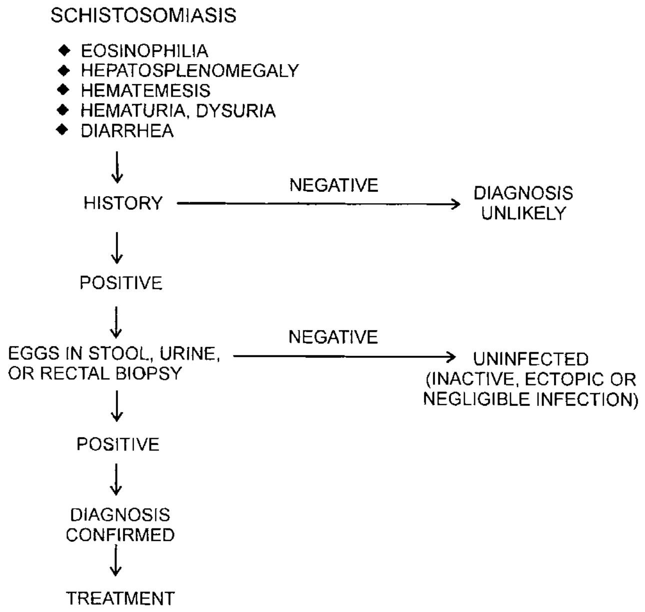
Biopsy Specimens. Rectal biopsy specimens have been particularly useful in detecting eggs in patients with light, chronic, or inactive infections (Fig. 20.13). The biopsy tissue can be crushed between two glass slides; the tissue can also be stained without routine sectioning. This technique is more effective than histologic examination and allows assessment of the species and viability of the eggs prior to staining. The viability of the eggs can be determined by closely observing the miracidium for flame cell activity. Each miracidium contains two pairs of flame cells, and these are actively beating in live miracidia (Fig. 20.5). Eggs can also be recovered from tissue by digestion in 4% KOH at 37°C for 6 to 18 h and microscopic examination of the sediment. *S. mansoni* eggshells can be stained acid fast with a modified Ziehl-Neelsen stain. This technique has been used in tissue sections to differentiate *S. mansoni* eggs from *S. haematobium* eggs, as the latter are not acid-fast positive. The shell of *S. mansoni*, *S. intercalatum* and *S. japonicum* eggs also stains positive, unlike the eggs of other *Schistosoma* species (18) (Fig. 20.14). As seen in Fig. 20.14, it is also important to remember that while the egg shell may not be acid-fast, the miracidium larva within the shell may be acid-fast (*S. haematobium*).

Antibody Detection. A large number of serologic tests have been used in the diagnosis of schistosomiasis (19, 20); however, many have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (19, 21). See Algorithm 20.1. The most commonly and widely used methods that have been validated in large-scale field trials include ELISA, the circumoval precipitin test, the indirect hemagglutination test, the indirect immunofluorescence test, and the skin reaction test.

The skin test was used primarily in China during the 1950s; however, this test remains positive for many years after successful therapy and is no longer used. The circumoval precipitin test is based on patient serum precipitation with lyophilized eggs or purified live eggs seen under the microscope. This method is useful for the diagnosis of *S. mansoni* and *S. japonicum* due to its high sensitivity (92 to 100%) and specificity (96 to 100%). However, this test is time consuming (48 h), is complicated to execute, and has a varying period of seroconversion after treatment (20). Using indirect immunofluorescence with adult worm sections, gut-associated fluorescence may occur 44 days after infection and is consistently associated with acute schistosomiasis mansoni infection (Fig. 20.4). However, the need for a costly and complex microscope, experienced personnel, and special reagents limits the efficacy of this technique. The indirect hemagglutination technique uses



Algorithm 20.1 Schistosomiasis. doi:10.1128/9781555819002.ch20.Alg20.1

lyophilized red blood cells coated with crude soluble egg antigen for the detection of positive patient sera through agglutination. This technique can be used in field conditions and requires only basic laboratory equipment.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has then been confirmed by the enzyme-linked immunoelectrotransfer blot (EITB) test (19). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as do patients with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (19). It is possible that high titers posttherapy reflect treatment failure and reinfection. Recombinant antigens provide a promising approach for the diagnosis of schistosomiasis, but they are still in the experimental phase requiring validation.

Antigen Detection. ELISA has also been used to detect circulating schistosome antigens in the serum and urine of infected patients and may be one of the preferred methods of diagnosis (22, 23). In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor the efficacy of therapy (22, 23) (Table 20.2). Individuals treated with praziquantel experienced a rapid clearance of circulating anodic antigens (CAA) and circulating cathodic antigens (CCA); however, in individuals treated with other therapeutic drugs, clearance may take much longer. A dipstick assay based on the anti-CCA sandwich ELISA, on a nitrocellulose format, can detect CCA in the urine of *S. mansoni*-infected patients with a sensitivity of 92%. The results were at least as good as those obtained by ELISA or the Kato-Katz fecal smear examination. This rapid, simple approach may lend itself to more extensive use in future screening programs (24, 25). The reagent strip and cassette formats have proven to work well (26, 27).

Molecular Testing. In human schistosomiasis, the first application of PCR as a diagnostic tool in an area of endemicity was in an assay for *S. mansoni* DNA detection in stool samples. Comparing the PCR assay to stool examinations by the Kato-Katz technique, the PCR assay showed sensitivity of 96.7% and specificity of 88% when applied among 194 inhabitants from an area of endemicity in Brazil. This technique might prove to be useful in low-transmission settings due to its high sensitivity (96.7%) compared to the 79% sensitivity obtained by stool examination. The sensitivity of this technique was reevaluated in other studies in which it was applied to preselected individuals with low worm burden and schistosomiasis-positive patients after treatment (28). Under these specific conditions, both studies confirmed the high sensitivity of the PCR assay. The role of PCR-based assays in schistosomiasis diagnosis outside of research settings remains poorly defined, despite their significant potential in low-transmission settings and in situations where high sensitivity and specificity are required. Research initiatives tend to be focused on the development of point-of-care diagnostics that can rapidly and accurately identify infections in patients, promoting the use of standardized and validated commercial kits and applying molecular high-throughput multiplexing assays for simultaneous diagnosis of helminths and intestinal protozoan infections, particularly for returning travelers at specialized laboratories in the industrialized world.

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma mansoni

1. Eggs cannot be detected in stool until the worms mature (may take 4 to 7 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunologic tests for antigen or antibody may be helpful in diagnosing infection in these patients.
3. The zinc sulfate flotation concentration method should not be used; the eggs do not float. The sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the lateral spine may not be visible if the egg is turned on its side (Fig. 20.6).
5. Occasionally, eggs of *S. mansoni* are detected in the urine (crossover phenomenon).

(continued)

TABLE 20.2 Improved immunologic testing for the diagnosis of *S. mansoni* infection

Test	Comments	Reference
ELISA, IgG, IgM, IgA	Crude adult worm extract as an ELISA antigen provides a serologic method with high sensitivity and specificity for the diagnosis of acute and chronic schistosomiasis and for serologic distinction between the two forms of the disease.	90
Immunomagnetic beads with 1 ml of urine	Assay method uses larger sample volumes than ELISA; enhanced detection can be achieved. Valuable in areas with low prevalence or assessment of cure after therapy.	91
ELISA for cercarial elastase	Cercarial elastase is one of the first proteins released in the host by invading cercariae. Detection of antibodies to this protein indicates exposure but not necessarily active infection.	92
ELISA using egg antigen (CEF6)	In areas of endemicity there was a positive correlation between egg intensity and ELISA value. In other areas, specificity was 90%; false-positive results may have been due to inapparent or cured infection.	93
APIA	Solid-phase alkaline phosphatase immunocapture assay for detection of human IgG antibodies to the alkaline phosphatase of *S. mansoni* adults was evaluated. The method appears to be specific for *S. mansoni* and is useful in areas of endemicity where mixed infections occur.	94
Immunoblot	Sm31/32 protein fraction is highly immunogenic; may be a useful serologic marker for diagnosing and differentiating between acute and chronic infection.	95
Fast dot-ELISA	C5C4 MAb is used for rapid and simple diagnosis; the 63-kDa circulating antigen was detected in 92% of 330 urine samples; the false-positive rate in 130 noninfected individuals was 16%.	96
Indirect hemagglutination combined with ELISA	Erythrocytes coated with *S. mansoni* adult worm antigens and ELISA using *S. mansoni* egg antigens; combined use of these two tests led to high degrees of sensitivity and specificity for *S. mansoni*, *S. haematobium*, and combined infections.	74
Antigen detection in urine or serum	Test provides a quantitatively more stable diagnosis of *S. mansoni* than fecal egg counts based on a single stool exam.	97
Antigen detection in fecal specimens	Compared with the Kato-Katz parasitologic exam, PCR has a sensitivity of 96.7% and a specificity of 88%.	98
Antigen detection in urine using dipstick or reagent strip test	Lateral flow on nitrocellulose strip; detection of CCA; sensitivity equal to CCA ELISA; specificity of 96%.	99
Antigen detection in urine using dipstick	Commercially available antigen capture dipstick; detection of CCA; sensitivity of 83% and specificity of 81%; may be too expensive for wide use (US $2.60).	24
Antigen detection in urine using reagent strip test	Under field conditions, 83% sensitivity, 81% specificity for *S. mansoni*	26
Antigen detection in urine using urine-circulating cathodic antigen cassette	89% sensitivity, 100% specificity; in moderate and high-prevalence setting very effective	27

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma mansoni (continued)

6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed with fresh specimens, using the microscopic wet mount test or the hatching test; no preservatives can be used prior to these two tests.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel. Praziquantel, a pyrazinoquinolone, is the drug of choice for treating schistosome infections (29). The current recommendation is 40 mg/kg/day in two doses for 1 day. Praziquantel can also be taken orally in a single dose and is well tolerated by the host. Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. In heavily infected individuals, the side effects, although transient, may be very severe (30). Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Data suggest that a single dose of praziquantel (40 mg/kg of body weight) may have a longer-lasting effect than previously thought, possibly more than 2.5 years (31). Praziquantel has little effect on immature stages of the parasite, and this affects the cure rates as the immature parasites develop to maturity and egg production. The mechanism of action may involve glutathione *S*-transferase, a detoxifying enzyme found in many helminths. Cure rates have been reported to be from 70 to 95%. Praziquantel damages the tegument of the worm, thereby exposing the antigens to parasite-specific antibodies. The use of immunoglobulins along with praziquantel has been proposed to increase the efficacy of treatment.

Praziquantel is rapidly taken up through the gut (in humans more than 80% of the orally administered dose is absorbed from the gastrointestinal tract) and reaches its maximal plasma concentration within 1 to 2 hours. Although the exact mechanism by which praziquantel kills the parasite is not well understood, it is known that the immune response of the host (granulocytes, histiocytes, antibodies) plays an important role in drug efficacy. It is possible that disease states of humans that lead to immunodeficiencies, such as infection with HIV-1, may render praziquantel less effective in treating schistosomiasis. However, studies indicate that persons with HIV-1 infection can be treated effectively for schistosomiasis with praziquantel (32).

Repeated praziquantel therapy can lead to improvement of liver morbidity and prevention of hepatic fibrosis, even in a well-established focus of hyperendemic infection. These results were based on a parasitologic, clinical, and ultrasonographic longitudinal study in a focus of hyperendemic *S. mansoni* infection. Support is also emphasized for programs that encourage people to seek examination and treatment on their own. This type of chemotherapy-based control strategy is called passive chemotherapy.

Reduced efficacy of praziquantel in treating human *S. mansoni* infections and infected animal models has been reported (33, 34). Drug resistance to praziquantel has been demonstrated in the murine model, and there have been unsubstantiated field study reports of resistance. However, resistance to praziquantel in schistosomes is now considered a fact in strains selected in the laboratory. In at least two human populations in Senegal and Egypt with endemic infections, resistance or tolerance to praziquantel has been confirmed. Although the extent of the problem is unclear, it is important to determine the prevalence and significance of the problem and to develop alternate control strategies.

Oxamniquine. Oxamniquine, a nitroquinolone, is active only against *S. mansoni* infections and is very effective against the strains in the Americas and West Africa when given at 15 to 20 mg/kg of body weight. North and East African strains of *S. mansoni* are less sensitive to this drug, and doses of up to 60 mg/kg given over 2 to 3 days may be required to achieve the same results. The drug is more active against male than female worms and has little effect against immature worms. Side effects include abnormal electroencephalograms and dizziness. Oral treatment has reduced egg counts by 95%, with 70 to 100% cure rates. Despite being tolerant to praziquantel, a Senegal isolate of *S. mansoni* was fully susceptible to oxamniquine (35). Unfortunately, this drug is relatively expensive, making it more difficult to use in control programs, particularly if a higher dosage is required. Although mass therapy with this drug can lead to reduction of schistosomiasis morbidity, approximately 68% of patients do not show improvement in their condition (36). It is also important to remember that oxamniquine is contraindicated in pregnancy.

Summary. Patients who have been treated for schistosomiasis should be monitored posttherapy to determine the effectiveness of the treatment. Depending on the drug, follow-up stool or urine examinations may be needed for as long as 1 year posttherapy. It is not safe to assume that one course of therapy or disappearance of symptoms is indicative of cure. Optimal posttreatment reevaluation times have not been established. Patients, particularly those who were heavily parasitized, should be monitored for a reduction in the number of excreted and viable eggs within a few months of therapy.

For patients with secondary bacterial infections, appropriate antibiotics may also be needed to treat systemic infections. Patients suffering from severe Katayama syndrome and transverse myelitis may require steroid treatment. A complete review of the management and therapy of schistosomiasis can be found in Table 20.3.

Epidemiology and Prevention

S. mansoni infections occur in western and central Africa, Egypt, Madagascar, and the Arabian Peninsula. As a consequence of the African slave trade, the infection was established in the Western Hemisphere in Brazil, Suriname, Venezuela, and the West Indies. Human infections are nearly all derived from human sources, even though nonhuman primates, insectivores, marsupials, and rodents can carry the infection. The infection is transmitted by *Biomphalaria* sp., an aquatic snail.

The geographic distribution of the disease depends on the distribution of the intermediate snail hosts and the opportunity to infect humans and snails. Schistosomiasis is transmitted from infected people defecating or urinating in or near water where the appropriate snail host resides. Infections can persist indefinitely in humans. Most infected individuals have low worm burdens, but a few have very heavy infections. It is this latter group that probably makes the greatest contribution to the dissemination of schistosomiasis. The highest rates of infection have been found in

TABLE 20.3 Management and therapy of schistosomiasis[a]

Condition or disease manifestation	Approach	Comments
Schistosome cercarial dermatitis	Self-limited and may go undiagnosed; in severe cases, topical corticosteroids and parenteral antihistamines reduce symptoms	Other names include swimmer's itch, schistosome dermatitis, clam digger's itch, sawah itch, and koganbyo; symptoms will vary due to host susceptibility, schistosome type, and patient's previous exposure history.
Katayama syndrome	Corticosteroids for life-threatening disease; therapy according to schistosome species	Tourists who returned home within a month of exposure; history of water contact, possible swimmer's itch, serum sickness-like disease are clues for possible schistosomiasis.
Gastrointestinal disease	***S. mansoni*:** Praziquantel (40 mg/kg) single dose or oxamniquine (15 mg/kg) single dose for adults (20 mg/kg for children); North and East Africa (60 mg/kg) over 2–3 days in 3 or 4 equally divided doses ***S. japonicum*:** Praziquantel (60 mg/kg) 2 or 3 doses in a single day	Many complications of intestinal granulomas and/or polyp disease are the same as for inflammatory bowel disease (Crohn's and ulcerative colitis); misdiagnosis could have serious sequelae due to potential use of steroid therapy.
	Colonic polyps: Colonoscopy to confirm extent of disease; chemotherapy; surgery may be required for fibrotic obstructive bowel lesion; intussusception (barium enema should be used with care to avoid perforation); rectal prolapse/chemotherapy; anorectal fistulas/abscess, surgical drainage and antibiotic therapy	Seen in 10–15% of some Middle Eastern populations; symptoms are those of focal granulomatous large bowel disease; may mimic chronic severe mucohemorrhagic diarrhea; residual fibrotic scarring may lead to permanent partial bowel obstruction or wall deformation.
Hepatosplenic disease	***S. mansoni*:** Praziquantel or oxamniquine; ultrasonography to define extent of disease ***S. japonicum*:** Praziquantel; ultrasonography	May be genetic predisposition to hepatosplenic syndrome; jaundice characteristically absent; liver cell function generally normal until terminal stages
	Hypersplenism: Therapy	Moderate and generally tolerable to patient
	Ascites: Low-salt diet and diuretics	End-stage disease can involve massive ascites; usually irreversible
	Bleeding esophageal varices: Esophagoscopy to confirm diagnosis (transfusion and esophageal sclerotherapy; surgical shunt for portal hypertension in severe cases)	Liver sonography can estimate degree of portal hypertension (measure distention of portal vein).
Urinary disease	**Uncomplicated:** Praziquantel (40 mg/kg) single dose; ultrasonography or intravenous pyelogram to detect silent obstructive disease	Most infections are mild and asymptomatic.
	Obstructive uropathy: Chemotherapy; may require surgery	Most lesions occur in lower third of ureters or bladder; pyelonephritis/Gram-negative sepsis common
	Urinary tract infection: Antibiotics plus antischistosomal therapy; pyelonephritis may require parenteral antibiotics	Primarily Gram-negative infections
	Renal failure: Hemodialysis or renal transplantation	Bilateral ureteral obstruction common; may be accompanied by *Salmonella* bacteriuria and/or bacteremia
	Bladder cancer: Radial surgery, chemotherapy usually only palliative	Usually lags 10–20 yr behind the peak *S. haematobium* infection; bladder calcifications may resolve over years if the patient remains schistosome free.
Cardiopulmonary disease	**Larval pneumonitis:** Self-limited course; may require short-course therapy with steroids if respiratory distress present	Occurs days to weeks after heavy cercarial exposure; symptoms last 2–4 wk (marked eosinophilia).
	Reactionary pneumonitis: Discontinue therapy until resolution; may require short-course therapy with steroids if respiratory distress is present	Loeffler-like syndrome seen during therapy of heavy infections.
	Cor pulmonale: Antischistosome therapy; symptomatic therapy	Heart affected after exposure to chronic abnormal pressure gradients; antischistosomal therapy prevents disease progression but does not lead to improvement.
Central nervous system disease	**Praziquantel therapy:** steroids recommended to reduce inflammation and size of space-occupying lesions	Most occur with *S. japonicum* (2–4% of cases); parietal lobe is the most common site.
	Cerebral: Focal, generalized seizures **Spinal:** Transverse myelitis of various degrees	Most occur with *S. mansoni*, also *S. haematobium*; lesions may be reversible.
Miscellaneous	***Salmonella*-schistosome syndrome:** Simultaneous antischistosomal and antibacterial therapy	Occurs most commonly in males 15–30 yr old; antibiotic response is dramatic; disease remains if schistosome disease is not also treated.
	Hepatitis B or C virus-schistosome disease: Antischistosomal therapy; transmission precautions for hepatitis B or C	Prognosis more guarded with dual infections

[a] Adapted from reference 46.

children; the greatest cercarial exposure usually occurs in boys aged 5 to 10 years. Older children may have less recreational exposure but are more likely to be exposed while performing chores such as agricultural activities, washing dishes and clothes, and bathing younger siblings. Although adults also have less recreational exposure to water, they also have partial acquired immunity.

Information on the presence of cercariae in water is important when only one of many snails is infected yet capable of shedding enough cercariae to maintain high endemicity. The use of sentinel mice for this purpose is inaccurate, time-consuming, and costly. Filtration is also limited and is associated with many problems. A PCR assay for the detection of *S. mansoni* cercariae in water has been developed. The high sensitivity of this test permits the detection of a single cercaria; a single cercaria could be detected in repeated tests of water filtrates (37).

Studies indicate that there was little transmission of *S. mansoni* in Puerto Rico during the first half of the 1990s and confirm physician anecdotal data that no new infections have been seen during the past few years (38). Recent trends indicate that human schistosomiasis is disappearing from Puerto Rico (39). The Puerto Rico Public Health Department reports that from 1990 through 26 September 2005, only 21 cases were reported. The last single case was in 2005 in a 69-year-old male from the east coast, this case probably being an "old" case. Although low transmission is still possible in Puerto Rico, data suggest that human schistosomiasis has been eliminated from this area. However, in other areas the news is not as good. The emergence of *S. mansoni* in Upper Egypt has not followed any particular pattern; however, the high prevalence detected in certain areas could be associated with the increasing abundance of the snail vector seen in the canals. Underreporting may also be associated with changing surveillance data. Water resource development projects involving the construction of artificial bodies of water and canals for irrigation have contributed to the extension of the disease. The migration of infected persons into virgin areas where suitable snail hosts reside also contributes to the spread of schistosomiasis. These two important factors make control programs difficult.

Schistosoma japonicum

Fujii in 1847 published the first clinical description of *S. japonicum* infections in his Katayama memoir. Katsurada in 1904 described the ova and adult worms that he detected in dogs, cats, and humans and named the parasite *S. japonicum*. Also known as the oriental blood fluke, the parasite is confined to the Far East and has been separated from *S. mekongi*, a more recently described species also found in the Far East. There is enough genetic variation in *S. japonicum* strains isolated from different areas of endemic infection that there may be separate species. *S. japonicum*, distributed in southern China, the Philippines, and parts of Indonesia, is the only schistosome species whose transmission is zoonotic. Over 40 species of wild and domesticated animals can serve as reservoir hosts for this parasite, including cows, pigs, dogs, cats, goats, sheep, and rats.

Life Cycle and Morphology

In addition to infections in humans, *S. japonicum* infections can be found in many mammals exposed to infected water; thus, there are many reservoir hosts, in contrast to other major human schistosomes (Table 20.1). Fully embryonated eggs without an operculum (70 to 100 μm by 50 to 65 μm) are passed in the feces. The eggs are smaller and somewhat more spherical than those of *S. haematobium* and *S. mansoni*. Near one end of the egg is a minute lateral spine; this may be absent in some strains (Fig. 20.15 and 20.16).

The adult worms resemble those of *S. haematobium* and *S. mansoni*; however, they lack integumentary tuberculations. *S. japonicum* adults are found in the radicles of the superior mesenteric vein draining the small intestine (Fig. 20.17). The female worm may contain as many as 50 eggs at one time in the uterus. Because of the higher egg production (3,000 eggs per worm pair per day) and the smaller egg size, an infection with just a few worm pairs can be very serious because the eggs, free in the general circulation, can be filtered out in the liver, the lungs, and even the CNS. The miracidium, released from the egg on contact with water, must find a suitable snail host (*Oncomelania* spp.) to continue the life cycle. Cercariae of *S. japonicum* tend to attach themselves to the water surface film, where they remain unless disturbed.

Clinical Disease

The pathology caused by *S. japonicum* is similar to that caused by *S. mansoni* infections and may include cercarial dermatitis as the first sequence in the disease process (Table 20.4). Although the severity is dependent on the worm burden, the disease has a poor prognosis because of the higher egg production capacity of *S. japonicum* females and the smaller eggs. *S. japonicum* infections have been associated with hepatocellular carcinoma and colorectal cancer. The mechanism of this schistosome-associated carcinogenic enhancement is unknown. The adult worms also have a greater tendency to be found in ectopic sites. Although adult worms have never been detected in the brain, cerebral schistosomiasis is a distinct syndrome that occurs with *S. japonicum* infections. The entire intestinal tract may be involved, but the large intestine is often the primary site and the disease is more severe there.

Acute Disease: Katayama Syndrome. Acute schistosomiasis (Katayama syndrome) is associated with heavy primary infec-

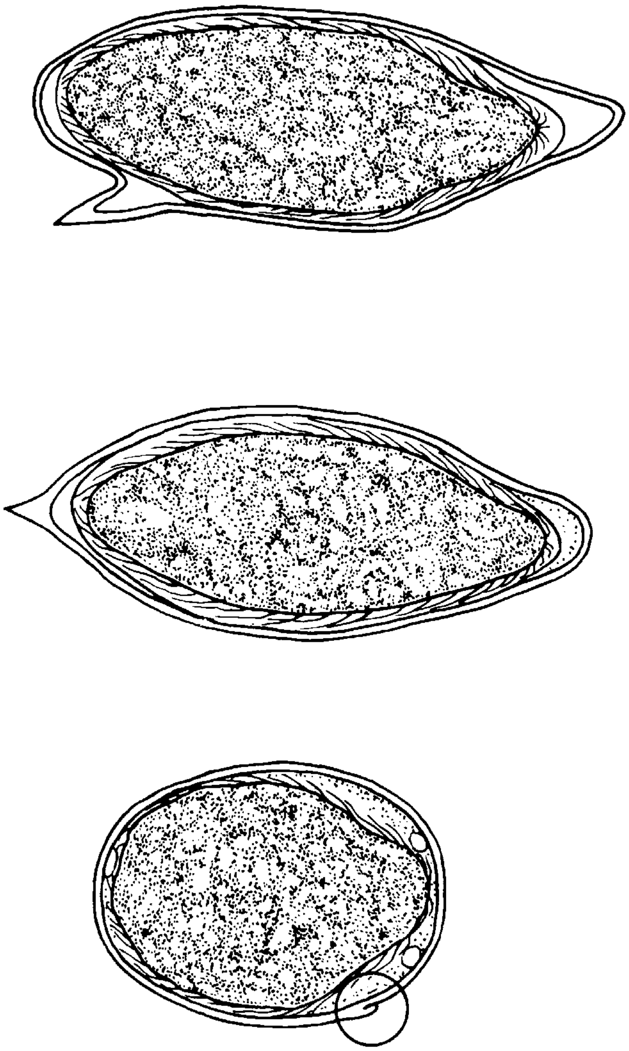


Figure 20.15 *Schistosoma mansoni* (top), *S. haematobium* (middle), and *S. japonicum* (bottom) eggs. Note how much smaller the *S. japonicum* egg normally is than those of the other two species, and note the small size of the lateral spine. (Illustration by Nobuko Kitamura.) doi:10.1128/9781555819002.ch20.f15

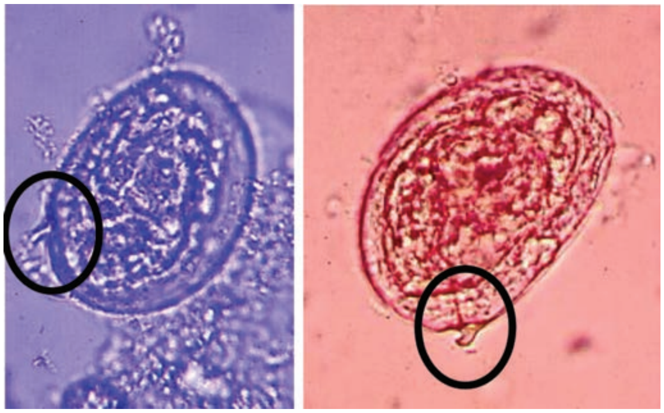

Figure 20.16 *Schistosoma japonicum* eggs. Note the small lateral spine within each oval. doi:10.1128/9781555819002.ch20.f16

tions and the initiation of egg production. The signs and symptoms include high fever, nocturnal fever peaks, coughing, generalized muscle pain, headache, hepatomegaly, lymphadenopathy, eosinophilia, and dysentery. Splenomegaly also occurs in approximately one-third of the patients, while all patients have eosinophilia. Diffuse pulmonary infiltrates are found; some patients have signs of meningoencephalitis. Generally, disease onset occurs about 40 or more days after exposure to a first infection or a large infection (40).

Intestinal Disease. As egg clusters accumulate, mucosal inflammation, hyperplasia, ulceration, microabscess formation, blood loss, and pseudopolyposis may occur. Lower abdominal pain is common and may be colicky and in the left lower quadrant. Diarrhea alternating with constipation is also common, with either visible blood, occult blood, or both. In severe chronic disease, bowel fibrosis and stenosis may occur with thickening of the mesentery.

Hepatosplenic Disease. Eggs that do not reach the intestinal lumen may be trapped or swept up by the portal blood flow. The eggs tend to accumulate in the venules within the portal triads, especially the left lobe; this is followed by granulomatous inflammation, fibrosis, venous obstruction, portal hypertension, and splenomegaly. Hepatosplenomegaly results from the granulomatous response surrounding the eggs. Although splenomegaly generally occurs during the early stages of chronic disease, the en-

Figure 20.17 *Schistosoma japonicum* paired adult male and female in a mesenteric vein. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch20.f17

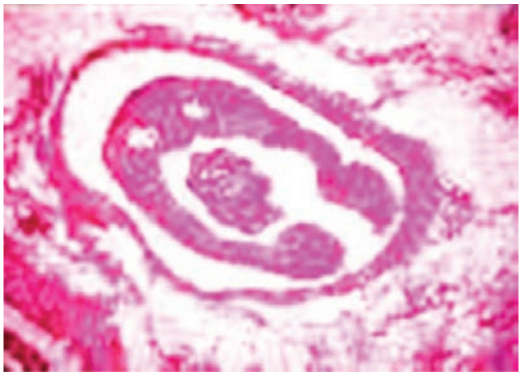

TABLE 20.4 Pathogenesis, pathology, and symptoms seen with *S. japonicum* infection

Stage of infection	Comments
Incubation (migration, maturation)	
Dermatitis	Associated with penetration of cercaria; urticarial rash; diarrhea at the end of this period
Lungs	Traumatic infiltrative changes, at times with hemorrhages, local accumulation of eosinophils, epithelioid cells, giant cells around pulmonary blood vessels (in wake of migrating larvae)
Liver	Acute hepatitis during larval growth in intrahepatic portal blood vessels
Small intestine	Hyperemia in wall of small intestine following arrival and during maturation of worms in superior mesenteric venules
Blood	Marked increase in number of circulating eosinophils
Egg deposition and extrusion	
Small intestine	Trauma with hemorrhage as eggs laid by female worms escape from venules through intestinal submucosa and mucosa into intestinal lumen; may be profuse dysentery; acute attack subsides in 3–10 wk; pseudotubercles form around eggs; repair occurs with scar tissue formation; giant cells develop within pseudotubercles, which become transformed to fibrous nodules
Blood	Blood picture changes from leukocytosis and hypereosinophilia to that of secondary anemia
Liver, spleen, lymph nodes	Liver increases in size as result of lesions around eggs; spleen becomes congested, fibrous reticulum increases, becomes greatly enlarged; mesenteric lymph nodes lose active lymphoid tissue
Tissue proliferation and repair	
Liver, spleen	Liver gradually decreases in size as parenchyma becomes replaced by scar tissue; spleen continues to enlarge; thoracic viscera are pushed upward; patient is weak with marked dyspnea on slight exertion; dilatation of superficial veins of abdomen and thorax is common
Intestine	Intestinal wall becomes thickened and fibrosed; papillomata develop on mucosa
Other problems	Ascites may be present; physical and mental retardation may occur in children; anemia is more pronounced
Blood vessels	Mesenteric and portal vessels become thrombosed; portal fibrosis due to egg deposition around the portal triads; severe fibrosis with white and hard tissue, frequently referred to as Symmer's fibrosis or pipe-stem fibrosis (fibro-obstructive hepatic schistosomiasis)
Cerebral disease	Patients classified as acute, chronic with granulomas or diffuse lesions, psychotic, or as having portal system encephalopathies; 2–4% (in some areas, this figure is higher) of all patients with *S. japonicum* schistosomiasis have acute or chronic cerebral involvement, including epileptic seizures

largement is due to tissue hyperplasia rather than granulomatous inflammation; thus schistosome eggs are rarely found in the spleen. In China, splenectomy is frequently used for severe hypersplenism (40).

After extended chronic disease, gross periportal fibrosis occurs with portal hypertension and secondary esophageal varices. Histology reveals wide bands of fibrous tissue extending along the portal tracts, hence the term "pipe-stem fibrosis," also seen with *S. mansoni* infections. These sequelae are more serious with *S. japonicum* infections, due primarily to the high daily egg production by the female worms. The parenchymal form of hepatic fibrosis occurs most commonly with *S. japonicum* infection and may be a subclinical find in groups who have been treated repeatedly and undergone overt liver disease resolution.

Central Nervous System Disease. Although not every patient with eggs in the CNS is symptomatic, symptoms can include Jacksonian convulsions and grand mal seizures. The use of praziquantel has led to improvement in over 75% of the cases in which it has been used. It is also unclear why Chinese schistosomiasis is associated with ectopic cerebral lesions while African disease tends to be associated with ectopic spinal lesions. Patients with CNS disease usually have the clinical manifestations of increased intracranial pressure associated with focal neurological signs; CNS disease is seen in from 2 to 4% of patients infected with *S. japonicum*. Apparently, the eggs reach the CNS through retrograde venous flow into the Batson vertebral epidural venous plexus, which connects the portal venous system and venae cavae to the spinal cord and cerebral veins. This route includes migration of the adult worms to sites close to the CNS followed by *in situ* deposition of eggs, or massive embolization of eggs from the portal mesenteric-pelvic system. The smaller, round eggs of *S. japonicum* reach the brain, while *S. mansoni* and *S. haematobium* eggs, which are larger and have sizable lateral and terminal spines, remain in the lower spinal cord (41).

Ectopic Disease. Egg granulomas of *S. japonicum* and, in rare cases, adult worms may be found outside the portal venous system, causing ectopic schistosomiasis. Many organs and tissues in a host's body can be involved, including the skin, subcutaneous tissue, lymph nodes, muscles, conjunctiva, tongue, brain, spinal cord, sympathetic nervous system, thyroid, breast, lung, cardiac muscle, pericardium, esophagus, ascitic fluid, kidney, ureter, urethra, bladder, adrenal cortex, inguinal hernia sac, and reproductive organs of both sexes (42).

Cancer and *S. japonicum* Infection. The incidence of colorectal cancer and *S. japonicum* infection correlates with the prevalence, intensity, and length of inflammatory bowel symptoms. This correlation has been reported from both China and Japan. In a study published in 2005 from rural China, schistosomiasis was thought to be responsible for 24% of colon cancers and 27% of liver cancers within that study group (43). Also, schistosome infection may have a negative effect on the prognosis of colorectal cancer. In a report by the National Cooperative Group on Pathology and Prognosis of Colorectal Cancer, the 5-year survival rate was 45.6% out of 430 cases complicated with schistosomiasis, which was significantly lower than in those without schistosomiasis (50.9% out of 2,717) (44).

Data regarding the association between schistosomiasis and colorectal cancer are highly suggestive; however, explanations for causes continue to be debated. Epithelial proliferation and polyp formation are associated with transformation to malignancy, and epithelial proliferation next to a chronic schistosomal lesion appears to be precancerous. Schistosome eggs as a potential causative agent for colorectal cancer may involve physical and chemical effects, changes of the secretion and excretion of the biliary acid, and the overall decline of host cellular immunity.

In reviewing the possible relationship between hepatic schistosomiasis and liver cancer, it appears that HBV and hepatitis C virus (known hepatic carcinogens) and related cirrhosis, as well as alcohol intake, may have a much stronger association than the actual *S. japonicum* infection (45).

Viral, Bacterial, and Alcohol Associations. Although hepatitis B has been reported to be more frequent in patients with schistosomiasis, the evidence is not that strong. Chronic bacteremic infections with *Salmonella* spp. have been associated with *S. haematobium*, *S. japonicum*, and *S. mansoni* infections (46). Common features of this association between *Salmonella* and *Schistosoma* infections include a long history of recurrent febrile illness, frequent isolation of *Salmonella* spp. from the blood, and chronic active schistosomiasis. The *Salmonella-Schistosoma* infection association is seen most frequently in males between the ages of 15 and 30 years. If the underlying schistosome infection is not treated, the *Salmonella* infection will continue to recur. However, this association appears to be rare for *S. japonicum* compared with the other schistosome species. There is evidence that there may be some association between alcoholic cirrhosis and hepatic fibrosis; however, details of specific mechanisms for this association are minimal.

Diagnosis

Schistosomiasis should be suspected in individuals who have had significant contact with water in areas of endemic infection. Symptoms of acute schistosomiasis include fever, diarrhea, abdominal pain, weight loss, and eosinophilia. Symptoms of chronic disease include chronic diarrhea, abdominal pain, and hepatomegaly or hepatosplenomegaly.

Diagnostic Procedures. Specific diagnosis of schistosomiasis by detection of eggs in stool specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with low worm burden or old (chronic) infections may have very few eggs in the feces or urine, and the infections are often not diagnosed because of the limits of sensitivity of examination techniques. Multiple stool examinations should be performed for any individual suspected of having schistosomiasis. Occasionally eggs of *S. japonicum* or *S. mansoni* are detected in the urine. The eggs of *S. japonicum* are more spherical than those of *S. mansoni* or *S. haematobium*; they measure 70 to 100 μm by 50 to 65 μm (Fig. 20.15 and 20.16). A minute lateral spine may be found at one end of the egg; however, it is absent in some strains of *S. japonicum*.

Data from China suggest that a single Kato-Katz smear may be quite adequate for detecting moderately to heavily infected individuals (100 eggs/g of stool); however, for estimating the true prevalence of infection within a community or for obtaining an accurate estimate of egg excretion, multiple Kato-Katz smears are recommended. It should be noted that large variations in egg counts and the lack of sensitivity of the Kato-Katz method, particularly in light and moderate infections, have been reported (47). Eggs also appear to be nonrandomly distributed in stool specimens between the center and surface of the stool; stirring the specimen prior to sampling decreased the count variability. Direct detection or concentration techniques can be used to detect eggs in stool. Direct microscopic examination of stool smears is not very sensitive but may be useful for screening purposes. The Kato thick smear is a simple and sensitive quantitation technique that has been used successfully in the field.

The zinc sulfate concentration technique is not recommended for schistosome eggs. The eggs will rupture and do not float but instead are found in the sediment. The formalin-ethyl acetate technique is recommended for concentrating eggs; however, because it involves fixation, it cannot be used to detect egg viability.

In chronic infections in which the worm burden is light, hatching tests can be performed. The miracidium hatching test has been widely used in China for many years; however, only 50 to 70% of the eggs will hatch, thus presenting problems for detection of light infections. The stool specimens are diluted with nonchlorinated water in a sedimentation flask or a beaker. The sides of the flask or beaker are covered with aluminum foil to prevent light from passing through. A light source is used to project a perpendicular light beam through the water at the top. Miracidia that hatch from the live eggs become concentrated in the light and can be detected swimming around. This motility can easily be observed with a hand lens. Aliquots of the surface water can be transferred to a small petri dish and observed under a dissecting microscope for miracidia. Observation periods should be frequent because of the limited life span of the miracidia. Ideally, observations should be made every 30 min over a period of 4 h. The hatching test is designed to mimic the conditions in nature with spring water and sunlight.

Biopsy Specimens. Although rectal biopsy specimens can be examined, this approach is neither practical nor convenient for population surveys. Also, it is difficult to differentiate dead from living eggs; these findings can lead to excessive therapy.

Sonography. Infection with *S. japonicum* currently affects about 1 million people, mainly in the Philippines and China. Individuals with chronic infection may develop liver fibrosis with portal hypertension, potentially resulting in life-threatening upper gastrointestinal hemorrhage. Apparently, there is no clear evidence about which sonographic features of infection with *S. japonicum* are related to portal hypertension and thus to a more likely fatal outcome. Using Doppler sonography, one study demonstrated that measurements of portal perfusion are a prognostic indicator of the risk of gastrointestinal hemorrhage and overall survival of these patients (48). This study also confirmed the suitability of Doppler sonography for research under tropical field conditions.

Antibody Tests. A large number of serologic tests have been used in the diagnosis of schistosomiasis (49); however, most have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (21, 49). See Algorithm 20.1.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has then been confirmed by the EITB test (49). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as in those with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (49). It is possible that high titers posttherapy reflect treatment failure and reinfection. In another study, the overall diagnostic effectiveness of the keyhole limpet hemocyanin dot-ELISA and the soluble egg antigen dot-ELISA for the detection of *S. japonicum* infection in regions of China with endemic infection was 97 and 92%, respectively (50).

ELISA has also been used to detect circulating schistosome antigens in the serum and urine of infected patients and may be the preferred method of diagnosis. In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor the efficacy of therapy. Individuals treated with praziquantel experience a rapid clearance of CAA and CCA; however, with other therapeutic drugs, clearance may take much longer.

Antigen Tests. The sensitivity of antigen tests is usually higher than that of routine fecal examinations for eggs; however, the specificity is lower. A rapid one-step enzyme immunoassay has been reported to have a sensitivity of 95% and a specificity of 100% (12). Unfortunately, antigen detection methods are not widely used in China. Limitations include the cost per case detected, complicated protocols, expensive reagents with a short shelf life, and a lack of complete understanding of the mechanics of circulating schistosome antigens. However, the potential advantages of the simple dipstick test(s) may lead to improved antigen testing, and the tests may become more widely available.

Molecular Tests. Differentiation between *S. japonicum* and *S. mekongi* eggs and/or cercariae via microscopic examination is difficult due to morphological similarities. A pyrosequencing assay designed to detect *S. japonicum* and *S. mekongi* DNA in fecal samples and infected snails was developed and evaluated as an alternative tool to diagnose schistosomiasis. The analytical sensitivity of the method enabled the identification of as little as a single cercaria artificially introduced into a pool of 10 noninfected snails and two eggs inoculated in 100 mg of noninfected fecal sample. These results suggest that the pyrosequencing assay is rapid, simple, sensitive, and accurate in identifying *S. japonicum* and *S. mekongi* in intermediate hosts and fecal samples of the final host (51). A recent study investigated iron localization in parasite eggshells. Iron is predominantly localized in pores in the eggshell. Magnetic microspheres spontaneously bound to parasite eggs without the presence of a magnetic field. *S. japonicum* eggs had a significantly higher affinity to bind microspheres than *S. mansoni* eggs. This magnetic fractionation method for isolation of parasite eggs from feces, which uses magnetic microspheres to form parasite egg-magnetic microsphere conjugates, lends itself to screening of large sample volumes and increased diagnostic sensitivity (52).

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma japonicum

1. Eggs cannot be detected in stool until the worms mature (may take 5 to 6 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunologic tests may be helpful in diagnosing infection in these patients.
3. The zinc sulfate flotation concentration method should not be used, since the eggs do not float; the sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the small lateral spine may be difficult to see if debris is deposited on the egg (this is common).Also, remember that not all *S. japonicum* eggs will have the small lateral spine (no spine visible from any angle).
5. Occasionally, eggs of *S. japonicum* are detected in the urine.
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens; no preservatives can be used prior to this test or the hatching test.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel. Praziquantel is the drug of choice for treating infection with *S. japonicum*; the adult and pediatric doses are the same (60 mg/kg/day in three doses within 1 day). Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. In heavily infected individuals, the side effects, although transient, may be very severe (51). Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Praziquantel has little effect on immature stages of the parasite, and this affects the cure rates as the immature parasites develop to maturity and egg production. The mechanism of action may involve glutathione *S*-transferase, a detoxifying enzyme found in many helminths. Cure rates have been reported to be from 70 to 95%. Praziquantel damages the tegument of the worm, thereby exposing the antigens to parasite-specific antibodies. The use of immunoglobulins along with praziquantel has been proposed to increase the efficacy of treatment.

Stem Cell Therapy. Stem cell therapy introduces new cells into damaged tissues, which help in treating many diseases and injuries. It has been documented that stem cell therapy is effective for the treatment of cancers, diabetes mellitus, Parkinson's disease, Huntington's disease, cardiovascular diseases, neurological disorders, and many other diseases. Recently, stem cell therapy has been introduced to treat parasitic infections. The culture supernatant of mesenchymal stem cells is found to inhibit activation and proliferation of macrophages induced by the soluble egg antigen of *S. japonicum*, and this treatment relieves *S. japonicum*-induced liver injury and fibrosis in mouse models (53). Although in the beginning stages, within the next few years stem cell therapy may become a therapeutic option for parasitic diseases.

Epidemiology and Prevention

S. japonicum infections occur in the Far East, including China, Indonesia, Japan, and the Philippines. There is a focus of enzootic infection in Taiwan; however, there is no evidence of locally acquired human infections. In addition to humans, numerous animals (cats, cattle, dogs, goats, horses, sheep, pigs, mice, rats, and water buffalo) are naturally infected in many areas of endemic infection. The infection is transmitted by *Oncomelania* snails, which are operculated, amphibious, and able to survive prolonged periods of desiccation. On contact with water, the snails become active again and shed infective cercariae. The widespread use of night soil as fertilizer significantly increases the occupational hazards of the disease for rice farmers. There is evidence that congenital *S. japonicum* infection of pigs can occur if sows are infected during mid to late pregnancy; this may have implications not only for pigs but also for other mammalian hosts of schistosomes, including humans. Praziquantel tends to be highly effective against *S. japonicum* in pigs without causing pathologic side effects in the liver.

The geographic distribution of the disease depends on the distribution of the intermediate snail hosts and the opportunity to infect humans and snails. Schistosomiasis is transmitted from infected people defecating or urinating in or near water where the appropriate snail host resides. Infections can persist indefinitely in humans. Most infected individuals have low worm burdens, but a few have very heavy infections. It is the latter group that probably makes the greatest contribution to the dissemination of schistosomiasis. The highest rates of infection have been found in children; the greatest cercarial exposure usually occurs in boys aged 5 to 10 years. Older children may have less recreational exposure but are more likely to be exposed while performing chores such as agricultural activities, washing dishes and clothes, and bathing younger siblings. Although adults also have less recreational exposure to water, they also have partial acquired immunity.

S. japonicum is a major public health concern in the People's Republic of China, with about 800,000 people infected and another 50 million living in areas at risk of infection. It is predicted that, long-term, the Three Gorges Dam will have an impact on the transmission of schistosomiasis in the geographic region of Dongting Lake, located in Hunan Province in southern China. Asian schistosomiasis has been endemic in this region for centuries, with a significant impact on the public health of the local population. Even with dedicated control programs, the snail habitats are huge (1,768 km^2) and are increasing at a rate of 34.7 km^2 annually. With the completion of the Three Gorges Dam, it was anticipated that this project would substantially increase the range of the snail habitats and hence increase the number of new cases of schistosomiasis with a high risk of transmission. However, based on a recent study, it appears that there has been no immediate impact of the dam on schistosomiasis transmission downstream (54). In many areas, human reinfections after praziquantel therapy remain very high (up to 20%), primarily due to occupational water contact. Efforts aimed at control or eradication of the infection in the future will remain very complex (55).

Domestic cattle and buffalo are the most important reservoir hosts in China, with humans and animals frequently coming in contact at water sources, which lead to increased transmission. Although praziquantel is used for periodic treatment of bovines, the animals are prone to reinfection.

Vaccine Development. While decades of vaccine development have included the discovery and testing of several candidate antigens, none have shown consistent and acceptable high levels of protection. Selection and manufacture of the final product will be difficult, particularly regarding funding issues related to Good Manufacturing Practice scale-up for extensive veterinary coverage and to support any future human trials. The final product will probably be a mixture of several molecules and will be used in an integrated program of control that would also include health education and targeted chemotherapy (56). A number of immunogens have been identified which could be used for vaccines, and vaccine development is ongoing (56–58). A number of other initiatives are also under way and include newer drugs, improved diagnostics, disease risk prediction, and transmission control using satellite-based remote sensing.

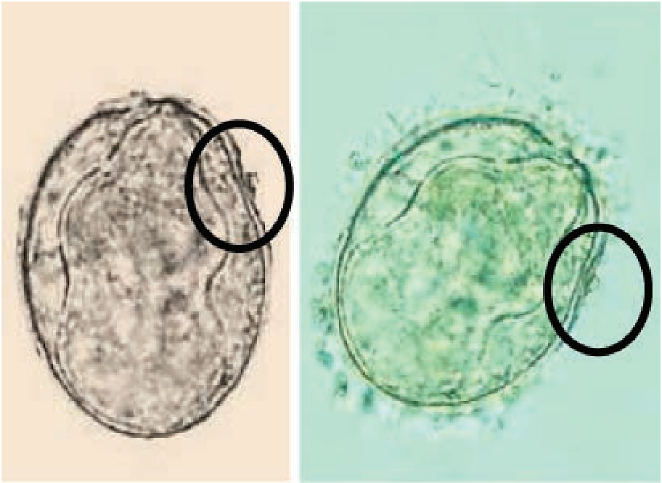
Schistosoma mekongi

Schistosomiasis resembling the disease caused by *S. japonicum* has been known to exist in the lower Mekong River basin since 1957. Further investigation has shown the etiologic agent to be a new species, *S. mekongi*; this species is responsible for most of the cases reported from mainland Indochina and has a prevalence of up to 68% in some areas (59).

Life Cycle and Morphology

Dogs as well as humans may serve as definitive hosts (Table 20.1). The adult worms are found in the mesenteric veins and resemble those of *S. japonicum*, although they lack tuberculations. Egg production occurs within 4 to 6 weeks after infection, and adult females may have many eggs in the uterus. The eggs of *S. mekongi* are similar in shape to those of *S. japonicum* but are smaller. They are subspherical, with a size range of 30 to 55 µm by 50 to 65 µm, and they have a small lateral spine near one end (Fig. 20.18). Fully embryonated eggs without an operculum are passed in the feces. When the egg comes in contact with freshwater, the miracidium is released. The miracidium must infect the aquatic snail *Lithoglyphopsis aperta* to continue the life cycle.

Figure 20.18 *Schistosoma mekongi* eggs. Note the subspherical shape and smaller size than *S. japonicum* eggs. Also note the very small lateral spine (ovals). (Courtesy of CDC Public Health Image Library.) doi:10.1128/9781555819002.ch20.f18



Clinical Disease

Few clinical studies have been conducted in areas of endemic infection; however, the pathologic effects of *S. mekongi* infections appear similar to those of other human intestinal schistosomes. *S. mekongi* appears to be no more or less pathogenic than *S. japonicum*, with hepatosplenomegaly and portal venous hypertension being the most important serious sequelae (Table 20.5). Brain involvement of the infection has also been confirmed (60).

TABLE 20.5 Distribution of infection and morbidity due to *Schistosoma mekongi* in northern Cambodia

Information	Comments
Study population 1	Household surveys in villages on east and west banks of Mekong River (1,396 participants)
Diagnostic method	Single stool examination (Kato-Katz smear)
Overall infection prevalence	49.3%
Infection intensity	118.2 eggs/g of stool
Prevalence and intensity distribution	No differences between east and west shores of Mekong (see below)
Morbidity	Severe morbidity common; hepatomegaly (48.7%), splenomegaly (26.8%), visible diverted circulation (7.2%), ascites (0.1%); significantly more hepatomegaly, splenomegaly, diverted circulation seen on west bank
Prevalence details	West bank, 71.8%; east bank, 71.9%; age group most affected was 10–14 yr; west bank, 172.4 eggs/g; east bank, 194.2 eggs/g
Peak age group (10–14 yr)	West bank, hepatomegaly (88.1%); east bank, hepatomegaly (82.8%)
Study population 2	20 primary schools on east and west banks (2,391 participants, age 6–16 yr)
Diagnostic method	Single stool examination (Kato-Katz smear)
Overall infection prevalence	40.0% (range 7.7–72.9% per school)
Infection intensity	110.1 eggs/g of stool (range 26.7–187.5 eggs/g per school)
Prevalence and intensity distribution	Significantly higher in schools on the east bank
Morbidity	Severe morbidity common; hepatomegaly (55.2%), splenomegaly (23.6%), visible diverted circulation (4.1%), ascites (0.5%), reported blood (26.7%) and mucus (24.3%) in stool; significantly more hepatomegaly, splenomegaly, diverted circulation, and blood in stool in schools on the east bank
Prevalence details	No differences in sex for prevalence and intensity of infection or prevalence of hepatomegaly; boys more likely to have splenomegaly, ascites, and bloody stools; overall prevalence and intensity of infection highly associated in this study population

Diagnosis

Schistosomiasis should be suspected in individuals who have had significant contact with water in areas of endemic infection, particularly along the Mekong River in Laos and Cambodia. Symptoms of acute schistosomiasis include fever, diarrhea, abdominal pain, weight loss, and eosinophilia. Symptoms of chronic disease include chronic diarrhea, abdominal pain, and hepatomegaly or hepatosplenomegaly.

Diagnostic Procedures. Specific diagnosis of schistosomiasis by detection of eggs in stool specimens is possible only after egg production has begun. Eggs may be found in feces as early as 5 weeks after infection. The ease of egg detection depends on the worm burden and the duration of the infection. Patients with low worm burden or old (chronic) infections may have very few eggs in the feces or urine, and the infections are often not diagnosed because of the limits of sensitivity of examination techniques. Multiple stool examinations should be performed for any individual suspected of having schistosomiasis. The eggs of *S. mekongi* are more round and tend to be smaller than those of *S. japonicum*; they measure 50 to 65 µm by 30 to 55 µm (Fig. 20.18). A minute lateral spine is found at one end of the egg; however, it may be very difficult to see.

Direct detection or concentration techniques can be used to detect eggs in stool. Direct microscopic examination of stool smears is not very sensitive but may be useful for screening purposes. The Kato or Kato-Katz thick smears are simple and sensitive quantitation techniques that have been used successfully; however, sensitivity is lacking in light infections.

The zinc sulfate concentration technique is not recommended for schistosome eggs. The eggs rupture and do not float but instead are found in the sediment. The formalin-ethyl acetate technique is recommended for concentrating eggs; however, because it involves fixation, it cannot be used to detect egg viability.

For diagnosis of chronic infections in which the worm burden is light, hatching tests can be performed. See chapter 4 and the discussion under *S. mansoni*.

Antibody Tests. A large number of serologic tests have been used in the diagnosis of schistosomiasis (19); however, most have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (19, 21). See Algorithm 20.1.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has been confirmed by the EITB test (21). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as in those with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (21). It is possible that high titers posttherapy reflect treatment failure and reinfection.

The dipstick dye immunoassay was developed in China for the detection of antibodies against *S. japonicum*. This assay has also been tested in the diagnosis of *S. mekongi* infections in Cambodia and Laos. When testing Cambodians, the sensitivity was 97.1%; when testing patients from Laos, the sensitivity was 98.6%. Cross-reactivity was found in patients infected with *Opisthorchis viverrini*; interpretation may therefore be more difficult in areas where both *S. mekongi* and *O. viverrini* are endemic (61).

Antigen Tests. ELISA has also been used to detect circulating schistosome antigens in the serum and urine of infected patients and may be the preferred method of diagnosis (20). In addition to diagnosis of infection, antigen levels have been used to assess disease severity in terms of intensity of infection and to monitor the efficacy of therapy (20). Individuals treated with praziquantel experienced a rapid clearance of CAA and CCA; however, with other therapeutic drugs, clearance may take much longer.

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma mekongi

1. Eggs cannot be detected in stool until the worms mature (may take 4 to 6 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunologic tests may be helpful in diagnosing infection in these patients.
3. The zinc sulfate flotation concentration method should not be used; the sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the small lateral spine may be difficult to see if debris is deposited on the egg (this is common) (Fig. 20.18).
5. These eggs tend to be more round and are smaller than those of *S. japonicum*.
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens by using the wet mount or hatching test; no preservatives can be used prior to the wet mount examination or the hatching test.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel is the drug of choice for treating infection with *S. mekongi*; the adult and pediatric dose is the same (60 mg/kg/day in three doses within 1 day). Side effects may include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools; however, these effects usually disappear within 48 h. In heavily infected individuals, the side effects may be more severe. Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Praziquantel has little effect on immature stages of the parasite. Cure rates have been reported to be from 70 to 95%. Praziquantel damages the tegument of the worm, exposing the antigens to parasite-specific antibodies. In treating the patient with brain involvement mentioned above, the response to praziquantel was excellent but repeated courses of corticosteroid therapy were required to suppress recurring neurologic symptoms (60).

Epidemiology and Prevention

S. mekongi infections occur in the Mekong River basin in Cambodia, Laos, and Thailand. Dogs and rodents also harbor the infection, which presents a problem for prevention of the spread of infection. The snail *Lithoglyphopsis aperta*, a member of the family *Hydrobiidae*, is aquatic, lives on solid debris in water, has a limited distribution, and is responsible for transmission of the disease. Although the snail host is sensitive to common molluscicides, control measures have not been undertaken on a concerted basis.

A baseline epidemiologic survey of *S. mekongi* was conducted along the Mekong River in northern Cambodia; this comprehensive study documents for the first time the public health importance of schistosomiasis mekongi in this area and the high level of morbidity associated with the infection (Table 20.5) (62). Schistosomiasis control in both Laos and Cambodia was based on universal treatment campaigns and resulted in a dramatic decrease of the prevalence of the infection and in morbidity control. However, even if the disease and the infection have been satisfactorily controlled, transmission still occurs, and in very limited areas the prevalence reaches rates of more than 15%. Today, 1.5 million people are estimated to be at risk of infection in Laos and in Cambodia.

Schistosoma malayensis

S. malayensis is a member of the *S. japonicum* complex, is closely related to *S. mekongi*, and differs genetically from the latter by ≈10%. In Asia, *S. japonicum*, *S. mekongi*, and *S. malayensis* cause human infection, with *S. japonicum* being the most dangerous. *S. malayensis* eggs from naturally and experimentally infected hosts are most similar to those of *S. mekongi*, with eggs of both species being, in general, smaller than those of *S. japonicum*. The egg index for *S. malayensis* is usually higher than for *S. japonicum* and lower than for *S. mekongi*. Apparently, among a stable population at risk of *S. malayensis* the prevalence is low. These findings support the hypothesis that *S. malayensis* is a zoonotic infection in humans and is unlikely to become a significant public health problem.

Schistosoma haematobium

Urinary schistosomiasis was common in the Nile River valley and has been found during examination of the kidneys of Twentieth Dynasty Egyptian mummies. Bilharz in 1851 documented the disease when he recovered adult worms from the veins of autopsy cadavers. Leiper in 1915 definitively proved the existence of two separate species, *S. haematobium* and *S. mansoni*, which until that time had been confused with one another. Although schistosomiasis is rare in western Europe, it is important to consider infectious disease in patients with obstructive uropathy, particularly in the context of traveling in or immigration from areas where *S. haematobium* infection is endemic.

Life Cycle and Morphology

Humans are the only significant reservoir hosts of *S. haematobium* (Table 20.1). Fully embryonated eggs without an operculum (112 to 170 µm by 40 to 70 µm) escape from the body in the urine. The eggs are light yellowish brown and contain a conspicuous terminal spine (Fig. 20.15 and 20.19).

The adult male worm contains minute integumentary tuberculations, smaller than those found on adult *S. mansoni* males. *S. haematobium* adults reside in the vesical and pelvic plexuses of the venous circulation. The adult female can contain 20 to 100 eggs in the uterus at one time. In addition to the vesical and pelvic plexuses, oviposition may occur in the rectal venules. To maintain the life cycle, the miracidium must find a suitable snail host (*Bulinus* sp.) when it is released from the egg in freshwater. The immature larval worms, after reaching the liver, may migrate via the inferior mesenteric veins to the rectal vein in order to mature. However, they most commonly migrate through the hemorrhoidal and pudendal veins to the vesical and pelvic plexuses. Within 3 months of exposure to cercariae, egg production begins.

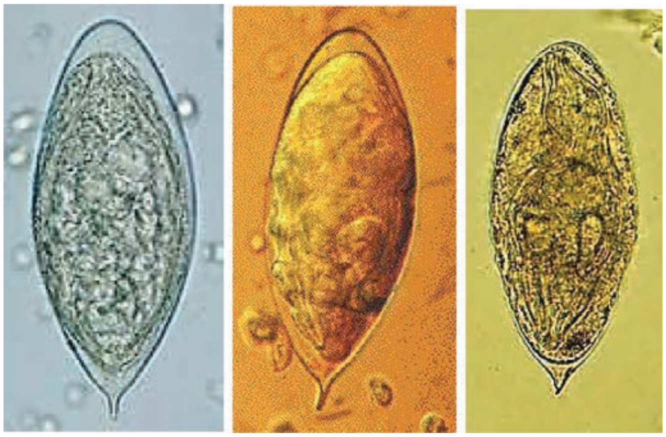


Figure 20.19 *Schistosoma haematobium* eggs. Note the terminal spine and slight size variations.
doi:10.1128/9781555819002.ch20.f19

Clinical Disease

Urogenital Disease. Light infections with urinary schistosomiasis usually produce no symptoms; however, in early disease there may be dysuria and hematuria due to cystitis from deposited eggs. Depending on the worm burden, symptoms may include dysuria, frequency, and terminal or total hematuria. Hematuria is so common that in some areas of endemic infection this phenomenon was considered to be analogous to menarche in girls (63). Symptoms are usually not seen for 3 to 6 months and may take a year or more to develop. Physical examination is usually normal, but urinalysis may reveal many red blood cells and a few white blood cells on microscopic examination; reagent strip results may indicate hematuria and proteinuria. Chronic disease may lead to major problems, including obstructive uropathy, chronic bacteriuria, bladder carcinoma, and bladder calcification (Table 20.6).

Eggs are most highly concentrated in the tissues of the bladder and lower ureter (Fig. 20.20 and 20.21). As the eggs become trapped in the tissues, granulomas and pseudoabscesses form, leading to fibrosis and ulceration. With extensive fibrosis, the bladder loses its contractility. The urethra frequently is occluded because of hyperplasia, polyp formation, and discharge of purulent debris plugs from the bladder. The ureters are also frequently involved, and obstruction can cause urine reflux, hydronephrosis, retrograde infections, and renal failure. Heavy infections in males may involve the penis, resulting in elephantiasis due to blockage of the scrotal lymphatics by egg deposition. Detection of *S. haematobium* eggs in 43% of semen samples with increased levels of eosinophil cationic protein suggests that the male genital organs are frequently affected (64).

Up to 75% of women with urinary schistosomiasis have *S. haematobium* eggs in the genitalia; urinary schisto-

TABLE 20.6 Disease manifestations seen with *Schistosoma haematobium* infection

Disease manifestation	Comments
Obstructive uropathy	Hydronephrosis, hydroureter, pyelonephritis, renal failure often silent clinically but can be demonstrated by intravenous pyelogram, ultrasonography, or renogram function testing; most lesions occur in lower third of ureters or bladder.
Pyelonephritis	Secondary to obstruction; Gram-negative sepsis; may be the leading cause of mortality in urinary disease.
Renal failure	Bilateral ureteral obstruction common; may be the direct result of obstruction, pyelonephritis, or ureterovesicular urinary reflux.
Chronic bacteriuria	Infection rates up to 5% in schoolboys with *S. haematobium* infection; coliforms are responsible, with *Salmonella* being the most common in some studies; treatment usually unsuccessful unless schistosome infection is also treated and schistosomal mucosal lesions are eliminated.
Bladder carcinoma	Bladder irritation, gross hematuria, weight loss, metastasis (inguinal, femoral, and retroperitoneal lymph nodes) tend to lag 10–20 yr behind age at which *S. haematobium* infection peaks; most cases diagnosed in patients aged 40–49 yr; biopsy is the usual method of confirmation; urinary cytology may be helpful.
Bladder calcification	The "fetal head" sign is seen in abdominal X rays and is caused by calcium deposits around schistosome eggs in the bladder and uterine walls (Fig. 17.20); sonography can also be used to see calcification in the bladder walls; although bladder loses contractility due to fibrotic walls, it does not become rigid; calcification resolves over years if patient remains free of schistosomiasis.
Cutaneous disease	Has been previously reported but is an unusual presentation; skin lesions, appearing 3 yr after exposure, have been seen as the only manifestation of schistosomiasis; routine biopsy confirmed infection; awareness of this infection when evaluating patients with unusual skin lesions who have traveled in areas of endemicity is recommended (100).
Other body sites	Myelopathy (acute transverse myelitis and subacute myeloradiculopathy) of the lumbosacral region is the most common neurological manifestation of *S. mansoni* or *S. haematobium* infection, whereas acute encephalitis of the cortex, subcortical white matter, basal ganglia or internal capsule is typical of *S. japonicum* infection (101).

somiasis is associated with sandy patches in the lower genital tract. Eggs have also been detected in biopsy specimens from vaginal mucosa. Female genital schistosomiasis (FGS) is often associated with eggs in the cervix, vagina, and/or vulva, as seen during examination of a wet cervical biopsy specimen crushed between two glass slides. There is significant correlation between the size of the genital lesions and the number of eggs per square millimeter of crushed tissue. Women with FGS also tend to have more tumors in the vulva than do women with schistosomiasis limited to the urinary tract (65). In one study, only 43% of the patients with FGS had hematuria. Also, since FGS frequently exists in women with scanty or no egg excretion in the urine and since this disease represents both an individual and public health hazard in areas of endemic infection, mass treatment targeted to women of childbearing age should be a consideration (66). *S. haematobium* eggs have been associated with homogeneous yellow sandy patches, mucosal bleeding, and abnormal blood vessels. However, the finding of eggs was not a predictor for ulcers, papillomata, leukoplakia, polyps, or cell atypia (65). Genital pathology due to sequestered *S. haematobium* ova is partially reversible 2 to 9 weeks after the adult worms have been killed by praziquantel. A reduction in inflammatory responses can be detected in histologic sections and vaginal lavage fluid. However, these sandy patch lesions associated with contact bleeding and vessel abnormalities may be refractive to treatment for up to 12 months and may be an important risk factor for potential acquisition and transmission of HIV (65, 67).

Obstructive Uropathy. Egg deposits in the ureter walls are the general causes of obstructed urinary flow; conditions leading to obstruction include polypoid patches, fibrosis, ureteritis cystica, calculi, and the total number of eggs present. Often these patients remain asymptomatic other than having symptoms related to cystitis or pain from the ureters.

Bladder Calcification. Calcified eggs produce the typical image, which consists of confluent sandy patches as seen in Fig. 20.22 (left). The tissues of the bladder are not calcified and may continue to function normally; however, the visual radiologic picture suggests a heavy infection. Calcified eggs can also be seen in the ureters and seminal vesicles and less often in the colon.

Bladder Carcinoma. Carcinoma of the bladder has been frequently noted in patients infected with *S. haematobium*. Many factors have been suggested as agents promoting schistosome-associated bladder cancer (Table 20.7). *N*-Nitroso compounds in association with secondary bacterial infections of the urinary tract may contribute to the high prevalence of bladder cancer (68). Bladder cancer is the most prevalent cancer in Egyptians. Many of the tumors involve the posterior wall of the bladder and are

noted to occur more frequently in males than in females. The extent of *S. haematobium* infection plays a significant role in the induction of different types of carcinoma, since squamous cell carcinoma is usually associated with moderate and/or high worm burdens while transitional cell carcinoma occurs more frequently in areas associated with lighter parasite loads. The predominance of squamous cell carcinoma in urinary bladder tissues in patients with schistosomiasis is probably due to continuous exposure to the larger quantities of carcinogens (*N*-nitroso compounds) in urine in patients with the disease (69).

Another factor that may play a major role in bladder carcinogenesis is continuous physical irritation and inflammation produced by *Schistosoma* eggs in the bladder mucosa. The adult *S. haematobium* worms inhabit the veins of the perivesical plexus, where the female lays eggs. Some eggs pass through the bladder mucosa and are excreted in the urine, while other eggs are trapped in the tissue. A chronic inflammatory response occurs, with the invasion of histiocytes and other inflammatory cells into the bladder, the formation of granulomas, and eventually fibrosis. Also, egg penetration through the mucosa stimulates urothelial hyperplasia and cell turnover. Generally in schistosomiasis patients, cancer originates throughout the bladder but rarely in the trigone, a frequent site of tumor origin in non-*Schistosoma* cases. Following a major decline in the prevalence of urinary schistosomiasis in Egypt, the occurrence of transitional cell carcinoma of the bladder has replaced that of squamous cell carcinoma. This change in the pattern of infection suggests the importance of *Schistosoma*-associated bladder cancer that, elsewhere, may be more widespread than is presently thought (70).

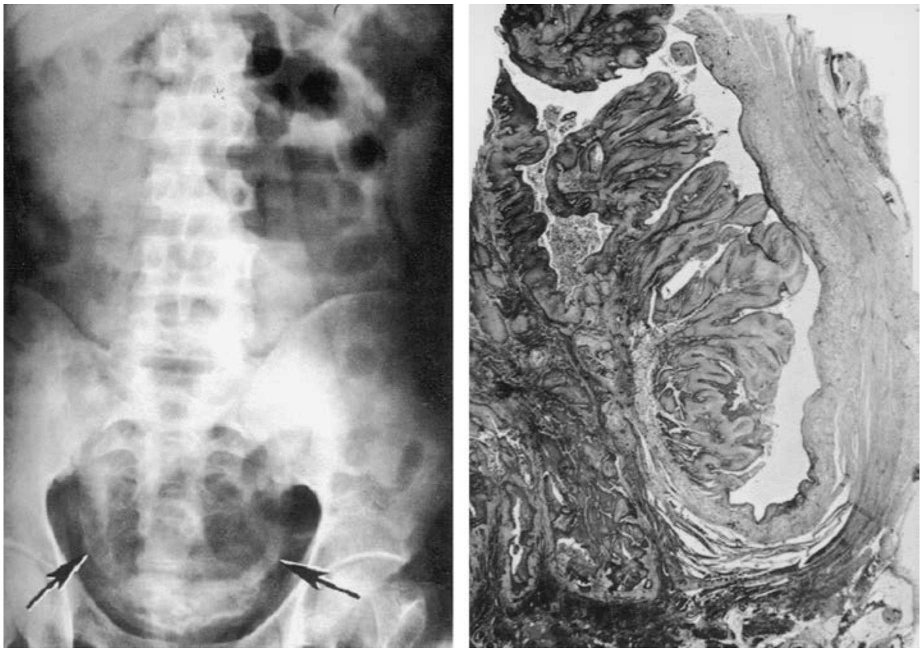

Figure 20.22 *Schistosoma haematobium*. (Left) X ray of the pelvis in a 24-year-old Egyptian with schistosomal obstructive uropathy. Linear calcification is seen in the base of the bladder and along the lower ureters, which are dilated (arrows). (Armed Forces Institute of Pathology photograph, courtesy of Marcia Young.) (Armed Forces Institute of Pathology photograph.)
doi:10.1128/9781555819002.ch20.f22

Other Body Sites. Periportal fibrosis with hepatomegaly and splenomegaly has been noted in patients in areas where infections are endemic. Splenic enlargement has been correlated with the intensity of *S. haematobium* infection. Cardiopulmonary disease can develop in patients with hepatosplenic schistosomiasis; eggs are carried via the mesenteric veins to the lungs through systemic collateral veins. Schistosomal cor pulmonale tends to be rare in infections with *S. haematobium*; eggs can be found in lung tissue at autopsy but are generally not clinically relevant. Although any *Schistosoma* species may involve the CNS, *S. mansoni* and *S. haematobium* more commonly involve the spinal cord than the brain. Severe disease presents as transverse myelitis.

As with *S. mansoni*, chronic bacteremic infections with *Salmonella* are seen, particularly in cases of chronic active schistosomiasis. Also, schistosomal appendicitis appears to be specific to infection with *S. haematobium* and is an uncommon cause of appendicitis in areas where schistosomiasis is not endemic. Therapy requires antischistosomal medication in addition to surgery (71).

Diagnosis

Diagnostic Procedures. *S. haematobium* eggs are usually detected in the urine, although in heavy infections they may also be found in the stool. The terminal hematuria portion of the urine specimen may contain numerous eggs trapped in the mucus and pus (Fig. 20.23). Peak egg excretion occurs between noon and 3 p.m. Samples collected during this time, or during a 24-h urine collection without preservatives, may be used for examination. Urine can be examined under a microscope after sedimentation or centrifugation. It is important to use saline and not water for the concentration procedures; this will avoid premature hatching of the eggs. Nuclepore filtration is an excellent method for the concentration of eggs in urine. Some data indicate that egg output in urine is an accurate method of confirming the diagnosis and shows less day-to-day variation than in ELISA detection of schistosome circulating antigens in urine (72).

Use of reagent strips to detect hematuria and proteinuria in areas of endemic infection has proven to be an effective screening technique for *S. haematobium* infections (73). The assay correctly identified 87% of egg-negative controls and 98% of parasitologically confirmed cases, including those in six individuals who had been treated but not cured. Also, antigen was detected in the urine of three individuals from whom two specimens had to be examined microscopically to confirm the infection. This suggests that the test is more sensitive than microscopy. To increase the sensitivity of the reagent strip tests, the tests should be performed during the period of peak egg excretion in the urine (noon to 3 p.m.). Although the use of reagent strips allows one to rapidly screen a population at risk, other conditions can yield a positive result. The strips should be used in conjunction with microscopic examination or serologic testing for confirmation of infection. Reagent strips coated with monoclonal antibodies (MAbs) to CCA were developed for testing urine specimens for *S. haematobium*. The levels of CCA are much higher in the urine than are the levels of CAA. Although not as sensitive as ELISA methods, this technique is suitable for screening large populations in areas of endemic infection. Eosinophilia has also been used to diagnose infections, with a positive predictive value of 80%.

TABLE 20.7 Mechanisms of bladder carcinogenesis due to *Schistosoma haematobium*

Mechanism	Comments
Inflammatory cells (IC)	Macrophages and neutrophils are important sources of endogenous oxygen radicals that are implicated in the formation of carcinogenic *N*-nitrosamines; IC induce mutations, sister chromatid exchanges, and DNA strand breaks; increased numbers of IC may enhance carcinogenic potential of aromatic amines by increasing their rate of activation.
Microorganisms	Hospitalized patients (39–66%) had bacteriuria; interaction between schistosomiasis and bacterial infection appears to depend on gender (more common in males than females); there may be a symbiotic relationship between worms and bacteria; bacterial infection of the urinary tract increases the risk of bladder cancer in patients with problems other than schistosomiasis; individuals with bacterial cystitis and schistosomiasis are potentially more exposed to nitrate and/or nitrite, increasing the risk of *in situ* formation of *N*-nitrosamines.
Genetic changes	Specific genes associated with neoplastic progression in schistosomal bladder cancer include the activation of H-*ras* (the *ras* gene family consists of frequently activated oncogenes), inactivation of *p53*, and inactivation of the retinoblastoma gene; alterations in genes and/or proteins can change function, leading to uncontrolled cell growth and tumor formation. Mutation of the coding sequence of the *p53* tumor suppressor gene is the most frequent genetic alteration in a number of human malignancies; 6 of 7 Egyptian bladder cancer patients had *p53* mutations; the frequency of *p53* mutations varies with different grades of schistosomiasis-associated bladder cancer; alterations in the *p53* gene may modulate gene expression for regulation of relevant DNA repair processes, as well as cell division and death by apoptosis. *Bcl-2* is overexpressed in some schistosomiasis-associated bladder cancers (expressed at high levels in squamous cell carcinoma but not transitional cell carcinoma); may be upregulated in later stages of tumor progression; *Bcl-2* may also be related to tumor cell lineage. A 9p gene, possibly *CDKN2*, may contribute to the development of the majority of schistosomiasis-associated bladder tumors, but the genes on 9q play a much less important role (102). Detection of early genetic changes may be valuable in identifying high-risk individuals.
Diet	Dietary fat is consistently high on a list of associated factors (attenuated when other diet components are included); small amounts of *N*-nitroso compounds are found in Egyptian food (cheese, fava beans, raw salted fish), all of which are consumed almost daily.
Carcinogen metabolism	Increased levels of enzymes responsible for activation of carcinogenic *N*-nitroso compounds, aromatic amines, and polycyclic aromatic hydrocarbons have been found in schistosomiasis; may increase and prolong bladder exposure to DNA-damaging agents; nitrite levels are about 20 times higher in *S. haematobium*-infected patients with bladder cancer than in those without bladder cancer; these compounds may play a role not only in initiation of the carcinogenic process, but also in its progression.
Carcinogens, consequences of DNA damage	Damage to bladder tissue DNA may be responsible for initiation of bladder cancer.

Antibody Detection. A recognized obstacle to serodiagnosis of acute or recent schistosome infection is the prolonged seronegative period. Antibody production in newly infected individuals usually starts 4 to 7 weeks after infection. However, although the majority of patients seroconvert within 3 months, prolonged seronegative periods of up to 6 months have been described. A large number of serologic tests have been used in the diagnosis of schistosomiasis (49); however, many have not been particularly useful because of cross-reactions with other helminth infections, continuation of elevated titers long after successful treatment, and slow immunologic response of the host. Because of the complex life cycle, a large number of antigens have been used in serologic tests. Only a few have been useful. The most frequently used tests are the circumoval precipitin test, the cercaria-Hullen reaction, the indirect fluorescent-antibody test, the indirect hemagglutination test, and ELISA (49, 74). See Algorithm 20.1.

ELISA methods using soluble adult worm or egg antigens for the detection of antibodies have been used as screening tests, and infection has then been confirmed by the EITB test (49). Individuals infected with schistosomes have elevated IgE and IgG4 responses, as in those with other helminthic infections. Few studies have investigated the persistence of antibodies over time after therapy (49). It is possible that high titers posttherapy reflect treatment failure and reinfection.

Antigen Tests. Based on 92% specificity and 90% sensitivity, an ELISA using MAb 290-2E6-A is one of the most promising assays for immunodiagnosis of *S. haematobium* infections (75). Another study of children from Kenya indicates that the soluble egg antigen (SEA) ELISA compared well with microhematuria within egg count classes and with egg counts within hematuria classes (76). Levels of SEA and egg output have shown similar correlations with sonographically detectable pathology; these correlations were better than

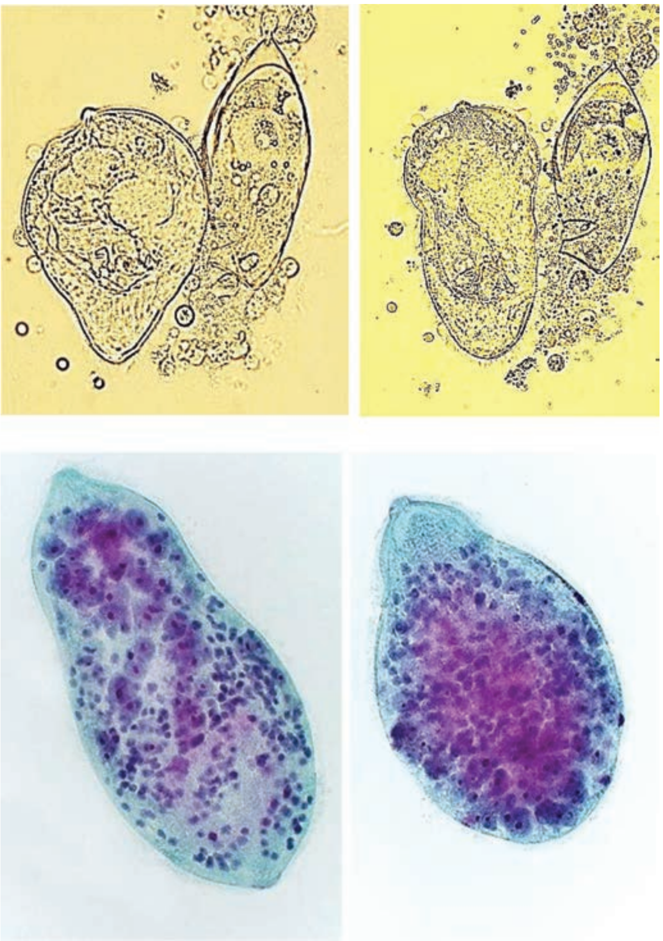

Figure 20.23 *Schistosoma haematobium*. (Upper images) Urine sediment from patient from the Sudan; note the miracidium larvae that have emerged from the eggshells (courtesy of Betty A. Forbes, Medical College of Virginia). (Lower images) Stained miracidium larvae (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman, from E. K. Markell). doi:10.1128/9781555819002.ch20.f23

the correlation between hematuria and pathology (76). Another antigen capture ELISA using MAb 128C3/3/21 has shown a correlation between the level of circulating antigen and the intensity of infection as measured by egg counts. There appears to be a direct relationship between antigen level and disease severity, as monitored by sonography. Also, a purified recombinant serine protease inhibitor that is species specific for *S. haematobium* has been used in serologic assays.

Using the SEA MAb, circulating schistosome antigen was undetectable in serum from patients with other parasitic infections but was detected in 90.5% of serum samples and 94% of urine samples from *S. haematobium*-infected patients. A significant reduction in circulating schistosome antigen levels was detected in serum and urine samples 12 weeks after praziquantel therapy (77). No cross-reactivity with *S. mansoni* was seen; circulating schistosome antigen was undetectable in 94% of serum samples and 84% of urine samples from *S. mansoni*-infected patients.

A MAb-based dipstick assay has been used with a sensitivity of 98.8% and specificity of 53.6%. Although the detection of microhematuria and proteinuria had a higher specificity, the sensitivity was much lower than that of the dipstick assay (78). The use of a circulating cathodic antigen strip approach for the diagnosis of urinary schistosomiasis has also been developed for pre- and posttreatment results with a sensitivity of 88% and 96%, respectively (79).

Molecular Tests. Recent studies using an internal transcribed spacer-based real-time PCR for the detection of *Schistosoma* DNA in urine samples have shown high sensitivity and specificity based on controls and known microscopy-positive samples (80). In field control situations, there is a need to detect low-level infections even in children, where infection occurs in the absence of eggs or hematuria. Unfortunately, these cases can still infect snails and perpetuate the cycle. In both situations a simple urine specimen, filtered through a filter paper, can be used for DNA detection, and a PCR procedure will give a definitive result (81).

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma haematobium

1. Eggs cannot be detected in urine until the worms mature (may take up to 3 months after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in urine; therefore, multiple urine examinations may be required. Biopsy and/or immunologic tests may be helpful in diagnosing infection in these patients.
3. Both 24-h and spot urine samples should be examined as wet mounts (after concentration using no preservatives [use saline so hatching will not occur]); the urine specimens should be collected with no preservatives. These eggs are also occasionally recovered in stool, and so both urine and stool specimens should be examined.
4. The membrane filtration technique using Nuclepore filters can be very helpful in diagnosing infection with *S. haematobium*.
5. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
6. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens using the wet mount or hatching test; no preservatives can be used prior to the wet mount or the hatching test. If the specimens are concentrated, use saline rather than water to prevent premature hatching of the eggs.

(continued)

KEY POINTS—LABORATORY DIAGNOSIS

***Schistosoma haematobium* (continued)**

7. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.
8. It is important to remember that the small and less commonly seen miracidium larva of *S. haematobium* may be present in the urine; motility in unpreserved specimens or stained morphology could confirm this diagnosis.
9. It is also possible to see *S. haematobium* eggs in semen specimens, even when repeated urinary and fecal examinations and serologic tests are negative.

Treatment

Praziquantel is the drug of choice for treating infections with *S. haematobium*. It can be taken orally in a single dose and is well tolerated by the host. Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. In heavily infected individuals, the side effects, although transient, may be very severe. Split doses have been recommended for treating heavy infections, but this may be a concern for population-based therapy, where individuals may not present themselves for follow-up therapy. Data suggest that a single dose of praziquantel (40 mg/kg of body weight) may have a longer-lasting effect than was previously thought: possibly more than 2.5 years. In certain population-based treatment programs, it appears that a 20-mg/kg dose of praziquantel may be sufficient to provide control of morbidity due to urinary schistosomiasis (82). Praziquantel has little effect on immature stages of the parasite, and this will affect the cure rates as the immature parasites develop to maturity and egg production. The mechanism of action may involve glutathione *S*-transferase, a detoxifying enzyme found in many helminths. Cure rates have been reported to be 70 to 95%. Praziquantel damages the tegument of the worm, thereby exposing the antigens to parasite-specific antibodies. Adults are more resistant to schistosome infection than are children, and the switch to an "adult" response suggests that praziquantel treatment may have an immunizing effect, with benefits beyond a transient reduction in infection levels (83). Treatment can significantly reduce urinary tract morbidity despite reinfection; important risk factors in adulthood are cumulative intensity and duration of infection during early adolescence. Data also indicate that therapy given in childhood or adolescence decreases the risk for some but not all manifestations of *S. haematobium* infection in later adult life (84).

Although the exact mechanism by which praziquantel kills the parasite is not well understood, it is known that the immune response of the host plays an important role in drug efficacy. It is possible that disease states of humans that lead to immunodeficiencies, such as infection with HIV-1, may render praziquantel less effective in treating schistosomiasis. However, recent studies indicate that persons with HIV-1 infection can be treated effectively for schistosomiasis with praziquantel (67).

Therapeutic failure of praziquantel in the treatment of *S. haematobium* infection in Brazilians returning from Africa has been reported. Patients were treated with a single dose of praziquantel (40 mg/kg, single dose). Two additional treatments were given, and cystoscopy between 6 and 24 months after each treatment confirmed the presence of viable eggs. These findings confirm the possible need for repeated therapy, as well as using the urinary bladder biopsy as the criterion of cure (85).

The efficacy of praziquantel during the incubation period of schistosomiasis has recently been studied for the first time (86). In a group of 18 tourists infected with *S. haematobium* in Mali, the authors observed the efficacy of praziquantel given at different phases of the infection. Early praziquantel treatment from days 10 to 15 after exposure was less effective than later treatment (days 28 to 40) in preventing acute schistosomiasis, while neither treatment effectively prevented chronic schistosomiasis.

Patients with *S. haematobium* infection are suitable recipients for kidney transplantation, although they are at risk for urologic complications. Long-term urologic follow-up is recommended, including urethrocystoscopy, due to the increased risk for bladder cancer.

Metrifonate, an organophosphorus cholinesterase inhibitor, is an alternative to praziquantel for the treatment of *S. haematobium* infections. The drug is given orally over a number of weeks. Side effects, which are mild and transient, include abdominal discomfort, diarrhea, dizziness, headache, vomiting, and weakness. Metrifonate should not be given to patients who have been recently exposed to insecticides or who are using therapeutic agents that can potentiate cholinesterase inhibition. It has been noted that the dorsal tegumental surface of adult male schistosomes contains acetylcholinesterase and nicotinic acetylcholinesterase receptors, which may be the target of metrifonate. Because the acetylcholine receptor expression is increased when the worms pair and become sexually mature, it appears that acetylcholine plays a vital function in nutrient transport. Because metrifonate requires multiple administrations, it is less convenient to use in community-based control programs.

Epidemiology and Prevention

S. haematobium infections occur in Africa, Asia Minor, Cyprus, the islands off the African east coast, and southern Portugal; there is a focus of endemic infection in India.

Humans appear to be the only important reservoir hosts, although naturally infected monkeys, baboons, and chimpanzees have been found. The intermediate snail host, *Bulinus* sp., can survive in the mud when the water dries up. The snails retain their infectivity and resume shedding cercariae when the rainy season begins. In some areas, cercariae are found in areas where infected snails are absent, and sometimes cercariae are absent in the presence of infected snails.

Data suggest that fewer than 1 in 100 contacts result in infection and less than 1 in 1,000 result in egg output. This suggests that there may be substantial attrition of invading cercariae even in naive individuals (87).

In many areas of endemic infection, awareness of urinary schistosomiasis and its symptom of blood in the urine is high, but specific knowledge about the parasite, its vector, and the interaction between them in the life cycle is lacking. Activities that require behavior and attitude modification can be identified and encouraged as components in the control of schistosomiasis.

An *S. haematobium*-derived recombinant glutathione *S*-transferase (Sh28GST) vaccine is capable of significantly reducing worm fecundity in experimentally infected primates. Although Freund's complete adjuvant induced higher levels of protection, the efficacy of *Mycobacterium bovis* as an adjuvant appeared sufficient to justify consideration of its use in a vaccine against human urogenital schistosomiasis (88).

A summary of the control methods that can be used for all types of schistosomiasis is given in Table 20.8. All of these initiatives are coupled with public health communication and training for populations in areas of endemic infection.

Schistosoma intercalatum

S. intercalatum infections were first noted by Fisher in the early 1930s, and the species has been extensively described. The infection has been found in central and western Africa. In areas where both *S. haematobium* and *S. intercalatum* are endemic, hybridization with the two trematodes appears to be occurring; natural hybrids have been found in Loum, Cameroon, and natural hybridization has been suspected in Gabon. Also, it appears that the competitive exclusion between *S. mansoni* and *S. intercalatum* may be an important factor restricting the distribution of *S. intercalatum* in Africa. *S. intercalatum* causes an intestinal form of schistosomiasis similar to that caused by *S. mansoni* but characterized by lesions, mainly situated at the rectum and sigmoid level. Urinary schistosomiasis caused by *S. haematobium* has a tendency to supplant rectosigmoidal schistosomiasis caused by *S. intercalatum*, especially in endemic areas where hybridization between the two species of schistosomes is occurring.

Life Cycle and Morphology

The life cycle is similar to that of the other schistosomes. Adult worms are found in the mesenteric veins, and eggs are shed in the feces. Eggs are fully embryonated without an operculum and resemble *S. haematobium* eggs in shape, having a terminal spine; however, *S. intercalatum* eggs tend

TABLE 20.8 Schistosomiasis control measures

Approach	Comments
Chemotherapy	
Mass	Most appropriate in population with prevalence rates of >30%; all members of population treated (no attempt at individual diagnosis
Targeted population	Relies on identification of individual moderate to heavy egg excretors; follow-up for evaluation of cure
Snail control	
Molluscicide use	Niclosamide commonly used; well suited for arid areas (seasonal infections) and small habitats; unfortunately, snail populations can reestablish themselves within 3 mo of molluscicide application
Biologic control	Use of natural predators of snail hosts (ducks, fish, turtles, fungi, other snails); not realistic on a mass level
Environmental modification	Prevention and/or reduction of breeding; site modification to produce detrimental conditions; cementing or closing over irrigation ditches; increasing canal water flow
Reduction of water contact and contamination	
Domestic water supplies	Clean water availability; however, population may continue to use contaminated water sources
Sanitary excreta disposal	Mandatory; combined with health education on biological transmission and importance of control measures; improvement in living standards is important
Vaccination	Continued problem of reinfection is a problem due to slow maturation of natural resistance; several antigens have reached an advanced stage of development and are undergoing testing; vaccination will be used in conjunction with all other control methods; vaccines can be used to attenuate infection and/or to prevent pathology and/or to reduce worm burdens

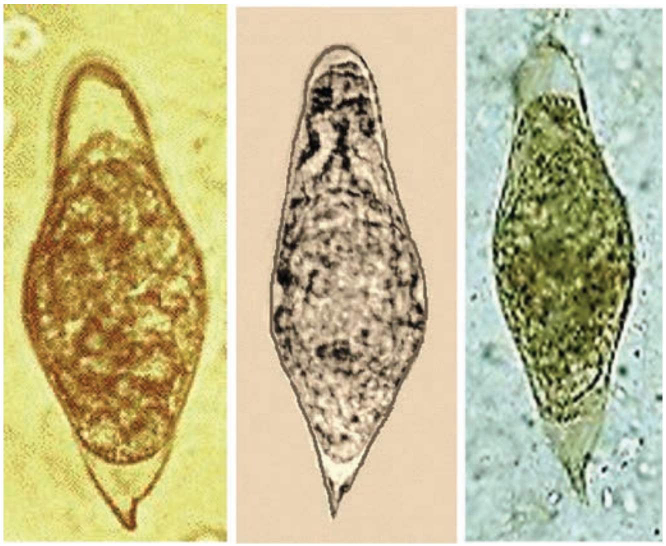

Figure 20.24 *Schistosoma intercalatum* eggs. The miracidium tends to have a bulge in the middle, the eggs are usually larger than *S. haematobium*, and they are seen in stool rather than urine. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.)
doi:10.1128/9781555819002.ch20.f24

to have a bulge in the middle (Table 20.1; Fig. 20.24). The eggs are 140 to 240 μm by 50 to 85 μm in size and can be differentiated from *S. haematobium* eggs since they are Ziehl-Neelsen acid-fast positive. This technique cannot be totally relied on, because if hybridization occurred between *S. intercalatum* and *S. haematobium*, the eggs identified from the urine by DNA analysis would be Ziehl-Neelsen stain positive. The snail intermediate hosts are *Bulinus forskalii, B. globosus*, and *B. africanus*.

Clinical Disease

Clinical manifestations are similar to those of *S. mansoni* infections. Pathology is confined to the mesenteric-portal system; rectal bleeding appears to be the most common finding. Rare pulmonary infections have also been noted. Other symptoms can include pain in the left iliac fossa with tenesmus, anorexia, nausea, abdominal pain, and diarrhea. There may also be changes in liver function tests. The prevalence and intensity of infection were noted to increase during the first 2 decades of life and gradually decrease thereafter. As with other species of *Schistosoma*, there is an association between *Salmonella* bacteremia and infection with *S. intercalatum*. Without treatment for schistosomiasis, the *Salmonella* infection cannot be cured. Complications of *S. intercalatum* infection include severe rectal or genital lesions.

Diagnosis

The infection can be diagnosed by finding the characteristic eggs in feces or in squash preparations of tissues from the rectum; occasionally, eggs are also found in the urine. The miracidium often has a bulge in the middle.

KEY POINTS—LABORATORY DIAGNOSIS

Schistosoma intercalatum

1. Eggs cannot be detected in stool until the worms mature (may take from 4 to 6 weeks after initial infection).
2. In very light or chronic infections, eggs may be very difficult to detect in stool; therefore, multiple stool examinations may be required. Biopsy and/or immunology may be helpful in these patients.
3. The zinc sulfate flotation concentration method should not be used; the sedimentation method is recommended.
4. It may be necessary to tap the coverslip to move the eggs; the terminal spine may be difficult to see if debris is covering the egg (this may occur).
5. Occasionally eggs of *S. intercalatum* are detected in the urine.
6. Patients who have been treated should have follow-up ova and parasite examinations for up to 1 year to evaluate treatment.
7. In active infections, the eggs should contain live or mature miracidia. Examination for the confirmation of flame cell activity must be performed on fresh specimens, using a wet mount or the hatching test; no preservatives can be used prior to the wet mount examination or the hatching test.
8. During the hatching test, the light must not come too close to the surface of the water, since excess heat can kill the liberated larvae. Also, the water should be examined about every 30 min for up to 4 h.

Treatment

Praziquantel is the drug of choice for treating infections with *S. intercalatum*. It can be taken orally in a single dose and is well tolerated by the host. Side effects, which are usually mild and transient, include abdominal discomfort, dizziness, drowsiness, headache, fever, and loose stools. These effects usually disappear within 48 h. A single dose of praziquantel (40 mg/kg of body weight) has been recommended.

Epidemiology and Prevention

S. intercalatum infections occur in the same geographic areas as *S. mansoni* infections, i.e., western and central Africa (Cameroon, Equatorial Guinea, Gabon, Nigeria, Democratic Republic of Congo, and Sao Tome), Egypt, Madagascar, and the Arabian peninsula. Human infections are nearly all derived from human sources, even though nonhuman primates, insectivores, marsupials, and rodents can carry the infection. Disease spread is linked to seasonal migration of nomad populations, as well as migrant African laborers. In regions of endemic infection, prevalences of 5 to 25% have been found. The infection is transmitted by *Bulinus* sp., an aquatic snail.

Review of 333 reports related to imported cases of schistosomiasis in Europe showed that male patients accounted for 64% of all cases. The average age of all patients was 29.5 years. The majority of patients were of European origin (53%). Europeans traveled predominantly for tourism (52%). Travel for people from areas of endemic infection was related to immigration and refuge (51%) and visits to relatives and friends (28%). The majority of infections were acquired in Africa; 92 infections were clearly attributable to *S. haematobium*, 130 to *S. mansoni*, and 4 to *S. intercalatum*. Praziquantel was the only treatment used, and no deaths were recorded (89).

Intestinal Protozoa: Amebae

Entamoeba histolytica
Entamoeba dispar
Entamoeba moshkovskii
Entamoeba bangladeshi
Entamoeba hartmanni
Entamoeba coli
Entamoeba polecki
Entamoeba gingivalis
Endolimax nana
Iodamoeba bütschlii
Blastocystis spp.

Entamoeba histolytica

Entamoeba histolytica was first described by Losch after it was isolated in Russia from a patient with dysenteric stools. Although Losch found the organisms in human colonic ulcers at autopsy and was able to induce dysentery in a dog that was inoculated rectally with the patient's stools, he failed to recognize the causal relationship. This organism was eventually more fully investigated and differentiated from *Entamoeba coli* and *Entamoeba hartmanni* with respect to both morphology and pathogenesis (1). Based on the genome, this organism has a number of metabolic adaptations shared with two other amitochondrial protist pathogens, *Giardia lamblia* and *Trichomonas vaginalis*. These adaptations include the use of oxidative stress enzymes usually associated with anaerobic prokaryotes, as well as reduction or elimination of most mitochondrial metabolic pathways. There is evidence for lateral gene transfer of bacterial genes into the *E. histolytica* genome, a large number of novel receptor kinases, and expansions of a variety of gene families, including those associated with virulence (2).

E. histolytica has been recovered worldwide and is more prevalent in the tropics and subtropics than in cooler climates. However, infection rates in unsanitary conditions in temperate and colder climates have been found to equal those seen in the tropics. The World Health Organization reported that *E. histolytica* causes approximately 50 million cases and 110,000 deaths annually (3). Only malaria and schistosomiasis surpass amebiasis as leading parasitic causes of death.

At least 11 amebae are found in the mouth or intestinal lumen (*E. histolytica*, *Entamoeba dispar*, *Entamoeba moshkovskii*, *Entamoeba bangladeshi*, *E. hartmanni*, *E. coli*, *Entamoeba polecki*, *Entamoeba gingivalis*, *Endolimax nana*, *Iodamoeba bütschlii*, and *Blastocystis* spp.). Of these, only *E. histolytica* and *Blastocystis* spp. have been considered to be pathogenic; however, *E. moshkovskii* and *E. bangladeshi* have been implicated as causing disease in humans, particularly in infants (4).

doi:10.1128/9781555819002.ch21

E. histolytica versus *E. dispar*

Although a large number of people throughout the world are infected, only a small percentage will develop clinical symptoms. Morbidity and mortality due to *E. histolytica* vary, depending on the geographic area, the organism strain, and the patient's immune status. For many years, the issue of pathogenicity has been very controversial, with essentially two points of view. Some thought that what was called *E. histolytica* was really two separate species of *Entamoeba*, one being pathogenic and causing invasive disease and the other being nonpathogenic and causing mild or asymptomatic infections. Others thought that all organisms designated *E. histolytica* were potentially pathogenic, with symptoms depending on the result of host or environmental factors, including the intestinal flora.

In 1961, with the development of successful axenic culture methods requiring no bacterial coculture, sufficient organisms could be obtained for additional studies. Approximately 15 years later, reports indicated that *E. histolytica* clinical isolates could be classified into groups by using starch gel electrophoresis and review of banding patterns related to specific isoenzymes (5). The four isoenzymes are glucophosphate isomerase, phosphoglucomutase, malate dehydrogenase, and hexokinase. Sargeaunt concluded from this work that there are pathogenic and nonpathogenic strains (zymodemes) of *E. histolytica* that can be differentiated by isoenzyme analysis. On the basis of analysis of thousands of clinical isolates, he also concluded that the zymodeme patterns were probably genetic rather than phenotypic.

Others argued that the bacterial flora present in the gut played a role in the potential pathogenicity of *E. histolytica*. Some of the *in vitro* culture studies indicated that bacteria enhance the virulence of *E. histolytica*. During the 1980s and early 1990s, these issues were discussed, with a number of questions still remaining unanswered (6).

According to Diamond and Clark (7), the most logical explanation of their failure to obtain conversion of "nonpathogenic" *E. histolytica* isolates to the "pathogenic" form during axenization of the amebae was culture contamination. In reviewing this possibility, they used a method based on analysis of stable DNA polymorphisms that allows the identification of individual pathogenic isolates. The DNA patterns obtained with the "converted" amebae were identical to those of reference isolates present in the laboratory at the time of conversion (7). Diamond and Clark also found that transfer of very few pathogenic organisms was necessary for the pathogens to become established in a nonpathogenic culture. Within the context of these studies, cross-contamination fully explained the conversion, and the designation of specific pathogenic *E. histolytica* and nonpathogenic *E. dispar* was confirmed (7).

Studies confirming the differences between the two organisms include direct sequencing of the PCR-amplified small-subunit rRNA gene of *E. dispar* and the design of primers for rapid differentiation from *E. histolytica*; differences in the *E. histolytica* and *E. dispar* phosphoglucomutases; molecular biology of the differences in the hexokinase isoenzyme; differences in the secretion of acid phosphatase; and the detection of DNA sequences unique to *E. histolytica* (8).

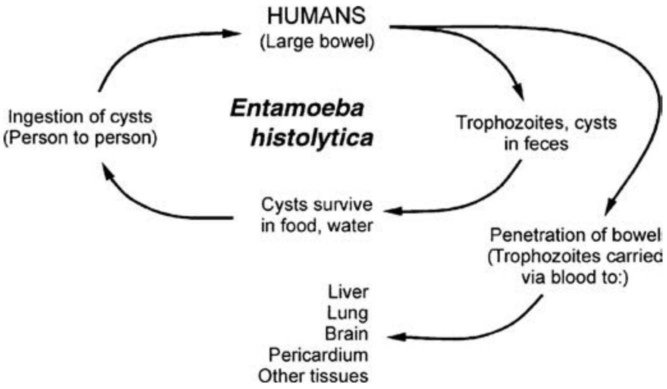
Genetic differences may not totally explain the overall differences. Among 79 *E. histolytica* isolates obtained from different geographic regions, a total of 53 different genotypes were observed among 63 isolates. The most extensive variations among the four loci were found in the serine-rich *E. histolytica* protein (SREHP) locus. However, no association between clinical presentation and the SREHP genotype was demonstrated (9).

Research has centered on explaining the molecular differences between the pathogenic *E. histolytica* and the nonpathogenic *E. dispar*. However, the molecules considered the most important for host tissue destruction (amebapore, galactose/*N*-acetylgalactosamine inhibitable lectin, and cysteine proteases) can be found in both organisms. Pathogenicity differences may be related to the composition and properties of the surface coat components (or pathogen-associated molecular patterns) and the ability of the innate immune response to recognize these components, thus eliminating the organisms (10). Targets of the host immune system modulation appear to be both neutrophils and macrophages, which are unable to abort the infection even when present at the site of the lesion (11). The total body of evidence supports differentiation of the pathogenic *E. histolytica* from the nonpathogenic *E. dispar* and their classification as two distinct species (12).

Life Cycle and Morphology

The life cycle is shown in Fig. 21.1. The cyst form is the infective form for humans.

Figure 21.1 Life cycle of *Entamoeba histolytica*.
doi:10.1128/9781555819002.ch21.f1



Morphology of Trophozoites (Table 21.1). Living trophozoites vary in size from about 12 to 60 μm in diameter. Organisms recovered from diarrheic or dysenteric stools are generally larger than those in a formed stool from an asymptomatic individual (Fig. 21.2 and 21.3). The motility has been described as rapid and unidirectional, with pseudopods forming quickly in response to the conditions around the organism. The motility may appear to be sporadic. Although this characteristic motility is often described, it is rare to diagnose amebiasis on the basis of motility seen in a direct mount. The cytoplasm is differentiated into a clear outer ectoplasm and a more granular inner endoplasm.

When the organism is examined on a permanent stained smear (trichrome or iron hematoxylin), the morphological characteristics of *E. histolytica*/*E. dispar* are readily seen. The nucleus is characterized by having evenly arranged chromatin on the nuclear membrane and having a small, compact, centrally located karyosome. The cytoplasm is usually described as finely granular with few ingested bacteria or debris in vacuoles. In organisms isolated from a patient with dysentery, red blood cells (RBCs) may be visible in the cytoplasm, and this feature is diagnostic for *E. histolytica*. Most often, infection with *E. histolytica*/*E. dispar* is diagnosed on the basis of organism morphology without the presence of RBCs.

Morphology of Cysts (Table 21.2). For reasons that are not specifically known, the trophozoites may condense into a round mass (precyst) and a thin wall is secreted around the immature cyst. There may be two types of inclusions within this immature cyst, a glycogen mass and highly refractile chromatoidal bars with smooth, rounded edges. As the cysts mature (metacyst), there is nuclear division with the production of four nuclei; on rare occasions, eight nuclei are produced and the cysts range in size from 10 to 20 μm. Often, as the cyst matures, the glycogen completely disappears; the chromatoidals may also be absent in the mature cyst. Cyst morphology does not differentiate between *E. histolytica* and *E. dispar*. Cyst formation occurs only within the intestinal tract; once the stool has left the body, cyst formation does not occur. The one-, two-, and four-nucleated cysts are infective and represent the mode of transmission from one host to another (Fig. 21.1 to 21.3).

Infection. After cyst ingestion, no changes occur in an acidic environment; however, once the pH becomes neutral or slightly alkaline, the encysted organism becomes active, with the outcome being four separate trophozoites (small, metacystic trophozoites). These organisms develop into the normal trophozoites when they become established in the large intestine.

Clinical Disease

The presentations of disease are seen with invasion of the intestinal mucosa and/or dissemination to other organs, the most common being the liver. However, it is estimated that only a small proportion (2 to 8%) of infected individuals will have invasive disease beyond the lumen of the bowel. Also, organisms may be spontaneously eliminated with no disease symptoms.

Asymptomatic Infection. Individuals harboring *E. histolytica* may have either a negative or weak antibody titer and negative stools for occult blood and may be passing cysts that can be detected if the routine ova and parasite examination is performed. Although trophozoites may also be found, they do not contain any phagocytized RBCs and cannot be differentiated from *E. dispar*. Isoenzyme analyses of organisms isolated from asymptomatic individuals generally indicate that the isolates belong to nonpathogens (*E. dispar*). Generally, asymptomatic patients never become symptomatic and may excrete cysts for a short period. This pattern is found for patients infected with either nonpathogenic or pathogenic species.

Intestinal Disease. Although the exact mode of mucosal penetration is not known, microscopy studies suggest that amebae have enzymes which lyse host tissue, possibly from lysosomes on the surface of the amebae or from ruptured organisms. Amebic ulcers most often develop in the cecum, appendix, or adjacent portion of the ascending colon; however, they can also be found in the sigmoidorectal area. From these primary sites, other lesions may occur. Ulcers are usually raised, with a small opening on the mucosal surface and a larger area of destruction below the surface, i.e., "flask shaped." The mucosal lining may appear normal between ulcers (Fig. 21.4).

The incubation period varies from a few days to a much longer time; however, in an area where *E. histolytica* is endemic it is impossible to determine exactly when the exposure took place. Normally, the time frame ranges from 1 to 4 weeks. Certainly not every patient infected with *E. histolytica* will develop invasive amebiasis; the outcome will depend on the interaction between parasite virulence factors and the host response.

There are four clinical forms of invasive intestinal amebiasis, all of which tend to be acute. They include dysentery or bloody diarrhea, fulminating colitis, amebic appendicitis, and ameboma of the colon. Dysentery and diarrhea account for 90% of cases of invasive intestinal amebiasis (11). Symptoms may range from none to those mimicking ulcerative colitis. Patients with colicky abdominal pain, frequent bowel movements, and tenesmus may present with a gradual onset of disease. With the onset of dysentery, bowel movements characterized by blood-tinged

TABLE 21.1 Intestinal protozoa: trophozoites of common amebae

Characteristic	***Entamoeba histolytica***	***Entamoeba dispar/ Entamoeba moshkovskii/ Entamoeba bangladeshi***	***Entamoeba hartmanni***	***Entamoeba coli***	***Endolimax nana***	***Iodamoeba bütschlii***
Size[a] (diam. or length)	12–60 µm (usual range, 15–20 µm); invasive forms may be over 20 µm	Same as *E. histolytica*	5–12 µm (usual range, 8–10 µm)	15–50 µm (usual range, 20–25 µm)	6–12 µm (usual range, 8–10 µm)	8–20 µm (usual range, 12–15 µm)
Motility	Progressive, with hyaline, fingerlike pseudopodia; motility may be rapid	Same as *E. histolytica*	Usually nonprogressive	Sluggish nondirectional, with blunt, granular pseudopodia	Sluggish, usually nonprogressive	Sluggish, usually nonprogressive
Nucleus: no. and visibility	Difficult to see in unstained preparations; 1 nucleus	Same as *E. histolytica*	Usually not seen in unstained preparations; 1 nucleus	Often visible in unstained preparations; 1 nucleus	Occasionally visible in unstained preparations; 1 nucleus	Usually not visible in unstained preparations; 1 nucleus
Peripheral chromatin (stained)	Fine granules, uniform in size and usually evenly distributed; may have beaded appearance	Same as *E. histolytica*	Nucleus may stain more darkly than in *E. histolytica*/*E. dispar*, although morphology is similar; chromatin may appear as solid ring rather than beaded	May be clumped and unevenly arranged on the membrane; may also appear as solid, dark ring with no beads or clumps	Usually no peripheral chromatin; nuclear chromatin may be quite variable	Usually no peripheral chromatin
Karyosome (stained)	Small, usually compact; centrally located but may also be eccentric	Same as *E. histolytica*	Usually small and compact; may be centrally located or eccentric	Large, not compact; may or may not be eccentric; may be diffuse and darkly stained	Large, irregularly shaped; may appear "blotlike"; many nuclear variations are common; may mimic *E. hartmanni* or *D. fragilis*	Large, may be surrounded by refractile granules that are difficult to see ("basket nucleus")
Cytoplasm appearance (stained)	Finely granular, "ground-glass" appearance; clear differentiation of ectoplasm and endoplasm; if present, vacuoles are usually small	Same as *E. histolytica*	Finely granular	Granular, with little differentiation into ectoplasm and endoplasm; usually vacuolated	Granular, vacuolated	Granular, may be heavily vacuolated
Inclusions (stained)	Noninvasive organism may contain bacteria; presence of RBCs diagnostic	Organisms usually contain bacteria; RBCs not present in cytoplasm	May contain bacteria; no RBCs	Bacteria, yeasts, other debris	Bacteria	Bacteria

[a] Wet preparation measurements (on permanent stains, organisms usually measure 1 to 2 µm less).

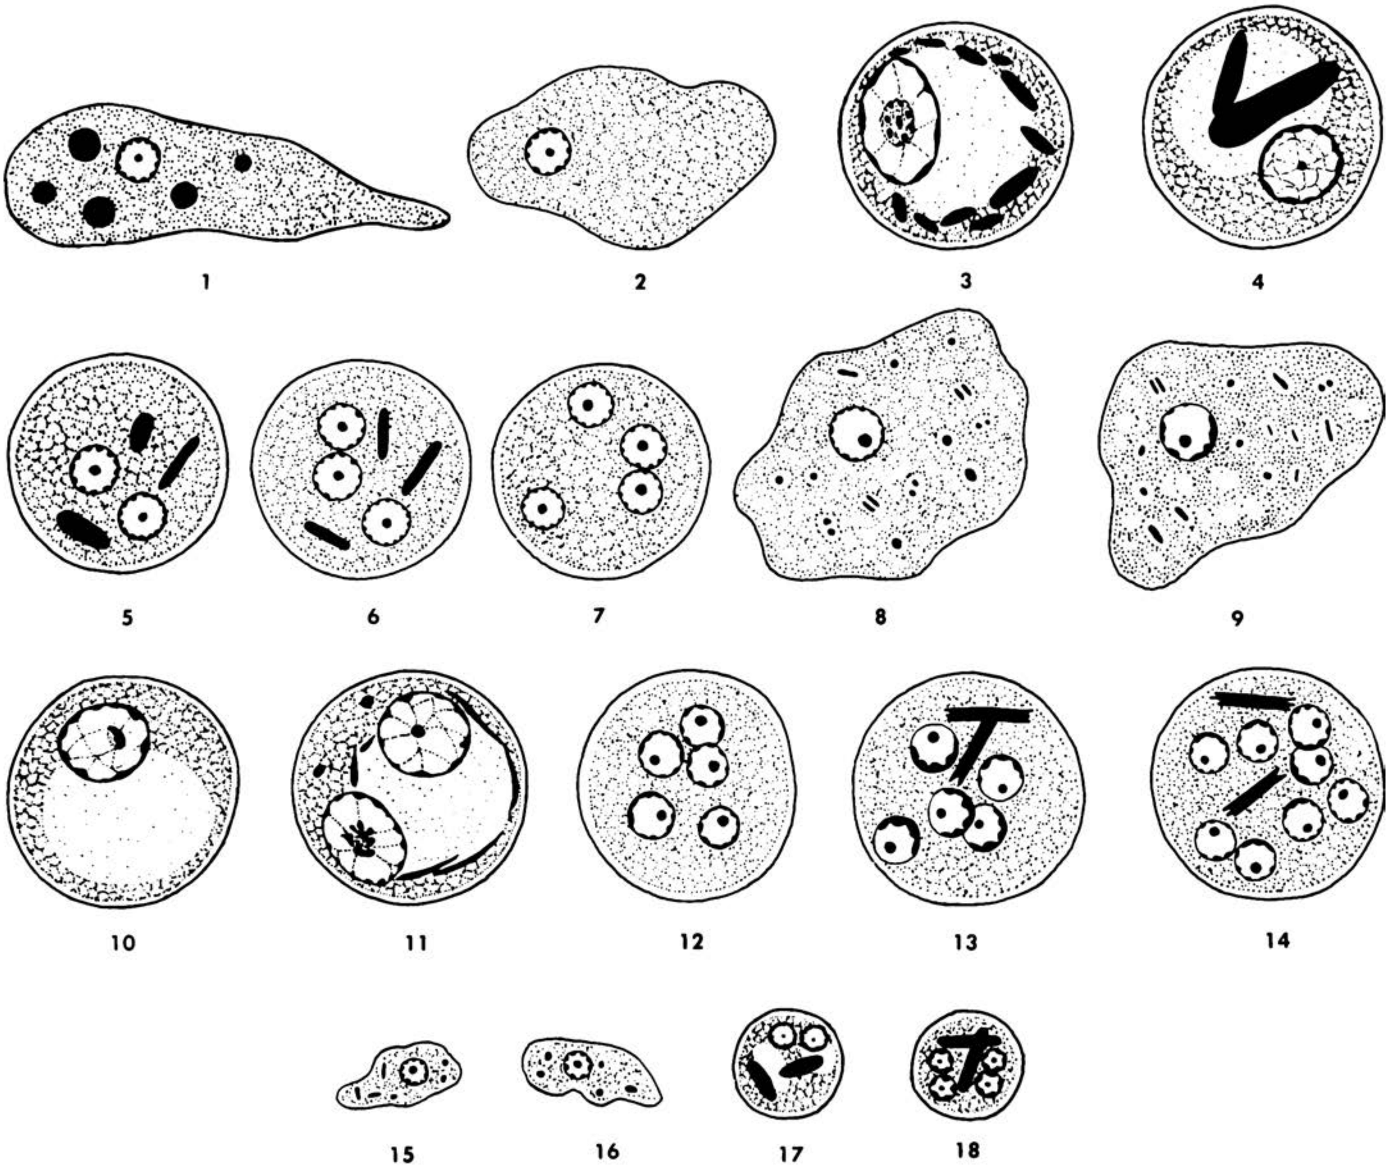


Figure 21.2 (1) Trophozoite of *Entamoeba histolytica*; (2) trophozoite of *E. histolytica*/*E. dispar*/*E. moshkovskii*; (3 and 4) early cysts of *E. histolytica*/*E. dispar*/*E. moshkovskii*; (5 to 7) cysts of *E. histolytica*/*E. dispar*/*E. moshkovskii*; (8 and 9) trophozoites of *Entamoeba coli*; (10 and 11) early cysts of *E. coli*; (12 to 14) cysts of *E. coli*; (15 and 16) trophozoites of *Entamoeba hartmanni*; (17 and 18) cysts of *E. hartmanni*. doi:10.1128/9781555819002.ch21.f2

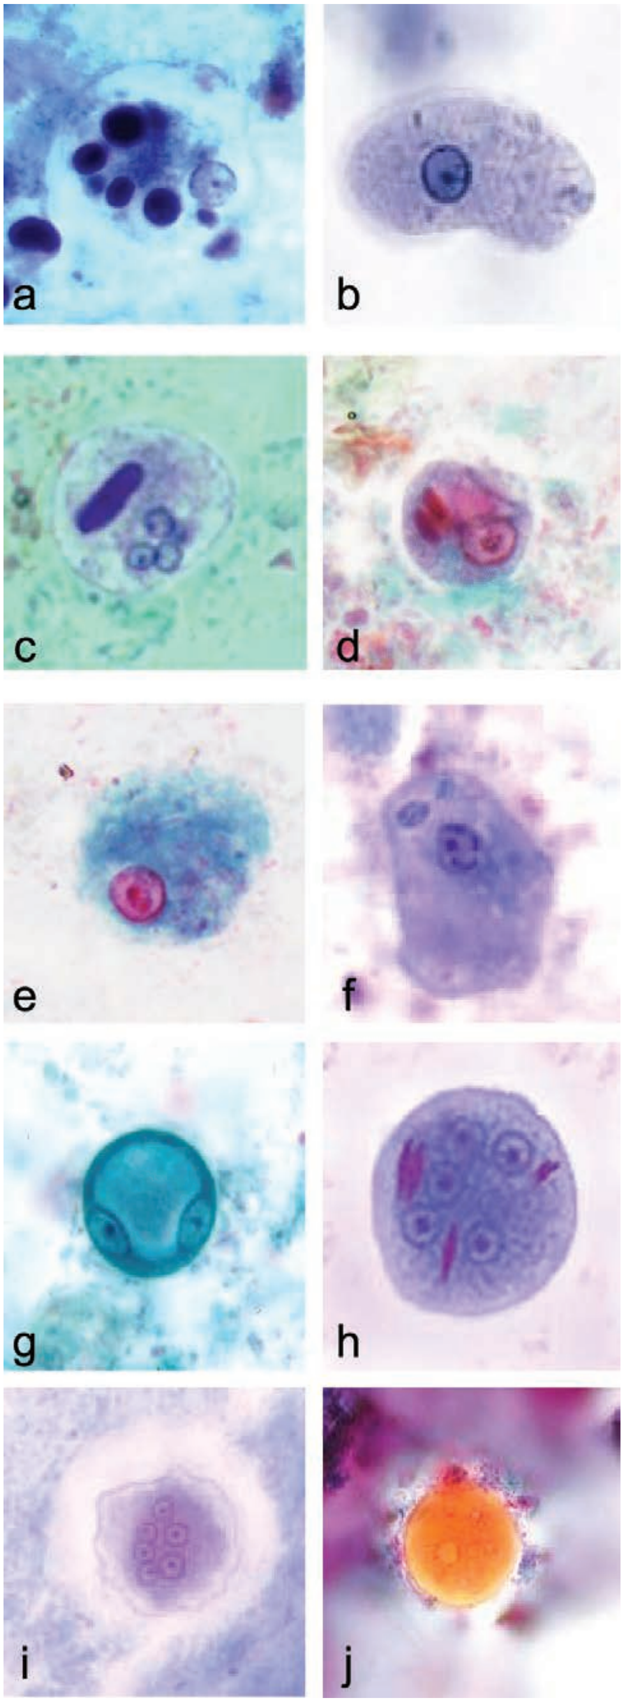
mucus are frequent (up to 10 per day). Although dysentery may last for months, it usually varies from severe to mild over that time and may lead to weight loss and prostration. In patients with severe cases, symptoms may begin very suddenly and include profuse diarrhea (over 10 stools per day), fever, dehydration, and electrolyte imbalances. If the clinical picture is acute, the illness may mimic appendicitis, cholecystitis, intestinal obstruction, or diverticulitis.

Hepatic Disease. Blood flow draining the intestine tends to return to the liver, most commonly the upper right lobe (Fig. 21.5 and 21.6). The organisms present in the submucosa can be carried via the bloodstream to the liver. Onset of symptoms may be gradual or sudden; upper right abdominal pain with fever from 38 to 39°C is the most consistent finding. Weakness, weight loss, cough, and sweating are less commonly seen. There tends to be hepatomegaly with



tenderness; however, liver function tests may be normal or slightly abnormal, with jaundice being very rare. There may be changes at the base of the right lung owing to the elevated diaphragm. The abscess can be visualized radiologically, sonically, or by radionuclear scan, and the majority of patients have a single abscess in the right lobe of the liver. The most common complication is rupture of the abscess into the pleural space. An abscess can also extend into the peritoneum and through the skin. Hematogenous spread to the brain, as well as to the lungs, pericardium, and other sites, is possible. For patients living in areas of endemic infection and patients with a relevant travel history, amebic abscess should be suspected in those with spiking fever, weight loss, and abdominal pain in the upper right quadrant or epigastrium and those with tenderness in the liver area. The presence of leukocytosis, a high alkaline phosphatase level, and an elevated right diaphragm suggests a hepatic abscess. Pyogenic and amebic liver abscesses are the two most common hepatic abscesses. The severity of a pyogenic abscess depends on the bacterial source and the patient's underlying condition. Amebic abscess tends to be more prevalent in individuals with suppressed cell-mediated immunity, men, and younger individuals (13–15).

E. histolytica cysts and trophozoites are found in the stools of only a few patients with liver abscess. About 60% of these patients have no intestinal symptoms or any history of dysentery.

Although hepatic abscess is secondary to earlier colonization in the wall of the large intestine and is the most common site for extraintestinal amebiasis, *E. histolytica* has been seen in almost every soft organ and tissue of the body, including the lungs, heart, skin, and brain. Amebiasis of the lungs usually develops as an extension of a hepatic abscess that has ruptured through the diaphragm; however, it can also originate as a secondary site from the original infection in the intestine. Typically, the patient experiences expectoration of liver-colored sputum. In a very low percentage of cases, the pericardium can be involved; this is more likely to occur in patients with an abscess in the left lobe of the liver.

Figure 21.3 (a) Trophozoite of *Entamoeba histolytica*. (b) Trophozoite of *Entamoeba histolytica/E. dispar/E. moshkovskii*. (c and d) Cysts of *E. histolytica/E. dispar/E. moshkovskii/E. bangladeshi* (d is a precyst with a single nucleus). (e and f) Trophozoites of *Entamoeba coli*. (g to i) Cysts of *E. coli* (g is a precyst with two nuclei). Note the chromatoidal bars in panel h and the shrunken cyst (which is often seen in permanent stained smears) in panel i. Panel j represents an artifact that mimics an *E. coli* cyst (permanent stain). (Panel g is courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch21.f3

TABLE 21.2 Intestinal protozoa: cysts of common amebae

Characteristic	***Entamoeba histolytica/ Entamoeba dispar/ Entamoeba moshkovskii/ Entamoeba bangladeshi***	***Entamoeba hartmanni***	***Entamoeba coli***	***Endolimax nana***	***Iodamoeba bütschlii***
Size[a] (diam or length)	10–20 μm (usual range, 12–15 μm)	5–10 μm (usual range, 6–8 μm)	10–35 μm (usual range, 15–25 μm)	5–10 μm (usual range, 6–8 μm)	5–20 μm (usual range, 10–12 μm)
Shape	Usually spherical	Usually spherical	Usually spherical; may be oval, triangular, or other shapes; may be distorted on permanent stained slide because of inadequate fixative penetration	Usually oval, may be round	May vary from oval to round; cyst may collapse because of large glycogen vacuole space
Nucleus: no. and visibility	Mature cyst, 4; immature, 1 or 2 nuclei; nuclear characteristics difficult to see on wet preparation	Mature cyst, 4; immature, 1 or 2 nuclei; 2 nucleated cysts very common	Mature cyst, 8; occasionally 16 or more nuclei are seen; immature cysts with 2 or more nuclei are occasionally seen	Mature cyst, 4; immature cysts, 2; very rarely seen and may resemble cysts of *Enteromonas hominis*	Mature cyst, 1
Peripheral chromatin (stained)	Peripheral chromatin present; fine, uniform granules, evenly distributed; nuclear characteristics may not be as clearly visible as in trophozoite	Fine granules evenly distributed on the membrane; nuclear characteristics may be difficult to see	Coarsely granular; may be clumped and unevenly arranged on membrane; nuclear characteristics not as clearly defined as in trophozoite; may resemble *E. histolytica*/ *E. dispar*	No peripheral chromatin	No peripheral chromatin
Karyosome (stained)	Small, compact, usually centrally located but occasionally eccentric	Small, compact, usually centrally located	Large, may or may not be compact and/or eccentric; occasionally centrally located	Smaller than karyosome seen in trophozoites, but generally larger than those of the genus *Entamoeba*	Large, usually eccentric refractile granules may be on one side of karyosome ("basket nucleus")
Cytoplasm, chromatoidal bodies (stained)	May be present; bodies usually elongate, with blunt, rounded, smooth edges; may be round or oval	Usually present; bodies usually elongate, with blunt, rounded, smooth edges; may be round or oval	May be present (less frequently than in *E. histolytica*/*E. dispar*); splinter shaped with rough, pointed ends	Rare chromatoidal bodies present; occasionally small granules or inclusions seen; fine linear chromatoidals may be faintly visible on well-stained smears	No chromatoidal bodies present; small granules occasionally present
Glycogen (stained with iodine)	May be diffuse or absent in mature cyst; clumped chromatin mass may be present in early cysts (stains reddish brown with iodine)	May or may not be present as in *E. histolytica*/*E. dispar*	May be diffuse or absent in mature cyst; clumped mass occasionally seen in mature cysts (stains reddish brown with iodine)	Usually diffuse if present (stains reddish brown with iodine)	Large, compact, well-defined mass (stains reddish brown with iodine)

[a] Wet preparation measurements (on permanent stains, organisms usually measure 1 to 2 μm less).

doi:10.1128/9781555819002.ch21.f4

Cutaneous Disease. Cutaneous amebiasis (amebiasis cutis) is a rare disease, which occurs as a complication of amebic dysentery; however, it is a public health concern worldwide, particularly in developing nations. Amebiasis of the skin usually develops as a perianal extension of acute amebic colitis or on the abdominal wall due to rupture or open drainage of an internal intestinal or hepatic lesion (16). Cutaneous amebiasis may also occur as a venereal infection of the penis after anal intercourse (17). It is characterized by a severe clinical course, which can be confused with other disorders. Therefore, knowledge of its clinical features, histopathology, and pathogenesis is essential. Most patients are male (overall male to female ratio, 1.9 to 1). The disease presents as painful ulcers containing rare to many amebae, which can be detected microscopically using routine stains. It is recommended that tissue or smears be prepared and examined from the edges of the ulcer instead of the necrotic centers. Ingestion of RBCs by the trophozoites can be found and represents a diagnostic sign of the organism pathogenicity. Most cases resolve with the use of specific antiamebic drugs; however, if left untreated, progression is rapid and unrelenting, sometimes with massive destruction of skin and subcutaneous tissues. Therefore, cutaneous amebiasis is a particularly virulent form of amebiasis (18).

doi:10.1128/9781555819002.ch21.f6

Brain abscess. Amebic abscess in the brain is quite rare and usually arises from either hepatic or pulmonary involvement (19). Brain abscess due to *E. histolytica* is most commonly seen in a small percentage of patients who also have an amebic liver abscess. After treatment for liver abscess with apparent improvement, the patient may develop symptoms and signs of central nervous system involvement. The average age of the patient is approximately

30, and symptoms include headache, vomiting, and altered mental status. Signs of amebic brain abscess include most commonly meningeal signs, facial nerve (VII) palsy, motor paralysis, and seizure. Although the cerebrospinal fluid may show some abnormalities, there is nothing that is disease-specific. Diagnosis is by serology and PCR of brain abscess aspirate or cerebrospinal fluid and treatment is with metronidazole. Certainly, brain involvement in amebic liver abscess should be suspected in patients with neurological signs and symptoms. Other rare ectopic sites include the spleen, adrenals, kidneys, ureters, urinary bladder, urethra, clitoris, and pericardium.

Pathogenesis

It has been estimated that *E. histolytica* infection kills more than 100,000 people each year. Key to the pathogenesis of this organism is its ability to directly lyse host cells and cause tissue destruction. Amebic lesions show evidence of cell lysis, tissue necrosis, and damage to the extracellular matrix. There is evidence that *E. histolytica* trophozoites interact with the host through a series of steps: adhesion to the target cell, phagocytosis, and cytopathic effect (11, 20). Numerous other parasite factors also play a role. From the perspective of the host, *E. histolytica* induces both humoral and cellular immune responses, with cell-mediated immunity representing the major human host defense against this complement-resistant cytolytic protozoan.

Our understanding of pathogenesis has expanded dramatically within the past few years. We now know that invasive strains of *E. histolytica* are resistant to complement-mediated lysis. These organisms activate complement via cleavage of C3 by an extracellular cysteine proteinase. Cysteine proteinases are important virulence factors encoded by at least three genes, one of which is unique to invasive strains (21). The amebic cysteine proteinases are homologous to proteinases released by transformed cells and probably represent a common mechanism of tissue invasion. The proteinase activity of amebae shows excellent correlation with their virulence. Cysteine proteinase can cleave the extracellular structural matrix and can degrade fibronectin and laminin, as well as type I collagen; this suggests that degradation of basement membrane is an important step in tissue invasion (21). Hemoglobin-degrading cysteine proteases also play an important role in iron acquisition by *E. histolytica*. Differences in the pathogenesis of *E. histolytica* and *E. dispar* also help explain the epidemiology, clinical syndromes, and pathology of amebiasis. Antibodies to the neutral cysteine proteinase have been detected in 83% of patients with invasive *E. histolytica* infections but not in patients with noninvasive *E. dispar* infections (22). Apparently, inhibition of the expression of cysteine proteinases does not affect *E. histolytica* cytopathic or hemolytic activity but inhibits phagocytosis. There is recent evidence that a cysteine protease (EhCP112) and a protein with an adherence domain (EhADH112) form the *E. histolytica* 112-kDa adhesin.

The first evidence of amebic pathology is depletion of the intestinal mucus and disruption of the epithelial barrier, which results from the action of cysteine proteinases as well as other factors (10, 21). Clinical isolates of *E. histolytica* in culture release 10- to 1,000-fold more cysteine proteinases than do *E. dispar* isolates. Trophozoites use cysteine proteinases to cleave and penetrate the extracellular matrix (collagen, elastin, fibrinogen, and laminin) in order to cause invasive disease (21). These enzymes also interfere with the host immune system; hence, the data supporting a key role of cysteine proteinases in virulence are quite compelling, especially since specific genes for cysteine proteinases appear to be present and overexpressed in *E. histolytica* and absent or underexpressed in *E. dispar*.

Several molecules that may be involved in the parasite-host interaction processes have been identified. A lectin inhibitable by galactose and *N*-acetyl-D-galactosamine (Gal/GalNAc) is present on the trophozoite surface. Adherence of *E. histolytica* trophozoites to colonic mucin, epithelium, and other target cells is mediated by the amebic Gal/GalNAc lectin (24). Lectin activity in the parasite is regulated by inside-out signaling; this inside-out signaling via the lectin cytoplasmic domain may control the extracellular adhesive activity of the amebic lectin and provides evidence of the role of lectin in virulence (25). Studies also confirm that dominant-negative mutations in the Gal/GalNAc lectin affect adhesion and cytolysis while mutations in meromyosin affect cytoskeletal function (26). Myosin IB also is involved in phagocytosis of human erythrocytes by *E. histolytica* (27). Recently, a distinct β_2 integrin-like molecule with a potential role in cellular adherence was identified. This amebic β_2 integrin appeared to be distinct from the amebic Gal/GalNAc lectin based on recombinant expression, amebic colocalization, and enzyme-linked immunosorbent assay (ELISA) studies. The presence of integrin-dependent binding may allow trophozoites to opportunistically adhere to activated intestinal epithelium or vascular endothelium during amebic colitis or hepatic abscess (28).

There are also correlations between differences in the cell surface phosphorylated glycolipids and virulence; lipophosphoglycan and lipophosphopeptidoglycan molecules are abundant in virulent strains of *E. histolytica* and are absent or present at low levels in avirulent *E. histolytica* strains and *E. dispar* (29).

Various amebic pore-forming proteins are known, of which the 5-kDa protein (amebapore) has been extensively studied. These proteins can insert into the lipid bilayers of target cells, forming ion channels (11).

Data obtained by using human myeloid cells as target cells *in vitro* have revealed that the target cells die due to necrosis with cell swelling, rupture of plasma membranes, and release of cell contents including nucleic acids. These findings confirm the notion that these particular target cells undergo necrosis when killed by viable trophozoites, as well as by isolated amebapores (11).

The role of zinc in the pathogenicity of *E. histolytica* may also be relevant. Apparently, zinc alters the functionality of the amebae *in vitro* by causing a decrease in replication and adhesion and *in vivo* by inhibiting amebic pathogenicity.

Diagnosis

Routine Diagnostic Procedures. The laboratory diagnosis of amebiasis, particularly intestinal amebiasis, depends on a number of procedures, any one of which can prevent organism recovery if not performed properly (Table 21.3). Organism detection depends on collection of the correct specimens, the number of specimens submitted, processing methods and diagnostic tests used, and examination by personnel who are well trained in identification of protozoa. This diagnosis can be one of the more difficult to achieve. Lack of appropriate training and diagnostic testing may lead to missed infections. In some cases, false positives may be due to identification of human white blood cells as amebae. A complete discussion of specimen collection and submission to the laboratory is presented in chapter 2.

The standard ova and parasite examination is the recommended procedure for recovery and identification of *E. histolytica* in stool specimens. Microscopic examination of a direct saline wet mount may reveal motile trophozoites, which may contain RBCs. However, the number of times these trophozoites with RBCs are present is limited. In many patients who do not present with acute dysentery, trophozoites may be present but do not contain RBCs and the organisms may be *E. histolytica* or *E. dispar*. An asymptomatic individual may have few trophozoites and possibly only cysts in the stool. Although the concentration technique is helpful in demonstrating cysts, *the most important technique for the recovery and identification of protozoan organisms is the permanent stained smear* (normally stained with trichrome or iron hematoxylin). A minimum of three specimens collected over a time frame of not more than 10 days is recommended (30–32).

Note that if the permanent stained smear is quite dark, a delicate *E. histolytica*/*E. dispar* organism may appear more like *Entamoeba coli*; on a very thin, pale smear, *E. coli* can appear more like *E. histolytica*/*E. dispar*. Also, when the organisms are dying or have been poorly fixed, they appear more highly vacuolated, thus looking like *E. coli* trophozoites rather than *E. histolytica*/*E. dispar*.

If slides are prepared properly and examined carefully, sigmoidoscopy specimens may be very helpful. At least six areas of the mucosa should be sampled. Smears from these areas should be examined after permanent staining. This does not take the place of the recommended minimum of three stool specimens submitted for ova and parasite examinations (direct, concentration, and permanent stained smear). Refer to Algorithm 21.1 for detailed information.

TABLE 21.3 Intestinal amebae: recommended diagnostic procedures

Organism	Recommended specimen	Diagnostic procedure[a]
Entamoeba histolytica	Stool	Complete ova and parasite exam
		Immunoassays for antigen detection
	Sigmoidoscopy material	Permanent stain

Algorithm 21.1 Intestinal amebiasis. Fecal immunoassay kits can be used on human stool specimens to identify organisms in the group *E. histolytica*/*E. dispar* or to differentiate *E. histolytica* from *E. dispar*. Currently available reagents require fresh or frozen specimens only. *, trophozoites containing RBCs confirmatory for *E. histolytica*; trophozoites with no ingested RBCs and/or cysts confirm only the *E. histolytica*/*E. dispar* group.

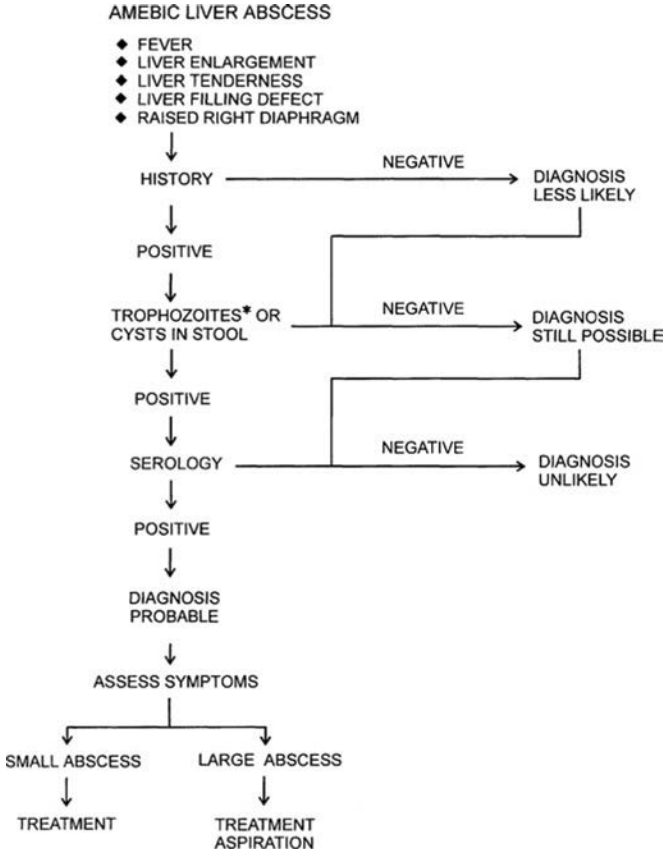
doi:10.1128/9781555819002.ch21.Alg21.1

Definitive diagnosis of liver abscess can be achieved by identification of organisms from liver aspirate material. However, this procedure is rarely performed, and often the specimen obtained is not collected properly. Aspirated material must be aliquoted into several different containers as it is removed from the abscess; amebae may be found only in the last portion of the aspirated material, theoretically material from the abscess wall, not necrotic debris from the abscess center. Refer to Algorithm 21.2 for detailed information.

Antigen Detection. A number of enzyme immunoassay reagents are commercially available, and their specificity and sensitivity provide excellent options for the clinical laboratory (Table 21.4). These tests can determine the presence of the *E. histolytica*/*E. dispar* group as being distinct from the rest of the *Entamoeba* species such as nonpathogenic *E. coli* or *E. hartmanni*. Other test reagents can actually separate *E. histolytica* from *E. dispar*. The majority of these procedures use the ELISA or enzyme immunoassay (EIA) formats (33). However, in some cases they have been found to be less sensitive than PCR and in other instances they have been found equal to PCR. Another product is available as a cartridge format that uses an immunochromatographic strip-based detection system for the *E. histolytica*/*E. dispar* group, *G. lamblia*, and *Cryptosporidium* spp. (3). These commercially available reagent kits require fresh or frozen stools; formalin has been found to interfere with the *Entamoeba* reagents. Any available antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens. There are limitations when using kits that include organisms in the genus *Entamoeba* (3). However, almost all reagent kits for the detection of *G. lamblia* and *Cryptosporidium* spp. can be used with formalin-based stool preservatives, the Universal Fixative (TOTAL-FIX), as well as fresh or frozen specimens.

To provide clinically relevant information to physicians for treatment of patients infected with pathogenic E. *histolytica*, methods involving monoclonal antibodies, purified antigens, or DNA probes are now available. Reagents have been developed to differentiate pathogenic *E. histolytica* from nonpathogenic *E. dispar* (33). Although some of these reagents are now available, routine use in clinical laboratories may not be accepted because of cost, limited numbers of cases, and infrequent identification of organisms in the genus *Entamoeba*. Reliable probes based on the hypothesis of zymodeme stability and two separate species (one pathogenic and one nonpathogenic) offer significant improvements over current serologic or direct detection methods; these probes may also help eliminate false-positive results due to misidentification of human cells or other nonpathogenic protozoa in patient specimens.

The laboratory now has the ability to routinely indicate to the physician whether the *E. histolytica*/*E. dispar* organisms seen in the stool specimen are pathogenic *E. histolytica* or nonpathogenic *E. dispar*. Without the use of these types of reagents, the only way to morphologically identify true pathogenic *E. histolytica* would be to observe the rare presence of trophozoites containing ingested RBCs. In the event the laboratory does not use these reagents, the presence of *E. histolytica*/*E. dispar* should be reported to the physician, along with some additional commentary



Algorithm 21.2 Amebic liver abscess. *, trophozoites containing RBCs confirmatory for *E. histolytica*; trophozoites with no ingested RBCs and/or cysts confirm only the *E. histolytica*/*E. dispar* group. doi:10.1128/9781555819002.ch21.Alg21.2

related to the newer information on pathogenicity. Ultimately, the physician will have to decide on the issue of therapy on the basis of the patient's clinical condition. However, without more accurate information on the pathogenicity of organisms seen in clinical specimens, from a public health point of view it may be appropriate to treat all infected patients. Also, depending on each state's requirements, pathogenic *E. histolytica*, as well as *E. histolytica*/*E. dispar*, is generally reported to the public health facility (county).

Antibody Detection. Serologic testing for intestinal disease is normally not recommended unless the patient has true dysentery; even in these cases, the titer (indirect hemagglutination as an example) may be low and thus difficult to interpret. The definitive diagnosis of intestinal amebiasis should not be made without demonstrating the organisms. For patients suspected of having extraintestinal disease, serologic tests are much more relevant (33). Indirect hemagglutination and indirect fluorescent-antibody tests have been reported positive with titers of ≥1:256 and ≥1:200, respectively, in almost 100% of cases of amebic liver abscess (3). Positive serologic results, in addition to clinical findings, make the diagnosis highly probable. In the absence of STAT serologic tests for amebiasis (tests with very short turnaround times for results), the decision about the identity of the causative agent often must be made on clinical grounds and on the basis of results of other diagnostic tests such as scans.

Serologic tests based on recombinant *E. histolytica* antigens, using SREHP and the 170-kDa subunit of the galactose-specific adhesin, have been developed. More than 50% of the patients examined had become seronegative by one or both recombinant tests within 180 days of their diagnosis of amebic liver abscess. In contrast, all patients remained seropositive by a standard conventional indirect-hemagglutination test at more than 6 months after presentation (34). These findings may make the recombinant-antigen tests more useful for the serologic diagnosis of amebiasis in areas of endemic infection.

In a study in Bangladesh, 199 (69%) of children tested were positive at least once using the *E. histolytica* antigen detection test. Although the incidence rate was not related to baseline nutritional status, age, sex, blood group, or duration of breast feeding, it was significantly related to the baseline *E. histolytica* anti-lectin IgG status of the children. Children who had recovered from a diarrheal episode with *E. histolytica*, but not *E. dispar*, had half the chance of developing subsequent *E. histolytica*-associated diarrhea, consistent with the development of species-specific acquired immunity (35).

In another study in Brazil, 30% of a sample population was colonized with *E. histolytica*. However, no correlation between seropositivity for anti-GalNAc lectin antibody and colonization was found. These results suggest that colonization does not necessarily produce immunity to reinfection (36).

Histology. A histologic diagnosis of amebiasis can be made when the trophozoites within the tissue are identified. Organisms must be differentiated from host cells, particularly histiocytes and ganglion cells. Periodic acid-Schiff staining is often used to help locate the organisms. The organisms appear bright pink with a green-blue background (depending on the counterstain used). Hematoxylin and eosin staining also allows the typical morphology to be seen, thus allowing accurate identification. As a result of sectioning, some organisms exhibit the evenly arranged nuclear chromatin with the central karyosome and some no longer contain the nucleus.

KEY POINTS—LABORATORY DIAGNOSIS

Entamoeba histolytica

1. When routine ova and parasite examinations are ordered, three specimens (stool) should be submitted for the diagnosis of intestinal amebiasis; fecal fixatives are highly recommended to eliminate the lag time between specimen passage and receipt/preservation in the laboratory.
2. Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool).
3. Presumptive identification on a wet preparation must be confirmed by using the permanent stained smear; wet mounts are recommended on liquid or very runny specimens. If the specimen is submitted in fixative, no direct mount is required (no organism motility would be visible with the use of a fixative). Without using *E. histolytica*-specific antigen detection tests, the presence of the organism(s) should be reported as follows. Trophozoites containing ingested RBCs within the cytoplasm should be reported as the true pathogen ("*Entamoeba histolytica* trophozoites present"). However, if cysts or trophozoites containing no ingested RBCs are seen, the report should indicate that the *Entamoeba* group is present ("*Entamoeba histolytica/E. dispar* group trophozoites and cysts present").
4. The six smears for permanent staining should be prepared at sigmoidoscopy but should not take the place of the ova and parasite examination.
5. Immunoassay procedures can be performed to confirm the presence of the *E. histolytica/E. dispar* group or can be used to differentiate pathogenic *E. histolytica* from nonpathogenic *E. dispar*. Remember that some of these reagent kits may require fresh or frozen stools only; formalin-preserved stool and stool containing polyvinyl alcohol are not acceptable.
6. The serologic test result for antibody may or may not be positive in intestinal disease and is much more likely to be positive in extraintestinal disease (liver abscess).

Treatment

Over the years, there has been much controversy concerning the possibility of pathogenic and nonpathogenic strains of *E. histolytica* and whether every patient found to harbor this parasite should be treated. Brumpt is credited with the first suggestion that *E. histolytica* consists of two morphologically identical organisms, one pathogenic and invasive (*E. histolytica*) and the other a harmless commensal (*E. dispar*). While carriers usually harbor nonpathogenic *E. dispar*, pathogenic *E. histolytica* also may be found in these individuals. At present, tests which routinely differentiate between *E. histolytica* and *E. dispar* are not used routinely by all diagnostic laboratories. The diagnosis of *E. histolytica/E. dispar* infection is most often based on organism morphology. For this reason, in general, patients in the United States who harbor these organisms may be treated, regardless of the presence or absence of symptoms.

There are two classes of drugs used in the treatment of amebic infections: luminal amebicides such as iodoquinol or diloxanide furoate, and tissue amebicides such as metronidazole, chloroquine, or dehydroemetine. Because differences in drug efficacy exist, it is important that the laboratory report for the physician indicate whether cysts, trophozoites, or both are present in the stool specimen (37).

Asymptomatic Infection. Patients found to have true *E. histolytica* in the intestinal tract, even if they are asymptomatic, should be treated to eliminate the organisms. Both diloxanide furoate and iodoquinol or paromomycin are available for treatment of patients who have cysts in the lumen of the gut. A study encompassing 14 years of experience of using diloxanide furoate for treating asymptomatic cyst passers in the United States indicates that the drug is safe and effective and may be particularly well tolerated in children (38). In general, these treatments are ineffective against extraintestinal disease. If the patient is passing both trophozoites and cysts, the recommended treatment is metronidazole plus iodoquinol (38).

Mild to Moderate Disease. For patients with mild to moderate disease, metronidazole (Flagyl) should be used when tissue invasion occurs, regardless of the tissue involved. Drugs directed against the lumen organisms should also be used in these instances.

Severe Intestinal Disease. Metronidazole plus one of the luminal drugs should be used for therapy.

Hepatic Disease. Metronidazole plus one of the luminal drugs should be used to treat hepatic disease. Some other combinations can also be used; some contain emetine, in which case the patient must be monitored very carefully for possible cardiotoxicity. The importance of using both luminal and tissue amebicides to treat patients with amebic liver abscess is emphasized. Asymptomatic colonization may be present with the true pathogen, *E. histolytica*. In patients treated with metronidazole (tissue amebicide), there is generally 100% clinical response to the hepatic lesions; however, failure to eliminate the organism from the bowel can lead to second bouts with invasive disease and intestinal colonization. Also, these carriers constitute a public health hazard since they are shedding infective cysts. Specific drugs and dosages are discussed in chapter 36.

Epidemiology and Prevention

Infections with *E. histolytica* are worldwide in distribution and are generally most prevalent in the tropics. In 1984, 500 million people were estimated to be infected with *E. histolytica*, and 40 to 50 million of these had extensive symptoms including colitis or extraintestinal abscesses. It is estimated that there are 100,000 deaths each year. Prevalence figures for the United States are generally thought to be <5%. It has also been estimated that for every case of invasive disease diagnosed, there are at least 10 to 20 asymptomatic individuals excreting infective cysts.

Population groups with a higher incidence of amebiasis include recent immigrants and refugees from South and Central America and from Southeast Asia. Residents in southeastern and southwestern parts of the United States also tend to have more infections with intestinal parasites, as do groups such as patients in mental institutions.

Following broad social changes seen in the late 1960s, the open expression of homosexuality, increased numbers of sexual contacts, increased frequency of sexual activities, and anonymity of sexual partners contributed to dramatic increases in the prevalence of sexually transmitted organisms, including *E. histolytica*. Although infections with this organism are usually associated with poor sanitation and underdeveloped areas of the world, epidemiologic studies in both Europe and the United States in the 1970s documented that sexual transmission of amebiasis occurred mainly among urban homosexual men. With the increase in sexually transmitted pathogens, a number of clinical syndromes were recognized; these clinical presentations were grouped together and referred to as "the gay bowel syndrome." Many published reports confirm that *E. histolytica* is one of the major pathogens in the gay bowel syndrome; however, this term is no longer commonly used. It is also well known that the clinical presentations within the homosexual community often differ from those seen in the heterosexual population.

Epidemiologic evidence of sexual transmission of *E. histolytica* has grown significantly since the early 1970s, particularly in areas such as New York City and San Francisco. In San Francisco, the incidence of reported symptomatic intestinal amebiasis among homosexual men between 20 and 39 years of age has increased over 1,000% during the last 10 years. Although percentages vary, it appears that approximately 30% of urban homosexual men may be infected with *E. histolytica*, a sharp increase over the estimated rate of less than 5% seen in the general population within the United States.

Direct oral-anal contact (anilingus) is a common practice among homosexual men, leading to both fecal exposure and oral contact with a variety of intestinal pathogens. Although anilingus has often been listed as a key risk factor in potential exposure, transmission can also occur during oral-genital sex after anal intercourse has occurred. It has also been shown that active heterosexuals can acquire infection with *E. histolytica* through sexual activities that provide an opportunity for fecal-oral contamination. The key factor is not necessarily homosexuality but the frequency of sexual activity and the potential for fecal-oral contact.

It is important to remember than in earlier studies in which "*E. histolytica*" was specifically mentioned, reference is actually being made to the *E. histolytica*/*E. dispar* group rather than the actual pathogen, *E. histolytica*. Genotyping of *E. histolytica* isolates could serve as a tool to fingerprint individual isolates, thus helping to determine geographic origins of isolates and routes of transmission. Molecular tools are now available not only to diagnose *Entamoeba* species accurately but also to study intraspecies genetic diversity (39).

With the advent of AIDS and the subsequent modifications in sexual practices within homosexual communities, the incidence of *E. histolytica* infection is thought to be much lower than before. In recent years, the coccidian parasites *Cystoisospora* (*Isospora*) *belli* and *Cryptosporidium* spp. and the microsporidia *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* have become much more of a problem in patients with AIDS.

There are certain urban areas (Mexico City, Mexico; Medellin, Colombia; and Durban, South Africa) where the incidence of invasive disease is considerably higher than in the rest of the world. Contributing factors (not well delineated) may include poor nutrition, tropical climate, decreased immunologic competence of the host, stress, altered bacterial flora in the colon, traumatic injuries to the colonic mucosa, alcoholism, and genetic factors.

Humans are the reservoir host for *E. histolytica* and can transmit the infection to other humans, primates, dogs, cats, and possibly pigs. However, contact with sewage-contaminated water provides another route of infection; therefore, amebiasis can be considered a zoonotic waterborne infection as well as being transmitted through human-to-human transmission (40). The cyst stages are very resistant to environmental conditions and can remain viable in the soil for 8 days at 28 to 34°C, 40 days at 2 to 6°C, and 60 days at 0°C. Cysts are normally removed by sand filtration or destroyed by 200 ppm of iodine, 5 to 10% acetic acid, or boiling. The asymptomatic cyst passer who is a food handler is generally thought to play the most important role in transmission.

A colonization-blocking vaccine could eliminate *E. histolytica* as a cause of human disease, particularly since humans serve as the only significant reservoir host (41). The application of molecular biological techniques has led to the identification and structural characterization of three amebic antigens, SREHP, the 170-kDa subunit of the Gal/GalNAc binding lectin, and the 29-kDa cysteine-rich protein, which all show promise as recombinant antigen-based vaccines to prevent amebiasis (41). An immunogenic dodecapeptide derived from the SREHP molecule has been genetically fused to the B subunit of cholera toxin to create a recombinant protein capable of inducing both antiamebic and anti-cholera toxin antibodies when administered by the oral route. Continued research should lead to the development of a cost-effective oral combination "enteric-pathogen" vaccine capable of inducing protective mucosal immune responses to several important enteric diseases including amebiasis (42).

Entamoeba dispar

In the past, an unexplained aspect of the epidemiology of amebiasis was the number of asymptomatic individuals who were passing cysts but had no clinical evidence of invasive disease. Extensive work involving isoenzyme analysis and molecular techniques has demonstrated conclusively that there are two genetically distinct but morphologically identical species of what was formerly known as *E. histolytica*. After many years of debate, the species that is associated with amebiasis in humans is now classified as *E. histolytica*. The other species, which is more common but is not capable of causing invasive disease, is called *E. dispar*. Studies confirming the differences between the two organisms include direct sequencing of the PCR-amplified small-subunit rRNA gene of *E. dispar* and the design of primers for rapid differentiation from *E. histolytica*; detection of differences in the phosphoglucomutases and cysteine proteinases from *E. histolytica* and *E. dispar*; molecular biology of the differences in the hexokinase isoenzyme pattern; detection of differences in the secretion of acid phosphatase; and detection of DNA sequences unique to *E. histolytica* (6, 7, 11, 43, 45, 46).

Life Cycle and Morphology

The life cycle is essentially identical to that of *Entamoeba coli* or any of the other nonpathogenic intestinal protozoa, and the cyst form is the infective form for humans (Fig. 21.7).

Morphology of Trophozoites (Table 21.1). Living trophozoites vary in diameter from about 12 to 60 μm. Motility has been described as rapid and unidirectional, with pseudopods forming quickly in response to the conditions around the organism; it may appear to be sporadic. Although this characteristic is often described, it is rare to diagnose these organisms on the basis of motility seen in a direct wet mount. The cytoplasm is differentiated into a clear outer ectoplasm and a more granular inner endoplasm. Based on the recent ability to culture these organisms in axenic culture systems and on light and electron microscopy studies, there may be some morphologic differences between *E. histolytica* and *E. dispar*. However, these differences would not be recognized by routine diagnostic methods such as the permanent stained smear. If organisms were seen that were consistent with *E. histolytica*/*E. dispar* on the permanent stained smear, the laboratory report would indicate that fact and would be written as "*Entamoeba histolytica*/*E. dispar*" or "*Entamoeba histolytica*/*E. dispar* group or complex."

When the organism is examined on a permanent stained smear (trichrome or iron hematoxylin), the morphological characteristics are easily seen. The nucleus generally has evenly arranged chromatin on the nuclear membrane and has a small, compact, centrally located karyosome. The cytoplasm is described as finely granular with few ingested bacteria or debris in vacuoles. Ingested RBCs are never seen in the trophozoites; if ingested RBCs are seen, this finding

Figure 21.7 Life cycle of *Entamoeba dispar*, the same as *E. moshkovskii* and *E. bangladeshi*.

HUMANS
(Large bowel)
Trophozoites, cysts in feces
Cysts survive in food, water
Ingestion of cysts (Person to person)
Entamoeba dispar

identifies the organism as the true pathogen *E. histolytica*, not *E. dispar*.

Morphology of Cysts (Table 21.2). Within the immature cyst, there may be two types of inclusions, a glycogen mass and highly refractile chromatoidal bars with smooth, rounded edges. As the cysts mature, nuclear division occurs with the production of four nuclei; the cysts range in diameter from 10 to 20 μm. Usually, as the cyst matures, the glycogen disappears and chromatoidal bars may or may not be present. Cyst morphology does not differentiate between *E. histolytica* and *E. dispar*. Cyst formation occurs only within the intestinal tract; once the stool has been passed from the body, cyst formation does not occur. The one-, two-, and four-nucleated cysts are infective and represent the mode of transmission from one host to another (Fig. 21.1 to 21.3).

Clinical Disease

Prior to the separation of *E. histolytica* into two distinct species (*E. histolytica* and *E. dispar*), it was suggested that some *E. histolytica* strains were pathogenic and some were not. Now that *E. dispar* has been classified as a nonpathogenic organism, totally separated from the pathogenic *E. histolytica*, treatment is usually not recommended. However, this recommendation is based on the separation of the two species by molecular means, not by morphology alone. Since few laboratories will be routinely identifying the two *Entamoeba* species to the level of *E. histolytica* or *E. dispar*, the clinician will have to decide on the basis of clinical findings whether the patient has true pathogenic *E. histolytica* or nonpathogenic *E. dispar* infection. The laboratory report will merely indicate the presence of the "*Entamoeba histolytica*/*E. dispar*" group.

Diagnosis

Routine Diagnostic Procedures. Infection with *E. dispar* cannot be diagnosed on the basis of morphologic criteria alone, even from the permanent stained smear. When the organism is seen in the routine ova and parasite examination, it cannot be differentiated from *E. histolytica* unless trophozoites are seen to contain RBCs in the cytoplasm, a finding that is diagnostic for *E. histolytica*. Using routine diagnostic methods and not immunoassay procedures specific for *E. histolytica*, morphologic criteria would provide characteristics of both; the laboratory report would indicate "*Entamoeba histolytica*/*E. dispar*."

Antigen Detection. Immunoassay procedures are available that can determine the presence of the *E. histolytica*/*E. dispar* group as being distinct from the rest of the *Entamoeba* species, such as nonpathogenic *E. coli* or *E. hartmanni*. Other test reagents can actually separate *E. histolytica* from *E. dispar*. Most of these procedures use the ELISA or EIA formats (46). In some cases, they have been found to be less sensitive than PCR (15), and in other instances they have been found equal to PCR (15, 43). Another product that is available as a cartridge format uses an immunochromatographic strip-based detection system for the *E. histolytica*/*E. dispar* group, *G. lamblia*, and *Cryptosporidium* spp. (3). These commercially available reagent kits require fresh or frozen stools; formalin has been found to interfere with the *Entamoeba* reagents. Any available antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens.

Epidemiology and Prevention

The mode of transmission is similar to that found with other protozoa and is related to the ingestion of infective cysts in contaminated food or water. Based on differences in numbers between symptomatic patients with amebiasis (*E. histolytica*) and those who remain asymptomatic (*E. dispar*), it is obvious that many more patients are infected with nonpathogenic *E. dispar* than with pathogenic *E. histolytica*. Since travel from temperate zones to tropical and subtropical areas continues to become more common, it is necessary to consider imported amebiasis in many areas of the world where the infection is normally seen less frequently than infections with the nonpathogenic *E. dispar*.

Entamoeba moshkovskii

Entamoeba moshkovskii is found worldwide and is generally considered to be a free-living ameba. Based on microscopic morphology, this organism is indistinguishable from *E. histolytica* and *E. dispar*, except in cases of invasive disease when *E. histolytica* contains ingested RBCs. Although first isolated from sewage, *E. moshkovskii* can also be found in clean riverine sediments to brackish coastal pools. Apparently, there are some differences that separate this organism from *E. histolytica* and *E. dispar*. However, these differences pertain to physiology rather than morphology: *E. moshkovskii* is osmotolerant, can be cultured at room temperature, and is resistant to emetine (40).

Life Cycle and Morphology

The life cycle is essentially identical to that of *E. dispar*, and morphological differences are minimal to none (Fig. 21.7). In wet preparations, trophozoites usually range in size from 15 to 20 μm and cysts normally range in size from 12 to 15 μm. It is important to remember that on the permanent stained smear there is a certain amount of artificial shrinkage due to dehydration; therefore, all of the organisms, including pathogenic *E. histolytica*, may be somewhat smaller (from 1 to 1.5 µm) than the sizes quoted for the wet-preparation measurements.

Morphology of Trophozoites (Table 21.1). Trophozoites do not ingest RBCs, and the motility is similar to that of both *E. histolytica* and *E. dispar* (Fig. 21.3). Nuclear and cytoplasmic characteristics are very similar to those seen in *E. histolytica*; however, trophozoites of *E. moshkovskii* do not contain ingested RBCs.

Morphology of Cysts (Table 21.2). Nuclear characteristics and chromatoidal bars are similar to those in *E. histolytica* and *E. dispar* (Fig. 21.3).

Clinical Disease

Human isolates of *E. bangladeshi* have been recovered from asymptomatic patients, as well as those with diarrhea. It remains unclear what impact these organisms may have on the normal gut flora. Studies similar to those undertaken with *E. moshkovskii* may help to clarify the overall pathogenicity of *E. bangladeshi* and relevant symptoms attributed to this organism. Since many organisms within the genus *Entamoeba* exhibit almost identical morphology, patient clinical isolates may need to be identified using molecular methods.

Diagnosis

Because *E. moshkovskii* can be easily confused with other amebae, particularly in a wet preparation, it is almost mandatory that the final identification be obtained from the permanent stained smear. However, without the use of molecular tools to specifically identify this organism, the results are usually reported as "*Entamoeba histolytica*/*E. dispar* group" with no mention of *E. moshkovskii*. The true prevalence of this organism may be much higher than suspected; this may also explain some of the microscopy-positive/antigen-negative results obtained when using the *Entamoeba* test kit.

Epidemiology and Prevention

The mode of transmission is similar to that for other protozoa and is related to ingestion of cysts in contaminated food or water. In areas where accurate identifications have been made, the prevalence of *E. moshkovskii* may be similar to or higher than that of *E. histolytica* (40). Using PCR techniques, in one study from Bangladesh *E. dispar*-infected children were almost twice as likely to have a mixed infection with *E. moshkovskii* (35%) than with *E. dispar* and *E. histolytica* (18%) or with *E. dispar* alone (18%) (39). Future epidemiologic studies of *E. histolytica* infection should include the capability of diagnosing all three species individually (*E. histolytica*, *E. dispar*, and *E. moshkovskii*) (48).

Entamoeba bangladeshi

Microscopy and culture for the genus *Entamoeba* have limited specificity because several species, which vary in their pathogenic potential, have morphologically similar cysts and trophozoites (49). In 2010–2011, during analysis of feces positive for *Entamoeba* organisms by microscopy or culture but negative for *E. histolytica*, *E. dispar*, and *E. moshkovskii* by PCR, a new species was identified, which was named *Entamoeba bangladeshi* nov. sp. in recognition of the support of the Bangladesh community for this research (4). The sequenced clones from two different isolates, one diarrheal and one surveillance specimen, were completely novel when compared with the small subunit rRNA gene sequences from other organisms and did not match any previously sequenced *Entamoeba* species. These isolates represent a new species of *Entamoeba* (GenBank accession nos. JQ412861 and JQ412862), here named *E. bangladeshi*.

Life Cycle and Morphology

The life cycle is essentially identical to that of *E. dispar* and *E. moshkovskii* and morphological differences are minimal to none (Fig. 21.7). In wet preparations, trophozoites usually range in size from 15 to 20 µm and cysts normally range in size from 12 to 15 µm. It is important to remember that on the permanent stained smear there is a certain amount of artificial shrinkage due to dehydration; therefore, all of the organisms, including pathogenic *E. histolytica*, may be somewhat smaller (from 1 to 1.5 µm) than the sizes quoted for the wet-preparation measurements. Overall, by light microscopy, no apparent differences between *E. bangladeshi* and *E. histolytica* were detected. The physical resemblance between *E. histolytica* and *E. bangladeshi* is a diagnostic problem because direct microscopic examination of fecal samples is still used as a diagnostic tool to detect *E. histolytica* in areas in which these species are endemic.

Morphology of Trophozoites (Table 21.1). Trophozoites do not ingest RBCs, and the motility is similar to that of *E. histolytica*, *E. dispar*, and *E. moshkovskii* (Fig. 21.3). Nuclear and cytoplasmic characteristics are very similar to those seen in *E. histolytica*; however, trophozoites of *E. bangladeshi* do not contain ingested RBCs.

Morphology of Cysts (Table 21.2). Nuclear characteristics and chromatoidal bars are similar to those in *E. histolytica*, *E. dispar*, and *E. moshkovskii* (Fig. 21.3).

Clinical Disease

Human isolates of *E. bangladeshi* have been recovered from asymptomatic patients, as well as those with diarrhea.

It remains unclear what impact these organisms may have on the normal gut flora. Studies similar to those undertaken with *E. moshkovskii* may help to clarify the overall pathogenicity of *E. bangladeshi* and relevant symptoms attributed to this organism. Since many organisms within the genus *Entamoeba* exhibit almost identical morphology, patient clinical isolates may need to be identified using molecular methods.

Diagnosis

E. bangladeshi is microscopically indistinguishable from *E. histolytica* in cyst and trophozoite stages (4). In xenic culture, *E. bangladeshi* has the ability to grow at 37°C and room temperature, a characteristic shared with *E. moshkovskii* and *E. ecuadoriensis* (environmental isolate) but which distinguishes it from *E. histolytica* and *E. dispar*. Tests were negative in *E. histolytica* ELISA and in species-specific PCRs. Currently, *E. bangladeshi* is only identifiable by its small subunit rRNA gene sequence. The positive specimens were obtained from infant feces in Mirpur, Dhaka, Bangladesh, N 23°4734″, E 90°2138″ (4).

Epidemiology and Prevention

The mode of transmission is similar to that for other protozoa and is related to ingestion of cysts in contaminated food or water. *E. bangladeshi* is grouped with the clade of *Entamoeba* infecting humans, including *E. histolytica*. *E. bangladeshi*, however, appears to be more distantly related than the noninvasive *E. dispar*, but closer than *E. moshkovskii*, to *E. histolytica*. Future epidemiologic studies of *E. histolytica* infection should include the capability of diagnosing all four species individually (*E. histolytica*, *E. dispar*, *E. moshkovskii*, and *E. bangladeshi*).

Entamoeba hartmanni

Entamoeba hartmanni is found worldwide and until 1957 was generally considered to be a small race of *E. histolytica*. Consequently, the prevalence figures prior to that time are thought to be inaccurate. It is now well accepted that this ameba is a separate species from *E. histolytica*.

Life Cycle and Morphology

The life cycle is essentially identical to that of *E. dispar*, and morphological differences involve size, although there is even an overlap in size between the two species (Fig. 21.8). In wet preparations, trophozoites range in size from 4 to 12 µm and cysts range in size from 5 to 10 µm. It is important to remember that on the permanent stained smear there is a certain amount of artificial shrinkage due to dehydration; thus, all of the organisms, including pathogenic *E. histolytica*, may be somewhat smaller (from 1 to 1.5 µm) than the sizes quoted for the wet-preparation measurements.

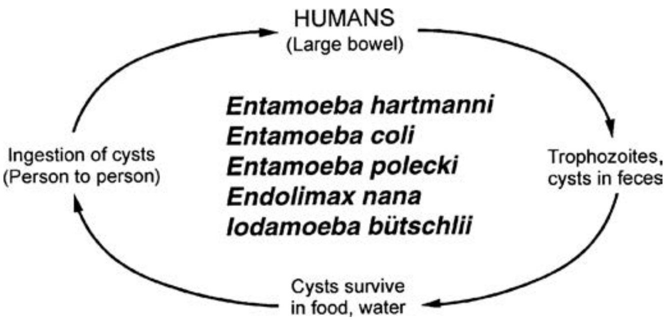

Figure 21.8 Life cycle of *Entamoeba hartmanni*, *Entamoeba coli*, *Entamoeba polecki*, *Endolimax nana*, and *Iodamoeba bütschlii*. doi:10.1128/9781555819002.ch21.f8

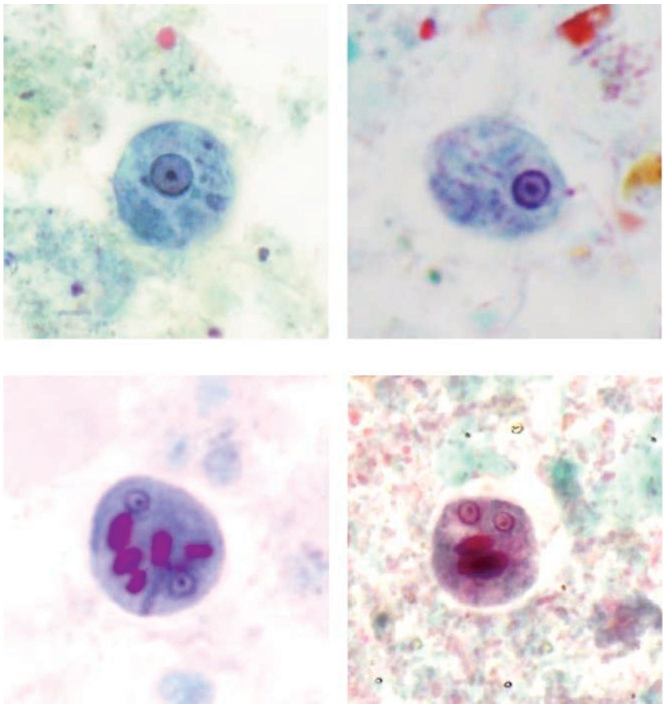
Morphology of Trophozoites (Table 21.1). Trophozoites do not ingest RBCs, and the motility is usually less rapid (Fig. 21.2 and 21.9). The trophozoites measure 5 to 12 µm (usual range, 8 to 10 µm). The nuclear and cytoplasmic characteristics are very similar to those seen in *E. histolytica*, with two exceptions. Frequently, cysts contain only one or two nuclei, even though the mature cyst contains four nuclei. Mature cysts of *E. hartmanni* also tend to retain

Figure 21.9 (Upper) Trophozoites of *Entamoeba hartmanni*; (lower) cysts of *E. hartmanni*. (Note that cysts often contain only two nuclei, instead of the mature four nuclei.) doi:10.1128/9781555819002.ch21.f9



their chromatoidal bars, a characteristic which is often not seen in *E. histolytica*/*E. dispar*.

Morphology of Cysts (Table 21.2). Chromatoidal bars are similar to those in *E. histolytica* and *E. dispar* but are smaller and more numerous (Fig. 21.2 and 21.9). Because differentiation between *E. hartmanni* and *E. histolytica*/*E. dispar* at the species level depends primarily on size, it is mandatory that laboratories use calibrated microscopes which are rechecked periodically for accuracy. The cysts measure 5–10 μm (usual range, 6–8 μm).

Clinical Disease

Although early studies incriminated *E. hartmanni* as a possible animal pathogen and suggested that it could transform from small "nonpathogenic" strains to large "pathogenic" ones, none of this information has been adequately confirmed by subsequent studies. Because *E. hartmanni* is accepted as being nonpathogenic, treatment is usually not recommended. However, presence of the organism is always reported; nonpathogens are acquired via fecal/oral contamination by the patient, the same way the pathogens are acquired. Thus, the report indicates the patient has ingested something contaminated with fecal material.

Diagnosis

Because *E. hartmanni* can be easily confused with other small amebae, particularly in a wet preparation, it is almost mandatory that the final identification be obtained from the permanent stained smear. Accurate measurement of organisms also confirms the tentative visual diagnosis (Table 21.3).

Epidemiology and Prevention

The mode of transmission is similar to that found with other protozoa and is related to ingestion of cysts in contaminated food or water. In areas where accurate identifications have been made, the prevalence of *E. hartmanni* is similar to that of *E. histolytica*.

Entamoeba coli

Although *Entamoeba coli* was probably recognized and described in the late 1800s, it was not until 1913 that the organism was proven to be nonpathogenic in human volunteers. *E. coli* is worldwide in distribution. Like *E. histolytica*, it tends to be more common in the warmer climates, but it has also been found in colder areas such as Alaska.

Life Cycle and Morphology

The life cycle is identical to that of *E. dispar* (Fig. 21.7).

Morphology of Trophozoites (Table 21.1). Living trophozoites tend to be somewhat larger than those of *E. histolytica* or *E. dispar* and range from 15 to 50 μm (Fig. 21.2 and 21.3). Motility has been described as sluggish with broad, short pseudopods. It may be extremely difficult to differentiate nonpathogenic *E. coli* from pathogenic *E. histolytica* in wet preparations. On the permanent stained smear, the cytoplasm appears granular with few to numerous vacuoles containing bacteria, yeasts, and other food materials. The nucleus has a moderately large karyosome that is frequently eccentric in position. The chromatin on the nuclear membrane is usually clumped and irregular in placement. If there are RBCs in the intestinal tract, *E. coli* may ingest these rather than bacteria; occasionally, the cytoplasm also contains ingested spores of *Sphaerita* sp. and possibly a *G. lamblia* cyst.

Morphology of Cysts (Table 21.2). Again, for reasons that are not specifically known, trophozoites discharge their undigested food and begin to round up prior to precyst and cyst formation. Early cysts usually contain a dense glycogen mass and may also contain chromatoidal bars, which tend to be splinter shaped and irregular. Eventually, the nuclei divide until the mature cyst, containing eight nuclei, is formed (Fig. 21.2 and 21.3). Occasionally, the number of nuclei reaches 16. The cysts measure 10 to 35 μm and almost always lose their chromatoidal bars as they mature. For some reason, as the cyst of *E. coli* matures, it becomes more resistant to fixation with various preservatives. Therefore, the cyst may be seen on the wet preparation but not on the permanent stained smear. Occasionally, on trichrome smears, the cysts appear distorted, shrunk, and somewhat pink. This is not an indication of poor reagents or techniques but, rather, an indication that these cysts do not fix well with the routinely used preservatives. Better fixation and more detailed morphology can be obtained by heating some of the fixatives prior to specimen preservation, although for most laboratories, this is not a practical approach.

Studies suggest that after cyst ingestion, the metacyst undergoes division of the cytoplasm, thus becoming metacystic trophozoites that will grow and divide within the lumen of the intestine. It is interesting that the total number of trophozoites formed from the mature cyst usually is fewer than eight.

Diagnosis

With the exception of the mature cyst, the morphologies of *E. histolytica*, *E. dispar*, *E. moshkovskii*, *E. bangladeshi*, and *E. coli* are similar in most of the stages. Therefore, it is very important to examine permanent stained smears, even if a tentative identification has been made from a wet preparation examination. Specific treatment is not recommended for this nonpathogen (Table 21.3). Consequently, correct differentiation between the five species is critical to good patient care. Since the five species are acquired by the patient in the same way, it is also important to remember that all can be found in the same patient. If few *E. histolytica*/*E. dispar* organisms are present among many *E. coli* organisms, additional searching and/or the use of species-specific immunoassay testing may be necessary to correctly identify the different species.

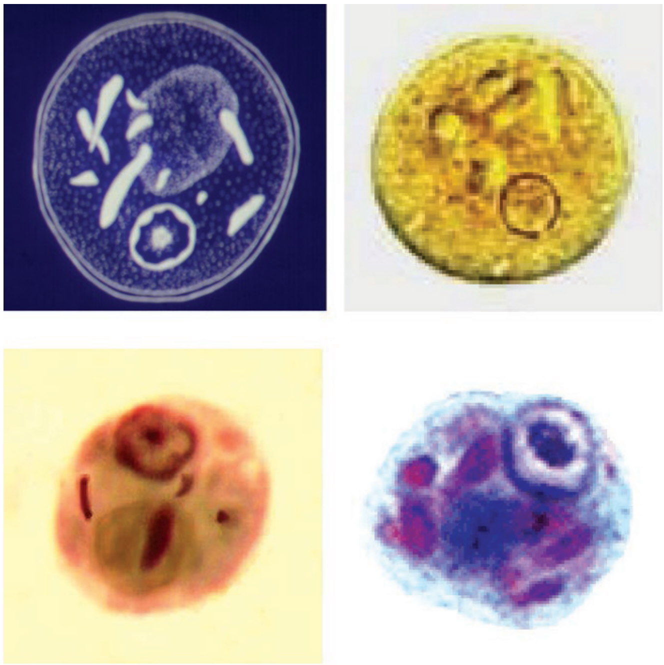
Epidemiology and Prevention

The mode of transmission is ingestion of cysts from contaminated food or water. Apparently, the infection is readily acquired, and in some warmer climates or areas with primitive hygiene conditions, the infection rate can be quite high. Prevention depends on adequate disposal of human excreta and improved personal hygiene (preventive measures which apply to the majority of the intestinal protozoa).

Entamoeba polecki

Entamoeba polecki was originally found in the intestines of pigs and monkeys and has also been found as a human parasite (Fig. 21.10). In certain areas of the world, such as Papua New Guinea, it is the most common intestinal ameba of humans. Few cases are reported, possibly in part because the organism resembles *E. histolytica*/*E. dispar*, *E. moshkovskii*, *E. bangladeshi*, and *E. coli*. The trophozoites resemble *E. coli* in that the cytoplasm is granular, containing ingested bacteria, and the motility tends to be sluggish (Table 21.5). The nuclear morphology is almost a composite of those of *E. histolytica*/*E. dispar*, *E. moshkovskii*, *E. bangladeshi*, and *E. coli*. Without some of the cyst stages for comparison, it would be very difficult to identify this organism to the species level on the basis of the trophozoite alone. The cyst normally has only a single nucleus, chromatoidal material like that seen in *E. histolytica*, and frequently an inclusion body (Fig. 21.10; Table 21.6). This mass tends to be round or oval and is not sharply defined on the edges. The material, which is not glycogen, remains on the permanent stained smear and stains less intensely than nuclear material or chromatoidal bars. Differentiation of this organism from either *E. histolytica* or *E. coli* is rarely accomplished on the basis of a wet preparation examination. The size on the permanent stained smear would range from 10 to 12 µm for the trophozoite and from 5 to 11 µm for the cyst. To date, there is no evidence of pathogenicity in humans; therefore, no therapy is recommended.

Figure 21.10 (Upper, left) Cyst of *Entamoeba polecki* (illustration) (note the large inclusion in the cytoplasm as seen in the drawing); (right) cyst of *E. polecki* (direct wet mount with iodine; large vacuole is more difficult to see; however, chromatoidal bars are present). (Lower, left and right) *E. polecki* cyst forms (the large inclusion is visible in both organisms).
doi:10.1128/9781555819002.ch21.f10



Entamoeba gingivalis

Entamoeba gingivalis was the first parasitic ameba of humans to be described. It was recovered from the soft tartar between the teeth. It has also been recovered from the tonsillar crypts and can multiply in bronchial mucus, thus appearing in sputum (Fig. 21.11). Since morphologically it is very similar to *E. histolytica*, it is important to make the correct identification from a sputum specimen—that is, *E. gingivalis*, which is considered to be a nonpathogen—rather than *E. histolytica* from a possible pulmonary abscess. The trophozoite measures approximately 5 to 15 µm, and the cytoplasm most often contains ingested leukocytes (Table 21.5). On the permanent stained smear, nuclear fragments of the white cells can be seen within the food vacuoles, which are usually larger than the vacuoles seen in *E. histolytica* (Fig. 21.11). This fact will help to differentiate the two, since *E. gingivalis* is the only species that ingests white cells. No cysts are formed by this species (Table 21.6). Although these amebae are most often recovered from patients with pyorrhea alveolaris, *E. gingivalis* is still considered to be nonpathogenic (49).

Organisms identified as *E. gingivalis* have been recovered in vaginal and cervical smears from women using intrauterine devices (IUDs); the organisms spontaneously disappeared after removal of the devices. However, more recent information has implicated this organism as causing symptoms in several clinical situations. A prospective study conducted in Egypt determined that *E. gingivalis* was

TABLE 21.5 Intestinal protozoa: trophozoites of less common amebae

Characteristic	*Entamoeba polecki*	*Entamoeba gingivalis*
Size (diam or length)	10–12 μm	5–20 μm (avg, 10–15 μm)
Motility	Usually nonprogressive, sluggish (like *E. coli*)	Multiple pseudopodia, vary from long and lobose to short and blunt
Nucleus: no. and visibility	Can occasionally be seen on a wet preparation; intermediate between *E. histolytica* and *E. coli*; 1 nucleus	Similar to *E. histolytica*, 1 nucleus
Peripheral chromatin (stained)	Fine granules (may be interspersed with large granules) evenly arranged on membrane; chromatin may also be clumped at one or both edges of membrane	Fine granules, closely packed
Karyosome (stained)	Small, usually centrally located	Small, well defined, usually centrally located
Cytoplasm appearance (stained)	Finely granular	Finely granular
Inclusions (stained)	May contain ingested bacteria	Ingested epithelial cells and host leukocytes

found in 12.64% of IUD users and in 6.9% of nonusers ($P > 0.3$). It was found that 90.9% of those harboring *E. gingivalis* in their genital tract had the parasite in their oral cavity. In the infected cases, vaginal discharge was more common (81.8%) than in noninfected cases (32.9%), and such difference was statistically significant ($P < 0.05$). Also, the authors found excessive vaginal discharge was more common than backache and menorrhagia in the infected cases. Higher incidence of *E. gingivalis* infection in IUD users is related to oral cavity infection, residence, the facility where the inserted IUD was inserted, and hand washing or nonwashing before checking the strings (50).

In an unusual case, *E. gingivalis* was identified in a left upper neck nodule by fine-needle aspiration. Apparently, the patient had an increased number of amebae within the oral cavity secondary to radiation therapy. Radiation therapy may have contributed to a fistula tract between the oral cavity and the surgical incision site, thus resulting in the formation of a small inflammatory nodule in the upper portion of the neck (51).

Another unusual case has been reported, *E. gingivalis* in acute osteomyelitis of the mandible, following bisphosphonate therapy for multiple myeloma. However, identification of the organism was not confirmed using molecular methods, but morphology only (52).

E. gingivalis has also been reported in pulmonary computed tomography-guided fine-needle aspiration material, from a 60-year-old man with a lung mass. The mechanism of pulmonary infection in this case is not known. However, a pulmonary polymicrobial environment probably contrib-

TABLE 21.6 Intestinal protozoa: cysts of less common amebae

Characteristic	*Entamoeba polecki*	*Entamoeba gingivalis*
Size (diam or length)	5–11 μm	No known cyst stage
Shape	Usually spherical	
Nucleus: no. and visibility	Mature cyst, 1; may be visible in wet preparations (rarely 2 or 4 nuclei)	
Peripheral chromatin (stained)	Similar to that seen in trophozoite	
Karyosome	Similar to that seen in trophozoite	
Cytoplasm (chromatoidal bodies, glycogen, inclusions [stained])	Abundant, angular pointed ends; threadlike chromatoidals may be present; half of cysts contain spherical or ovoid “inclusion mass”	

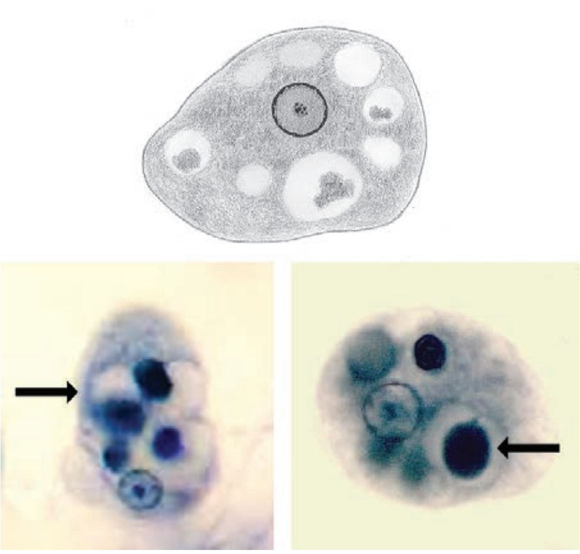


Figure 21.11 (Upper) Trophozoite of *Entamoeba gingivalis* (illustration by Sharon Belkin). (Lower, left and right) Trophozoites of *E. gingivalis* (note the ingested polymorphonuclear leukocytes—arrows). Both stained with iron-hematoxylin.
doi:10.1128/9781555819002.ch21.f11

uted to this clinical condition, secondary to aspiration pneumonia (53).

Although *E. gingivalis* is considered a nonpathogen, it has been found in the oral cavities of HIV-1-infected patients with periodontal disease. Its presence was not related to the degree of immunodeficiency but to the HIV diagnosis (54).

Endolimax nana

Endolimax nana is one of the smaller nonpathogenic amebae and was distinguished as a separate ameba around 1908. It is also worldwide in distribution and is seen in most populations at least as frequently as *E. coli*.

Life Cycle and Morphology

E. nana has the same stages in the life cycle as does *E. dispar*: trophozoite, precyst, cyst, and metacystic forms (Fig. 21.8). The trophozoite usually measures from 6 to 12 µm, with the normal range being 8 to 10 µm (Table 21.1).

Motility has been described as sluggish and nonprogressive with blunt, hyaline pseudopods. In the permanent stained smear, the nucleus is more easily seen. There is normally no peripheral chromatin on the nuclear membrane, and the karyosome tends to be large, with either a central or eccentric location within the nucleus (Fig. 21.12 and 21.13). There is tremendous nuclear variation in this organism, and occasionally it mimics *Dientamoeba fragilis* and *E. hartmanni*. The more organisms there are on the smear, the more likely it is that some of them will mimic other species of the amebae. The cytoplasm may have small vacuoles containing ingested debris or bacteria.

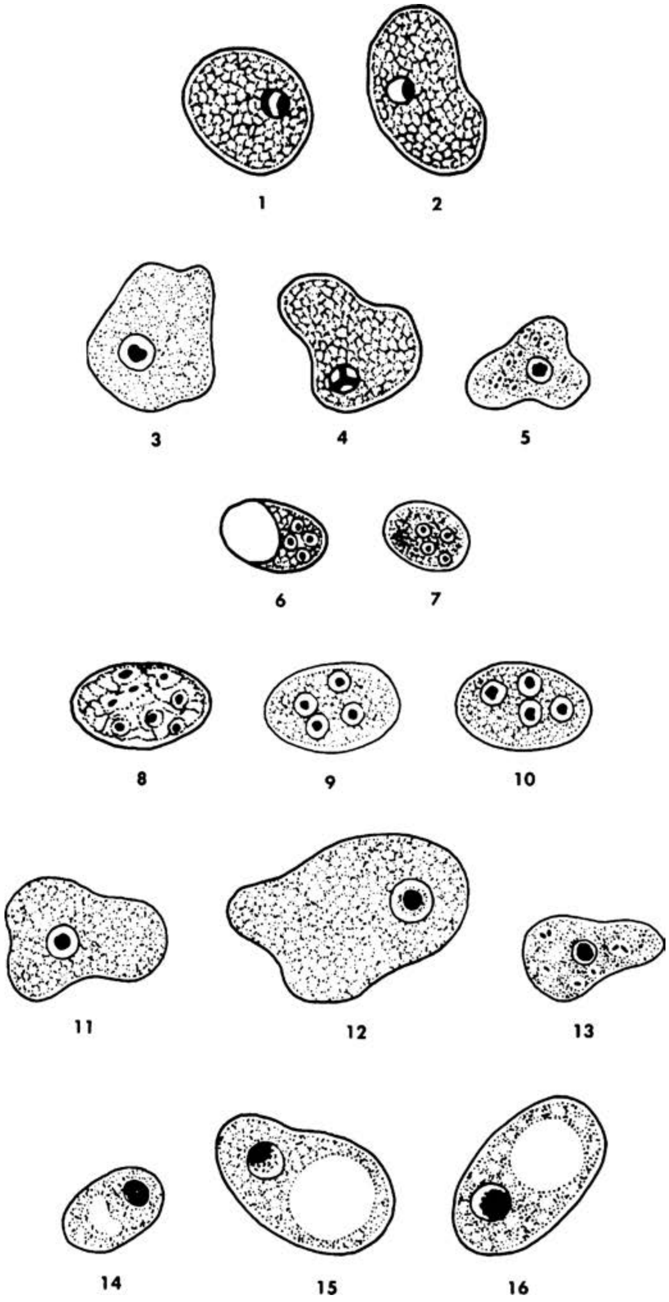

Figure 21.12 (1 to 5) Trophozoites of *Endolimax nana*; (6 to 10) cysts of *E. nana*; (11 to 13) trophozoites of *Iodamoeba bütschlii*; (14 to 16) cysts of *I. bütschlii*.
doi:10.1128/9781555819002.ch21.f12

Cysts usually measure 5 to 10 µm, with a normal range of 6 to 8 µm (Table 21.2). In some instances, cysts as large as 14 µm have been seen. The cyst is usually oval to round, with the mature cyst containing four nuclei. Occasionally, very small, slightly curved chromatoidal bars are present

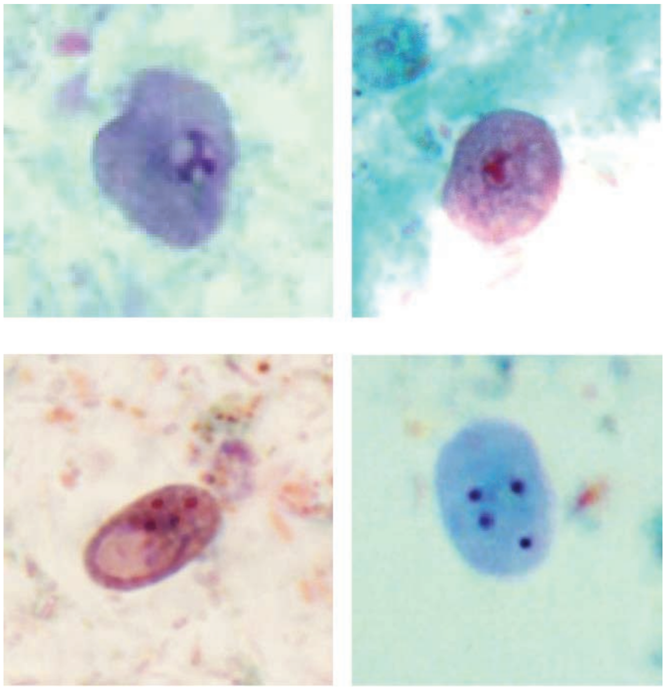

Figure 21.13 (Upper, left and right) Trophozoites of *Endolimax nana* (note the nuclear variation in both organisms). (Lower) Cysts of *E. nana*, containing four karyosomes with no peripheral chromatin; (left) note the vacuole. This can be confused with an *I. bütschlii* cyst; however, an *E. nana* cyst contains four nuclei, not just one. doi:10.1128/9781555819002.ch21.f13

(Fig. 21.12). It is unusual to see the two-nucleated stage, and there are frequently both trophozoites and cysts in clinical specimens. In some cases, there may be a large vacuole within the cyst (Fig. 21.13); although the vacuole might be suggestive of *Iodamoeba bütschlii*, *E. nana* cysts contain four nuclei, not one.

Diagnosis

Although *E. nana* is a nonpathogen and no therapy is recommended, it is still important to differentiate it from other amebae, some of which are pathogenic. Because these organisms are small, the definitive diagnosis of *E. nana* may have to be made on the basis of the permanent stained smear (Table 21.3). If the original fixation is good, the cysts may be identified on the basis of the wet preparation such as the concentration sediment or flotation surface film. The four nuclear karyosomes appear very refractile in the wet preparation.

Epidemiology and Prevention

As with the other organisms that have been discussed, the mode of transmission is ingestion of the mature cysts in contaminated food or water. The cysts of *E. nana* tend to be less resistant to desiccation than do those of *E. coli*. This organism is also found in the same areas of the world as are the other amebae, that is, in warm, moist climates and in other areas where there is a low standard of personal hygiene and poor sanitary conditions. Prevention would depend on improved personal hygiene and an overall upgrading of sanitary conditions and waste disposal.

Iodamoeba bütschlii

Iodamoeba bütschlii, one of the nonpathogenic amebae, is also worldwide in distribution and was identified in the early 1900s. The original species name of "williamsi" probably referred to atypical cysts of *E. coli*. Although it is found in areas where the other amebae have been recovered, its incidence is not as high as that of *E. coli* or *E. nana*. One of the most striking morphological features of this organism is the large glycogen vacuole which appears in the cyst and readily stains with iodine on a wet preparation smear.

Life Cycle and Morphology

The stages within the life cycle are exactly the same as those seen with *E. nana*. The trophozoite normally varies from 8 to 20 μm and is described as having fairly active motility in a fresh stool preparation (Table 21.1). The cytoplasm is rather granular, containing numerous vacuoles with ingested debris and bacteria. In general, the vacuolated cytoplasm is more obvious than that seen in *E. nana* trophozoites. The nucleus has a large karyosome, which can be either centrally located or eccentric (Fig. 21.12 and 21.14). On the permanent stained smear, the nucleus may appear to have a halo. Chromatin granules fan out around the karyosome. If the granules are on one side, the nucleus may appear to have the "basket nucleus" arrangement of chromatin, which is often found in the cyst stage. The trophozoites of *I. bütschlii* and *E. nana* may be very similar and difficult to differentiate at the species level, even on the permanent stained smear. Both organisms are considered to be nonpathogens, and *E. nana* is recovered in clinical specimens much more frequently than *I. bütschlii*.

The cysts rarely have a classic round appearance but tend to be somewhat oval (Table 21.2). The glycogen vacuole is so large that occasionally the cyst collapses on itself. Since there is no nuclear multiplication in the cyst form, the mature cyst contains only a single nucleus. The cysts measure approximately 5 to 20 μm and are rarely confused with those of other amebae (Fig. 21.12 and 21.14).

Diagnosis

Although the cyst can often be identified from the wet smear preparation, particularly if the vacuole is stained with iodine, the trophozoites may be difficult to detect and identify without the permanent stained smear (Table 21.3). Although these amebae are nonpathogens, they are always re-

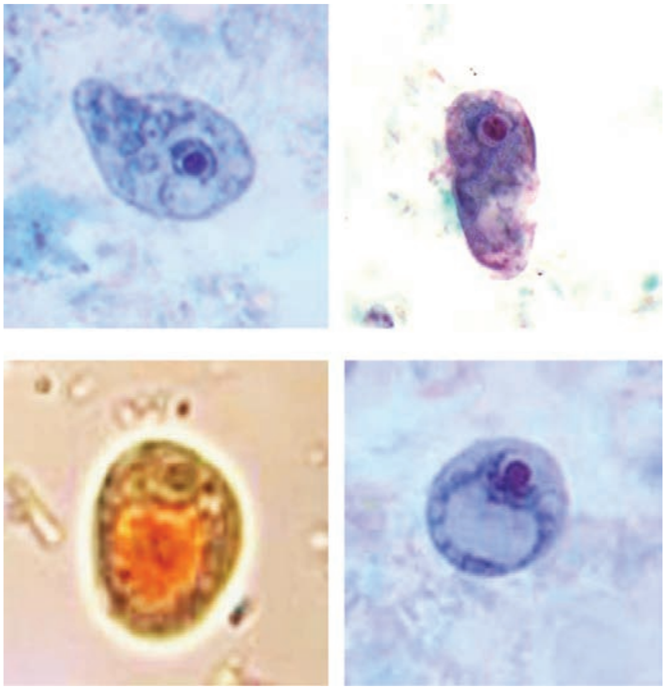

Figure 21.14 (Upper, left and right) Trophozoites of *Iodamoeba bütschlii* (note the very large karyosome within the nucleus). (Lower, left) Cyst of *I. bütschlii* wet mount stained with iodine (note the large glycogen vacuole—stains brownish with iodine); (right) *I. bütschlii* cyst on trichrome-stained permanent stain (also note the large vacuole—appears clear on permanent stain). doi:10.1128/9781555819002.ch21.f14

ported. Their presence in the intestine indicates the patient has ingested something contaminated with fecal material containing the cysts. This is important information for the physician, since pathogens are also acquired the same way.

Epidemiology and Prevention

The mode of transmission is ingestion of infective cysts in contaminated food or water. Prevention would depend on improved personal hygiene and sanitary conditions.

Blastocystis spp.

It is estimated that over 1 billion humans worldwide could be colonized with *Blastocystis* spp. *Blastocystis* sp. (formerly *Blastocystis hominis*), an inhabitant of the human intestinal tract, was first described in 1912. Over the years, this organism been classified as an organism related to *Blastomyces* spp., the cyst form of a flagellate, a yeast of the genus *Schizosaccharomyces*, and a member of the stramenopiles (examples are brown algae such as kelp, diatoms, slime nets, and water molds). However, currently this organism is classified as an unusual anaerobic, single-celled stramenopile (55–58). Although this classification is acceptable at the molecular level, there are discrepancies in morphology between *Blastocystis* and other stramenopiles. Stramenopiles have flagella surrounded by lateral hair-like mastigonemes, which are absent in *Blastocystis*. Based on these issues, revisions have been proposed for the current five-kingdom classification; *Blastocystis* would be placed in a separate sixth kingdom named “Chromista” (class Blastocystea, subphylum Opalinata, infrakingdom Heterokonta, subkingdom Chromobiota, kingdom Chromista [57]).

Blastocystis comprises a multitude of subtypes (species) many of which have been identified only recently; molecular epidemiological studies have revealed a significant difference in the distribution of subtypes across host species and geographical regions. Worldwide, *Blastocystis* is very commonly found in the stools of individuals with and without intestinal symptoms. Following the introduction of molecular methods, the prevalence and intrageneric diversity of *Blastocystis* are becoming better defined. Confirmation of the existence of these species and determination of their pathogenic status may also explain why some patients are asymptomatic and some have clinical symptoms.

Subtypes

Based on small subunit rDNA analysis, *Blastocystis* comprises at least 17 lineages (species); the so-called subtypes (STs) ST1 to ST4 account for probably more than 90% of human carriage, while the remaining approximately 10% are colonized by isolates belonging to ST5 to ST9. All of these STs, apart from ST9, have also been found in various nonhuman hosts (56).

Based on information from multiple studies from various countries, no definitive link has been confirmed between STs and clinical phenotypes. However, at least two main cofactors may complicate the issue. Significant variation in the distribution of STs is seen across geographic ranges; in some areas certain STs are quite common, while in other areas, they may be totally absent. The second cofactor involves the use of different methodologies for subtyping; this also impacts results from ST survey data. The two methods currently in use are screening fecal samples by PCR using either (i) ST-specific primers (sequence-tagged site primers) or (ii) genus-specific primers with subsequent sequencing for ST identification (one method is barcoding covering the 600 5′-most bases of the small subunit rDNA). Both approaches have advantages and disadvantages; see reference 56 for additional information.

Life Cycle and Morphology

Blastocystis reproduces primarily by binary fission and has a membrane-bound central body (previously called a vacuole) that takes up 90% of the cell and plays a role in the programmed cell death of the organism (Fig. 21.15 to

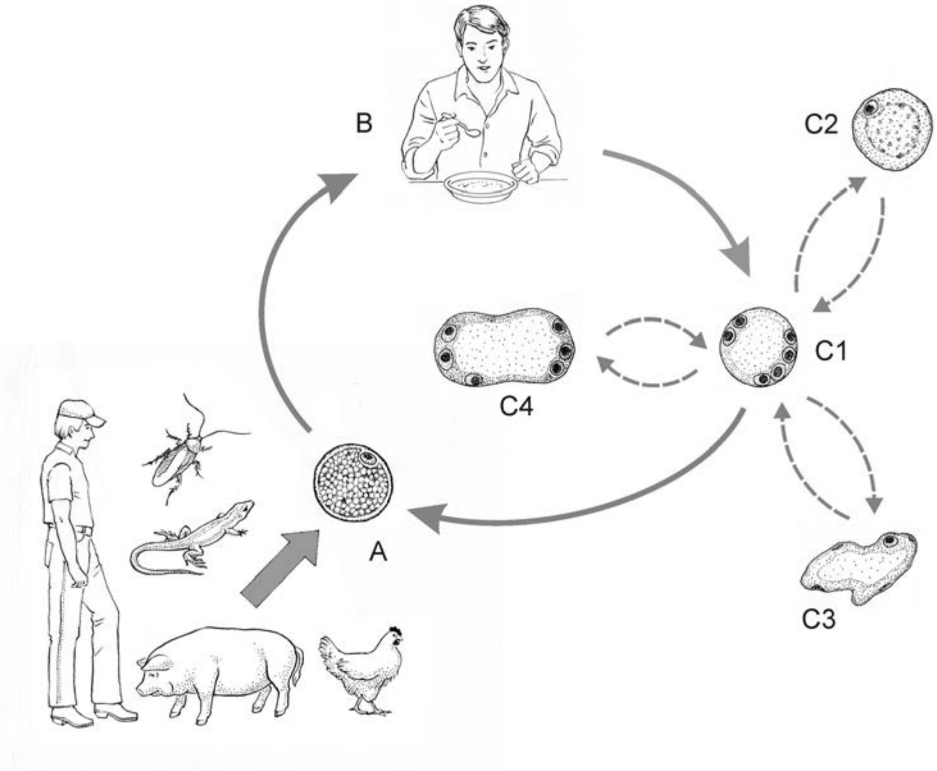

Figure 21.15 Life cycle of *Blastocystis* spp. (A) Cyst forms are excreted in the feces of infected hosts. (B) Humans acquire infection by consumption of food or water contaminated with feces containing cysts. (C) Excystation occurs in the large intestine to release the vacuolar form. The vacuolar form (C1) can transform into the granular form (C2) or the ameboid form (C3) and vice versa. The vacuolar form multiplies by binary fission (C4) (other modes of reproduction such as plasmotomy and budding can also occur). The vacuolar form undergoes encystation in the lumen of the large intestine to produce the cyst form, which is shed in the feces. (Adapted with permission from references 55 and 59.)

doi:10.1128/9781555819002.ch21.f15

21.17; Table 21.7). Budding and plasmotomy are also recognized forms of reproduction. Other structures with unknown function are not yet defined. The organism is strictly anaerobic, normally requires bacteria for growth, and is capable of ingesting bacteria and other debris. The generation time of the organism observed *in vitro* in axenic media is 17 to 22 h. In cultures on xenic media followed by axenization the generation time is shorter, ranging 7 to 12 h. Generation time is also found to vary among different subtypes.

When ingested, the cysts develop into vegetative forms. The cyst form undergoes excystation in the large intestine to liberate the vacuolar form. The vacuolar forms can transform into any of the other forms. Frequent observations of the ameboid, avacuolar, and multivacuolar forms in diarrhea suggest these forms might play a role in the pathogenesis. The vacuolar forms encyst in the intestinal lumen to form cysts which are shed in the feces for further transmission (59).

Organism Types. Recognized morphologic types include the vacuolar, granular, ameboid, avacuolar, and multivacuolar forms. The classic form (vacuolar form) that is usually seen in the human stool specimen varies tremendously in size, from 6 to 63 μm (commonly 5 to 15 μm) in humans, and is characterized by a large central body, which is involved with carbohydrate and lipid storage (visually like a large vacuole) (Fig. 21.16, 21.17; Table 21.7). The granular form resembles the vacuolar form; however, there are granules in the central body and the cytoplasm. The three types of granules are metabolic, reproductory, and lipid. The granular forms range from 15 to 25 μm. The more amebic form (ameboid form) is occasionally seen in diarrheal fluid but may be extremely difficult to recognize. Although this form has one or two pseudopodia, the ameboid forms are nonmotile. Due to their size and morphology, they mimic neutrophils and macrophages; thus, they are easily missed in routine microscopy examinations. Generally, *Blastocystis* is identified on the basis of the more typical round form with the central body. The avacuolar and the multivacuolar forms are smaller, measuring 5 to 8 μm in diameter, and extreme size variations do not occur. The avacuolar form has no central body, while the multivacuolar forms have multiple small vacuoles of different sizes interconnected to each other or lying discrete in the cytoplasm. They are usually uninucleate but occasionally have two nuclei. In the past, these two forms were considered intermediates during transformation of the common vegetative forms; however, recent observations suggest that the avacuolar and the multivacuolar forms are the predominant forms *in vivo* and are not recognized during microscopic examination.

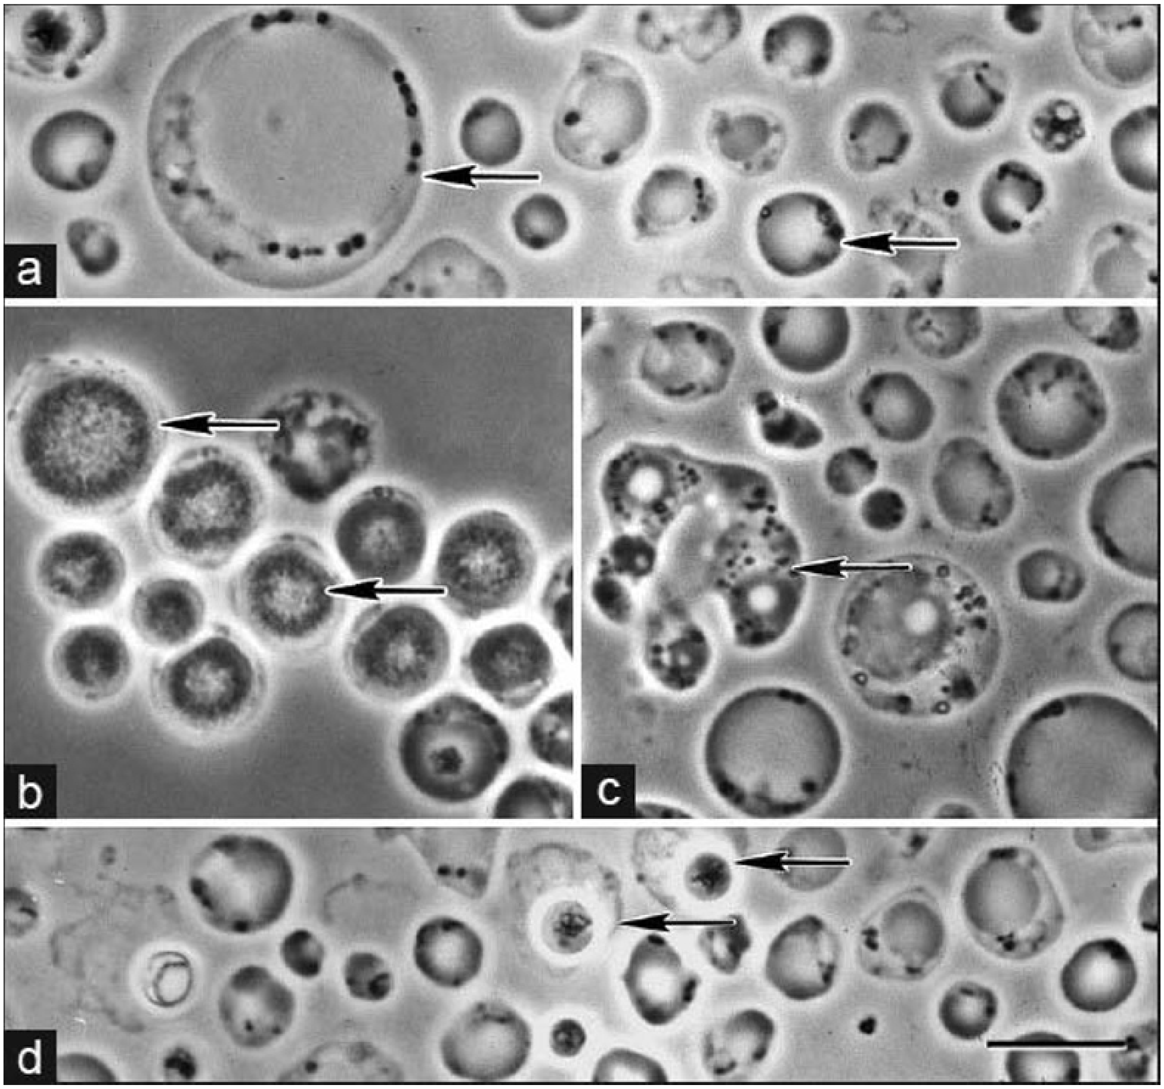

Figure 21.16 Various forms of *Blastocystis*. (a) Vacuolar forms of *Blastocystis* having a large centrally placed vacuole showing extensive variation in size (arrows). (b) Granular forms with distinct granules filling the central body. (c) Ameboid form with characteristic pseudopodia. (d) Cyst forms. Note the smaller size and the characteristic refractile cyst wall surrounded by loose irregular outer coat. Bar, 10 µm. (Reproduced from reference 58.) doi:10.1128/9781555819002.ch21.f16

Both thin- and thick-walled cysts have been confirmed and usually measure 3 to 6 µm. It is suggested that the thin-walled cysts are autoinfectious, leading to multiplication of the organism in the intestinal tract; however, this information appears to be inconclusive. The thick-walled cysts are probably responsible for external transmission via the fecal-oral route, particularly since the cyst wall protects the organism during adverse conditions. The cysts remain viable for up to 1 month at 25°C even on exposure to air. This type of life cycle, or something similar, might explain the high percentage of positive carriers in many studies, showing that the percentage of patients infected with *Blastocystis* is often much higher than the percentage of those infected with other intestinal protozoa (60).

Clinical Disease

When *B. hominis* is present in the absence of other pathogenic parasites, bacteria, or viruses, it may be the cause of diarrhea, cramps, nausea, fever, vomiting, and abdominal pain and may require therapy. In one recent study of patients with irritable bowel syndrome, there was a set of patients in whom the presence of *Blastocystis* did not appear to be incidental (61). Possible relationships between *Blastocystis* and intestinal obstruction and perhaps even

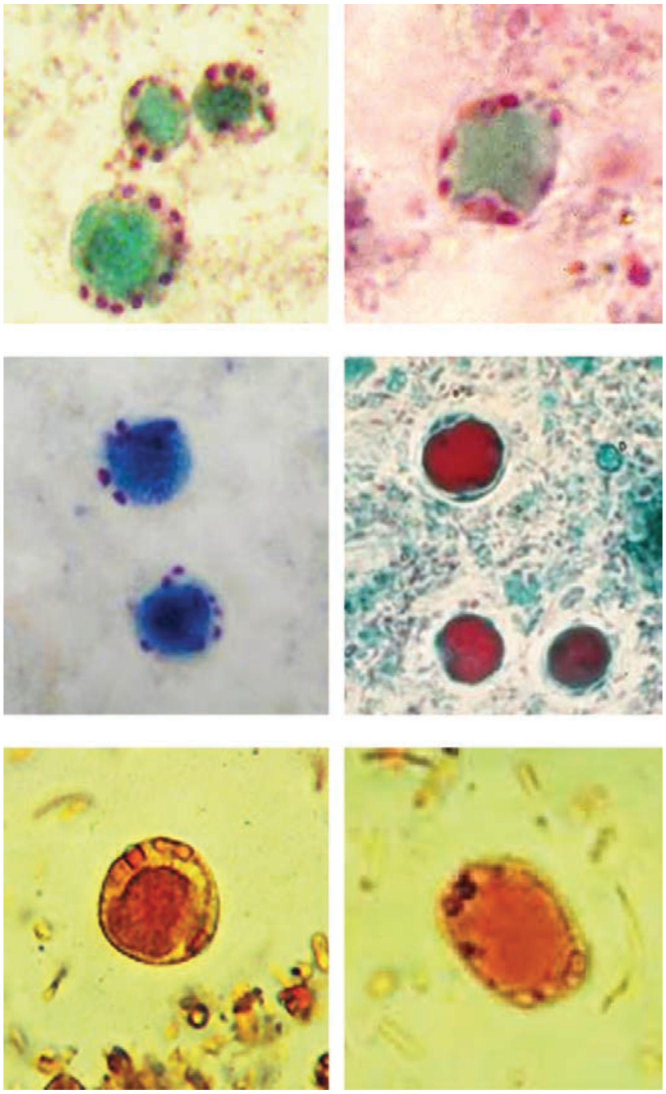

Figure 21.17 (Top, middle) Stained central-body forms of *Blastocystis* spp.; note the multiple nuclei around the edges, outside the central-body area. (Bottom) *Blastocystis* central-body forms in iodine wet mounts; note dividing form in right image (binary fission) and the large central "vacuole."
doi:10.1128/9781555819002.ch21.f17

infective arthritis have been suggested. In patients with other underlying conditions, the symptoms may be more pronounced. The incidence of this organism appears to be higher than suspected in stools submitted for parasite examination. For symptomatic patients in whom no other etiologic agent has been identified, *Blastocystis* should certainly be considered a possible candidate. Other studies suggest that when a symptomatic *Blastocystis* infection responds to therapy, the improvement probably represents elimination of some other undetected pathogenic organism (*E. histolytica*, *G. lamblia*, or *D. fragilis*) (62). Data from other geographic areas indicate that although it is commonly seen in stool samples, *Blastocystis* is thought to be nonpathogenic. Although for a number of years the true role of this organism in terms of colonization or disease was still somewhat controversial, it is now generally considered a causative agent of intestinal disease.

In a study of 1,216 adults, including immunocompromised patients, institutionalized psychiatric or elderly subjects, immigrants from developing countries, travelers to developing tropical countries, and controls, the results showed a high prevalence of parasites in all the risk groups studied, and *Blastocystis* was the parasite most frequently detected in each studied group. *Blastocystis* showed a significant correlation with gastrointestinal symptoms only when detected in the group including subjects with a severe immunodepression (63).

Intestinal Disease. Disease ranges from asymptomatic colonization to severe symptoms. There may be vague abdominal complaints such as pain, bloating, and flatulence. Generally the diarrhea is mild in the immunocompetent patient and more severe and chronic in those who are immunocompromised. There may also be symptoms of irritable bowel syndrome.

Extraintestinal Disease. The following symptoms and conditions have been seen in extraintestinal infections. Often these patients have been found to have other underlying diseases or are immunocompromised. Acute or chronic urticaria has been seen, and palmoplantar pruritus has also been reported (64, 65). Chronic angioedema has been associated with *Blastocystis* infection (66). In another study, a relationship between *Blastocystis* infection and iron deficiency anemia was confirmed; however, there was no correlation found between the genotype and the occurrence of iron deficiency anemia (67). It is also highly recommended that *Blastocystis* be considered in ulcerative colitis patients with refractory symptoms (68).

Diagnosis

Routine Diagnosis. Routine stool examinations are very effective in recovering and identifying *Blastocystis*, although the permanent stained smear is the procedure of choice since the examination of wet preparations may not easily reveal the organism. If the fresh stool is rinsed in water before fixation (for the concentration method), *Blastocystis* organisms, other than the cysts, are destroyed, thus possibly yielding a false-negative report (32). In many areas of the world, *Blastocystis* is the most common parasite found in stool specimens. The characteristic form that is usually seen in human fecal

TABLE 21.7 Key features of *Blastocystis*[a]

Organism form	Size (µm) (most typical)	Central vacuole (membrane-bound body), "central-body form"	No. of nuclei (most typical)	Sites where found	Description
Vacuolar	3–120; 4–63 human (5–15)	Present	1–4 (1–2)	Feces, culture	Central vacuole fills 70–90% of cell; giant cells with multiple nuclei occasionally seen; cytoplasm and organelles limited to thin peripheral rim (may be difficult to see in wet preparations); most common form seen in microscopy of fecal specimens
Granular	15–80 (15–25)	Present	1–4	Feces, culture	Granules within central vacuole
Multivacuolar	5–8	Present or absent	1–2 (1)	Feces, culture	Rarely seen
Avacuolar	~5	Absent	1–2 (1)	Intestine, feces	Rarely seen in feces; very large nuclei
Ameboid	~10	Present (single large vacuole or multiple small ones) or absent	1–2	Feces, culture	Rarely reported; no general consensus on morphology; resemble neutrophils or macrophages; pseudopods may be seen, but these stages are not motile; more often seen in feces of symptomatic patients
Cyst	3–10 (3–6)	Absent	1–4 (2)	Feces, culture	Rarely seen in culture; cyst wall present (varies in thickness); may be covered by a fibrillar layer; oval or round shape; thick, multilayered cyst wall; might lose surface coat and appear as "naked" cysts; viable up to 1 month at 25°C even on exposure to air; transmissible infective forms; common form seen in stored fresh stool specimens

[a] Adapted from references 53–60.

specimens varies in size from 6 to 40 µm and contains a large central body resembling a vacuole, which may be involved with carbohydrate and lipid storage. The amebic form can occasionally be seen in diarrheal fluid but may be difficult to recognize (69). The organisms should be quantitated on the report form, i.e., as rare, few, moderate, or many. It is also important to remember that other possible pathogens should be adequately ruled out before a patient is treated for *Blastocystis*.

Antibody Detection. Both ELISA and fluorescent-antibody tests have been developed for detection of serum antibody to *B. hominis* infections (44, 70). By using ELISA and a threshold dilution of 1/50, 27 of 30 serum samples (28 patients with no protozoan parasites other than *Blastocystis*) were positive at 1/50 or higher; 42 control blood bank serum samples were all negative at 1/50 (44). A strong antibody response is consistent with the ability of this organism to cause symptoms. Also, demonstration of serum antibody production both during and after *Blastocystis* symptomatic disease provides immunological evidence for the pathogenic role for this protozoan, although it may take 2 years or more with chronic infections before a serologic response is detected (44).

Molecular Testing. Using advanced microscopy and sequence-confirmed PCR, a high prevalence of *Blastocystis* infection was found. Most cases were caused by subtypes ST1, ST2, ST3, and ST4. A significantly higher prevalence was found among patients with a history of recent travel to tropical countries (23). A quantitative TaqMan 5′ nuclease real-time PCR (TaqMan PCR) including an internal process control was developed for the detection of *Blastocystis* and shown to be applicable to genomic DNAs extracted directly from feces. This approach was found to be more sensitive than results obtained using xenic *in vitro* culture (5).

KEY POINTS—LABORATORY DIAGNOSIS

Blastocystis spp.

1. Although the intestinal protozoa are not routinely quantitated on the report, *Blastocystis* should be quantitated (rare, few, moderate, many).
2. A minimum of three ova and parasite examinations (including the permanent stained smear) and/or some of the immunoassays should be performed to ensure that no other protozoa are found before attributing symptoms to *Blastocystis*.
3. Other possible microbial agents should also be considered.
4. Remember that there is still controversy regarding quantitation of these organisms on the laboratory report form. Although there was thought to be correlation between numbers of organisms present and patient symptoms, some physicians have seen symptomatic patients in whom even small numbers of *Blastocystis* are present, apparently with no other causative agents present in the stool specimen(s). For this reason, quantitation of the organisms is still recommended. However, it is important to communicate with your physician clients so that they know how you are reporting and/or quantitating this organism. The approach must be determined by each laboratory after discussions with physician clients.

Treatment

Although there is not a great deal of clinical evidence, there have been studies on the *in vitro* susceptibility of *Blastocystis* to numerous drugs. At present, metronidazole (Flagyl) appears to be the most appropriate drug, ranging from 250 to 750 mg three times a day for 10 days to 1.5 mg/day for 10 days, or used in combination with other drugs such as paromomycin or cotrimoxazole (trimethoprim-sulfamethoxazole) (56). In cases of treatment failure, cotrimoxazole and nitazoxanide may be considered as second-choice drugs. Treatment should be considered if diarrhea is persistent and no other pathogen apart from *Blastocystis* is identified in fecal specimens. The development of a new drug sensitivity assay may improve our ability to scientifically evaluate the activities of various drugs against this organism. Because this organism is so widespread throughout the world, it is always going to be somewhat difficult to differentiate between treatment failure and reinfection.

Epidemiology and Prevention

From present information, it appears that *Blastocystis* is transmitted via the fecal-oral route through contaminated food or water. Although other possible modes of transmission are not defined, the incidence and apparent worldwide distribution indicate the traditional route of infection. Studies suggest the existence of numerous zoonotic isolates, with frequent animal-to-human and human-to-animal transmissions, and of a large potential reservoir in animals for infections in humans. Prevention would probably involve improved personal hygiene and sanitary conditions (57, 58). When genotypic results from animal isolates were compared with the diversity of genotypes of human *Blastocystis* spp. isolates, the human isolates were defined as the same as the subtypes of the pet isolates, as well as the tap water isolates. Thus, the possibility of zoonotic transmission appears to be very likely (12).

Very specific prevention measures for all of the intestinal protozoa can be seen in Table 21.8. These recommendations are relevant for all organisms that can be acquired through the ingestion of food or water contaminated with fecal material.

TABLE 21.8 Measures for the prevention of infection with intestinal protozoa

1. Wash hands with soap and water after using the toilet and before handling food.
2. Avoid water or raw food that may be contaminated.
3. Wash and peel all raw vegetables and fruits before eating.
4. When traveling in countries where the water supply may be unsafe, avoid drinking unboiled tap water and avoid uncooked foods washed with unboiled tap water. Bottled or canned carbonated beverages, seltzers, pasteurized fruit drinks, and steaming hot coffee and tea are safe to drink.
5. If you work in a child care center where you change diapers, be sure to wash your hands thoroughly with plenty of soap and warm water after every diaper change, even if you wear gloves.

Intestinal Protozoa: Flagellates and Ciliates

- *Giardia lamblia* (*G. duodenalis*, *G. intestinalis*)
- *Dientamoeba fragilis*
- *Pentatrichomonas hominis* (*Trichomonas hominis*)
- *Trichomonas tenax*
- *Chilomastix mesnili*
- *Enteromonas hominis*
- *Retortamonas intestinalis*
- *Balantidium coli*

Giardia lamblia (*G. duodenalis, G. intestinalis*)

The flagellate *Giardia lamblia* (syn. *Giardia duodenalis*, *Giardia intestinalis*) was first discovered by Leeuwenhoek in 1681 in his own stool specimens but was not described until 1859 by Lambl. The organism was named after Professor A. Giard of Paris and Dr. F. Lambl of Prague (1). *G. lamblia* is worldwide in distribution and apparently is more prevalent in children than in adults and more common in warm climates than in cool ones. It is the most commonly diagnosed flagellate in the intestinal tract, and it may be the most commonly diagnosed intestinal protozoan in some areas of the world. Although a number of papers on the nomenclature of *Giardia duodenalis* replacing *G. lamblia* or *G. intestinalis* have been published, apparently this change has not been formally recognized by the International Code of Zoological Nomenclature. Therefore, we will maintain the name *G. lamblia* for this edition.

Although various criteria, including host specificity, body dimensions, and variations in structure, have been used to differentiate species of *Giardia* (*G. duodenalis*, *G. intestinalis*), there is still considerable debate over the appropriate classification and nomenclature regarding this group of organisms. On the basis of work by Filice related to structural variations, three groups have been proposed: amphibian *Giardia* spp. (represented by *G. agilis*), the muris group from rodents and birds (represented by *G. muris*), and the intestinalis group from a variety of mammals (including humans), birds, and reptiles (represented by *G. duodenalis*) (2). During the 1980s, the name *G. duodenalis* was supported and in the 1990s *G. intestinalis* was supported by various investigators. Despite disagreement concerning the various species names, all three continue to be used to describe this organism. Meyer prefers to use *Giardia duodenalis*, which is often followed by the name of the animal from which the organism was obtained (3). Within the United States, the term *Giardia lamblia* (*G. duodenalis*, *G. intestinalis*) has been commonly used for many years and will continue to be used throughout this text to refer to those organisms found in humans and other mammals; this designation will, we hope, eliminate any confusion, since the majority of health workers are used to this name and

doi:10.1128/9781555819002.ch22

TABLE 22.1 *Giardia* species[a]

Species	Hosts	Morphology: Light microscopy	Morphology: Electron microscopy	Molecular data
G. agilis	Amphibians	Long, slender; long teardrop-shaped median body	Focal contacts by the lateral crest of the ventral disk, the ventrolateral flange, the lateral shield, and by numerous microvillus-like appendages found along the lateral border of the trophozoite	NA[b]
G. ardeae	Herons	Pear shaped; 1 or 2 transverse, claw-hammer-shaped median bodies	Ventral disk and caudal flagellum similar to *G. muris*	Closer to *G. lamblia* than to *G. muris*
G. lamblia[c]	Humans and many other mammals, birds, reptiles	Pear shaped; 1 or 2 transverse, claw-hammer-shaped median bodies; sucking disk shorter than half the body length	Nuclei have a defined position, and fibrils perform an anchoring system; median bodies vary in number, shape, and position, are found in mitotic and interphasic trophozoites, are present in about 80% of the cells, and are not completely free in the cells	Clade with multiple genotypes
G. microti	Voles and muskrats	Pear shaped; 1 or 2 transverse, claw-hammer-shaped median bodies	Cysts contain 2 trophozoites with mature ventral disks	Similar to *G. lamblia* genotypes
G. muris	Rodents, birds, reptiles	Short and rounded; small round median body	Cysts contain 1 trophozoite; divides on excystation	Distant from *G. lamblia*
G. psittaci	Psittacine birds	Pear shaped; 1 or 2 transverse, claw-hammer-shaped median bodies	Incomplete ventrolateral flange, no marginal groove bordering adhesive disk	Not more diverse genetically than other *Giardia*

[b] NA, not available.

[c] Although a number of papers on the nomenclature of *Giardia duodenalis* replacing *G. lamblia* or *G. intestinalis* have been published, apparently this change has not been formally recognized by the International Code of Zoological Nomenclature. Therefore, we will maintain the name *G. lamblia* for this edition.

continue to report the presence of the organism by using the term "*Giardia lamblia*" (Table 22.1).

Molecular classification methods have been helpful in understanding the pathogenesis and epidemiology of human and animal *Giardia* infections. These studies have confirmed the division of *Giardia* human isolates into two major genotypes (Table 22.2). Adam has proposed that genotype A be accepted as the designation for Nash group 1 (A-1), Nash group 2 (A-2), assemblage A, and the Polish isolates. Genotype B would designate Nash group 3, assemblage B, and the isolates from Belgium. He feels it may also be appropriate to use a similar designation for assemblages C through G, since these also reflect both genetic and host differences (2, 4). Subassemblages AI, AII, BIII, and BIV are commonly identified in human cases (5). Another assemblage, H, has been identified in marine vertebrates (6). To date, eight main assemblages of *Giardia* have been described, but only A and B genetic groups are known to infect humans.

Life Cycle and Morphology

The life cycle is seen in Fig. 22.1. Both the trophozoite and the cyst are included in the life cycle of *G. lamblia*. Trophozoites divide by means of longitudinal binary fission, producing two daughter trophozoites. The most common location of the organisms is in the crypts within the duodenum. The trophozoites are the intestinal dwelling stage and attach to the epithelium of the host villi by means of the ventral disk. The attachment is substantial and results in disk "impression prints" when the organism detaches from the surface of the epithelium. Trophozoites may remain attached or detach from the mucosal surface. Since the epithelial surface sloughs off the tip of the villous every 72 h, apparently the trophozoites detach at that time.

There are several hypotheses on possible mechanisms for attachment by the ventral disk; these include microtubule mediation, hydrodynamic action, contractile protein activity, and the interaction of lectins with surface-bound sugars. Because there is conflicting information, the attachment process probably depends on multiple mechanisms. Attachment to enterocyte-like differentiated Caco-2 cells is primarily by cytoskeletal mechanisms, which can be inhibited by interfering with contractile filaments and microtubules; attachment by mannose-binding lectin also seems to mediate binding (7). In addition to the ventral disc, *Giardia* trophozoites have a complex three-dimensional microtubule cytoskeleton, including eight flagella (anterior, caudal, posterior-lateral, and ventral) with cytoplasmic and

TABLE 22.2 *Giardia* genotypes[a]

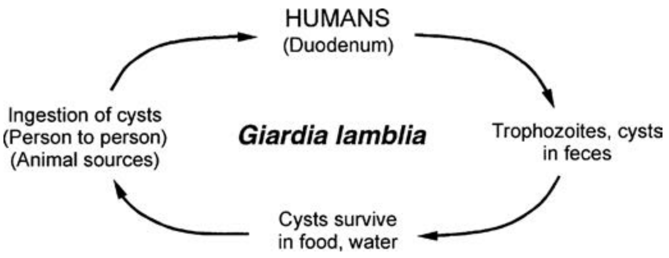
Adam designation	Nash group	Mayrhofer assemblage	Subassemblages in humans	Origin	Hosts
Genotype A-1	1	A (group 1)	AI	Poland	**Human**, beaver, cat, lemur, sheep, calf, dog, chinchilla, alpaca, horse, pig, cow, water buffalo, gerbil, moose, Mediterranean mussels, squirrel monkey, roe deer
Genotype A-2	2	A (group 2)	AII		**Human specific,** beaver, monkey
	3	A (group 3)			Red deer, cat
Genotype B	3	B (group 3)	BIII	Belgium	**Human,** beaver, guinea pig, dog, monkey, cat, deer, coyote, rabbit
	3	B (group 4)	BIV	Belgium	**Human specific**
		C			Dog, coyote
		D			Dog, cat, coyote
		E (or A, livestock)			Cow, sheep, alpaca, goat, pig, gerbil
		F			Cat, pig
		G			Rodents
		H			Seal, gull

[a] Adapted from references 2, 4, 5, and 6.

membrane-bound regions, the median body, the funis, and the supernumerary microtubules (8).

The development of viable cysts by *Giardia* is essential for its survival in the environment and for spreading the infection through contaminated food and water. For reasons which are not fully known, cyst formation takes place as the organisms move down through the jejunum after exposure to biliary secretions. However, it has recently been reported that DNA topoisomerase II is involved in regulation of cyst wall protein genes and differentiation (9). It also appears that glucosylceramide transferase activity is critical for encystation and viable cyst production in *Giardia* (10). The trophozoites retract the flagella into the axonemes, the cytoplasm becomes condensed, and the cyst wall is secreted. During this process, encystation-specific vesicles are developed that transport cyst wall proteins to the plasma membrane of the trophozoite before the production of the protective cyst wall (10). As the cyst matures, the internal structures are doubled, so that when excystation occurs the cytoplasm divides, thus producing two trophozoites. Excystation would normally occur in the duodenum or appropriate culture medium (Fig. 22.1) (2).

Figure 22.1 Life cycle of *Giardia lamblia* (*G. duodenalis*, *G. intestinalis*). doi:10.1128/9781555819002.ch22.f1



The process of encystment consists of two morphologically different stages (intracellular and extracellular) and requires approximately 16 h to complete. The extracellular phase is initiated with the appearance of cyst wall antigen on small protrusions of the trophozoite membrane, which becomes enlarged over time to form caplike structures ranging up to 100 nm in diameter. Caplike structures involved with filament growth have been detected over the entire surface of the trophozoite including the adhesive disk and flagella. Encysting cells round up, lose attachment to the substratum, and become enclosed in a layer of filaments. The internal portion includes two trophozoites with four nuclei. If methods could be found to interfere with the development of the filamentous layer of the cyst wall, regulation of viable *Giardia* cyst release from the host could be modified or eliminated (2).

Changes observed in *Giardia* lipids (increased fatty acid unsaturation and the accumulation of storage lipids) are consistent with parasite differentiation into a cyst stage that can survive outside the host at reduced temperatures and with reduced available nutrient resources. *Giardia* not only has the capacity to synthesize isoprenoid lipids *de novo* but also can metabolize fatty acids by the addition of double bonds (2). Studies have also shown that bile acids found in high concentrations in the small intestine enhance trophozoite survival, multiplication, and differentiation into the cyst stage. Results also indicate that cholesterol starvation is necessary and sufficient for the stimulation of *Giardia* encystations *in vitro* and probably in the intestines of mammalian hosts (11).

It has been determined that oxygen uptake rate and metronidazole sensitivity in *Giardia* cysts are greatly reduced compared with those in trophozoites. The resistance to metronidazole may be due to a change in metabolic flux away from the pyruvate ferredoxin oxireductase pathway. However, after the induction of excystation, oxygen uptake increases exponentially during the following 30 min and metronidazole sensitivity returns within 15 min and is fully restored within 30 min (2). Excystation occurs with exposure to the contents of the proximal small intestine; the process is quite rapid. Externally, the flagella emerge through the cyst wall, followed by the entire trophozoite. Findings on several aspects of *Giardia* differentiation can be found in the review by Adam (2). The process is divided into three distinct parts: (i) the stimulus for encystations and the regulation of encystation-specific gene expression, (ii) the synthesis and intracellular transport of cyst wall components, and (iii) the assembly of the extracellular cell wall.

Although *Giardia* has many features of the prokaryotes (anaerobic metabolism, an enzyme that reduces oxygen directly to water, cysteine as the "keeper" of the redox balance, a plasmid, and toxin-like genes), unlike prokaryotes it also has a sophisticated, highly developed cytoskeleton, bounded nuclei, linear chromosomes capped with telomeric repeats, and telomere positional regulation of gene expression (12, 13). Studies have also clarified the pathway of formation of ethanol, one of the major end products of the fermentative metabolism in *Giardia*, which lacks mitochondria. In contrast to most eukaryotes, in which ethanol formation proceeds from pyruvate via acetaldehyde, the *Giardia* pathway starts from acetyl coenzyme A, a more distal product of extended glycolysis (14).

Trophozoite (Table 22.3). The trophozoite is usually described as being teardrop shaped from the front, with the posterior end being pointed (Fig. 22.2 to 22.4). If one examines the trophozoite from the side, it resembles the curved portion of a spoon. The concave portion is the area of the sucking disk (Fig. 22.2). There are four pairs of flagella, two nuclei, two axonemes, and two slightly curved bodies called the median bodies. The trophozoites usually measure 10 to 20 µm in length and 5 to 15 µm in width.

Cyst (Table 22.4). The cysts may be either round or oval, and they contain four nuclei, axonemes, and median bodies (Fig. 22.3 and 22.4). Often, some cysts appear to be shrunk or distorted, and one may see two halos, one around the cyst wall itself and one inside the cyst wall around the shrunken organism. The halo effect around the outside of the cyst is particularly visible on the permanent stained smear. Cysts normally measure 11 to 14 µm in length and 7 to 10 µm in width.

Clinical Disease

From available data, it appears that the incubation time for giardiasis ranges from approximately 12 to 20 days. Because the acute stage usually lasts only a few days, giardiasis may not be recognized as the cause but may mimic acute viral enteritis, bacillary dysentery, bacterial or other food poisoning, acute intestinal amebiasis, or "traveler's diarrhea" (toxigenic *Escherichia coli*). However, the type of diarrhea plus the lack of blood, mucus, and cellular exudate is consistent with giardiasis.

Although the organisms in the crypts of the duodenal mucosa may reach very high densities, they may not cause any pathology. The organisms feed on the mucous secretions and do not penetrate the mucosa as *G. muris* has been shown to do in mice, from which trophozoites have been recovered in the deeper tissues. Although organisms have been seen in biopsy material obtained from inside the intestinal mucosa, others have been seen attached only to the epithelium. For some reason, in symptomatic patients there may be irritation of the mucosal lining, increased mucus secretion, and dehydration (15).

A study by Chen et al. has demonstrated a *G. duodenalis* cysteine-rich surface protein (CRP136) that has 57% homology to the product of the gene encoding the precursor of the sarafotoxins, a group of snake toxins from the burrowing adder that are known to cause symptoms similar to those of humans acutely infected with *Giardia* species (16). Thus, CRP136 represents the first evidence for a potential *Giardia* toxin.

Onset may be accompanied by nausea, anorexia, malaise, low-grade fever, and chills, and there may be a sudden onset of explosive, watery, foul-smelling diarrhea. Other symptoms include epigastric pain, flatulence, and diarrhea with increased amounts of fat and mucus in the stool but no blood (13). Weight loss often accompanies these symptoms. Although there is speculation that the organisms coating the mucosal lining may act to prevent fat absorption, this does not completely explain why the uptake of other substances normally absorbed at other intestinal levels is prevented. During the acute phase of giardiasis, jejunal active-antigen uptake is increased, leading to a delayed recruitment of mucosal and connective tissue mast cells. These changes may play a role in the increased incidence of hypersensitivity reactions and allergic disease associated with *Giardia* infection (17). Severe malabsorption has also been linked with isolated levothyroxine malabsorption, leading to severe hypothyroidism (18) and secondary impairment of pancreatic function (19). In both cases, treatment with metronidazole led to complete remission of symptoms. Occasionally, the gallbladder is also involved, causing gallbladder colic and jaundice. *G. lamblia* has also been identified in bronchoalveolar lavage fluid (20).

TABLE 22.3 Intestinal protozoa: trophozoites of flagellates

Characteristic	Shape and size	Motility	No. of nuclei and visibility	No. of flagella (usually difficult to see)	Other features
Dientamoeba fragilis	Shaped like amebae; 5–15 μm; usual range, 9–12 μm	Usually nonprogressive; pseudopodia are angular, serrated, or broad lobed and almost transparent	Percentage may vary, but 40% of organisms have 1 nucleus and 60% have 2 nuclei; not visible in unstained preparations; no peripheral chromatin; karyosome is composed of a cluster of 4 to 8 granules	No visible flagella	Cytoplasm finely granular and may be vacuolated with ingested bacteria, yeasts, and other debris; may be great variation in size and shape on a single smear
Giardia lamblia (*G. duodenalis, G. intestinalis*)	Pear shaped; length, 10–20 μm; width, 5–15 μm	"Falling-leaf" motility may be difficult to see if organism is in mucus	2; not visible in unstained mounts	4 lateral, 2 ventral, 2 caudal	Sucking disc occupying 1/2–3/4 of ventral surface; pear-shaped front view; spoon-shaped side view
Chilomastix mesnili	Pear shaped; length, 6–24 μm (usual range, 10–15 μm); width, 4–8 μm	Stiff, rotary	1; not visible in unstained mounts	3 anterior, 1 in cytostome	Prominent cytostome extending 1/3–1/2 length of body; spiral groove across ventral surface
Pentatrichomonas hominis (*Trichomonas hominis*)	Pear shaped; length, 5–15 μm (usual range, 7–9 μm); width, 7–10 μm	Jerky, rapid	1; not visible in unstained mounts	3–5 anterior, 1 posterior	Undulating membrane extends length of the body; posterior flagellum extends free beyond end of body
Trichomonas tenax	Pear shaped; length, 5–12 μm (avg, 6.5–7.5 μm); width, 7–9 μm	Jerky, rapid	1; not visible in unstained mounts	4 anterior, 1 posterior	Seen only in preparations from mouth; axostyle (slender rod) protrudes beyond the posterior end and may be visible; posterior flagellum extends only halfway down body and there is no free end
Enteromonas hominis	Oval; length, 4–10 μm (usual range, 8–9 μm); width, 5–6 μm	Jerky	1; not visible in unstained mounts	3 anterior, 1 posterior	One side of body flattened; posterior flagellum extends free posteriorly or laterally
Retortamonas intestinalis	Pear shaped or oval; length, 4–9 μm (usual range, 6–7 μm); width, 3–4 μm	Jerky	1; not visible in unstained mounts	1 anterior, 1 posterior	Prominent cytostome extending approximately 1/2 length of body

The acute phase is often followed by a subacute or chronic phase. Symptoms in these patients include recurrent, brief episodes of loose, foul-smelling stools; there may be increased distention and foul flatus. Between passing the mushy stools, the patient may have normal stools or may be constipated. Abdominal discomfort continues to include marked distention and belching with a rotten-egg taste. Chronic disease must be differentiated from amebiasis; disease caused by other intestinal parasites such as *Dientamoeba fragilis*, *Cryptosporidium* spp., *Cyclospora cayetanensis*, *Cystoisospora* (*Isospora*) *belli*, and *Strongyloides stercoralis*; and inflammatory bowel disease and irritable colon. On the basis of symptoms such as upper intestinal discomfort, heartburn, and belching, giardiasis must also be differentiated from duodenal ulcer, hiatal hernia, and gallbladder and pancreatic disease.

Ophthalmic examinations were performed on 141 children with active or past giardiasis. Salt-and-pepper retinal changes (with normal electroretinographic findings) were diagnosed in 28 (19.9%) of the children, all of whom were consistently younger than those with normal retinas. Although these findings indicate that asymptomatic, nonprogressive retinal lesions were particularly common in younger children with giardiasis, the risk does not seem to be related to the severity of the infection, its duration, or the use of metronidazole, but may reflect a genetic disposition (21).

Studies document antigenic variation with surface antigen changes during human infections with *Giardia*;

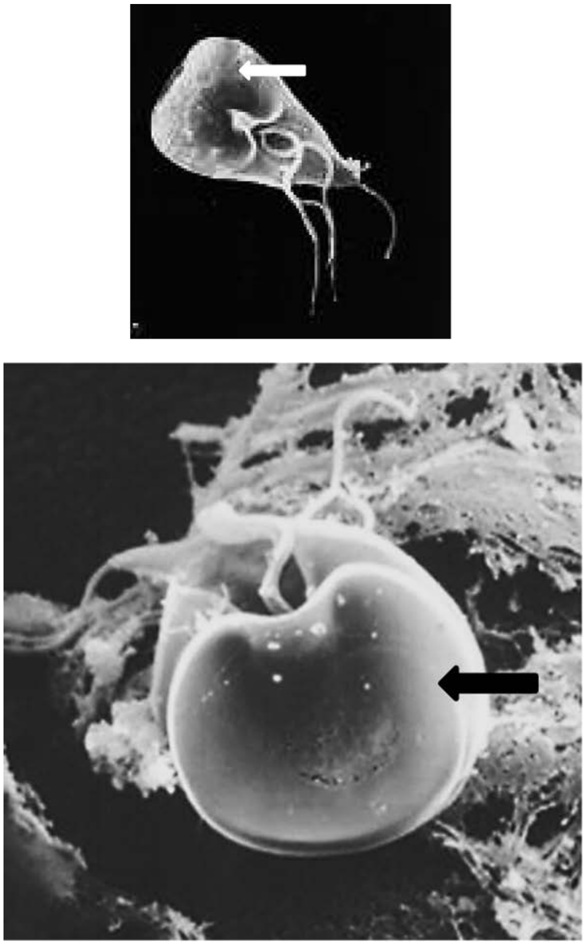


Figure 22.2 *Giardia lamblia* (*G. duodenalis*, *G. intestinalis*) trophozoites. Scanning electron micrographs. Note the sucking disk (arrows). (Upper, courtesy of the CDC Public Health Image Library; lower, courtesy of Marietta Voge.)
doi:10.1128/9781555819002.ch22.f2

although the biological importance of this work is not clear, it suggests that this variation may provide a mechanism for the organism to escape the host immune response (22) and to be responsible for chronic and recurrent infections in susceptible individuals (23). The variant-specific surface proteins are a family of related, highly unusual proteins that cover the surface of the organism; these proteins are resistant to the effects of intestinal proteases, thus allowing the parasites to survive in the protease-rich small intestine. Antigenic variation at the surface membrane of trophozoites occurs frequently; one would suspect that the higher the rate of change, the more likely that a chronic infection would be seen. However, certain surface antigens that allow the organisms to survive better in the intestinal tract may not be immunologically selected. A comprehensive analysis of the superfamily 2 helicases from *Giardia* indicates that variable expression of these helicases is present during antigenic variation and encystation (24).

Although patients with symptomatic giardiasis usually have no underlying abnormality of serum immunoglobulins, a high incidence of giardiasis occurs in patients with immunodeficiency syndromes, particularly in those with common variable hypogammaglobulinemia (25). Giardiasis was the most common cause of diarrhea in these patients and was associated with mild to severe villous atrophy. Successful treatment of giardiasis led to symptomatic cure and improvement in mucosal abnormalities, with the exception of nodular lymphoid hyperplasia.

With the advent of AIDS, there was speculation that *Giardia* might be an important pathogen in this group of individuals. However, clinical findings to date do not seem to confirm this possibility (26). Despite a suppressed immune system in AIDS patients, the immune response to *Giardia* does not seem to be very different from that seen in non-AIDS patients. It does not appear that drugs such as corticosteroids, cyclosporin A, and other immunosuppressive agents of cell-mediated immunity affect the outcome of *Giardia* infections in humans.

Diagnosis

Routine Diagnostic Procedures. Routine stool examinations are normally recommended for the recovery and identification of intestinal protozoa (27). However, in the case of *Giardia*, because the organisms are attached so securely to the mucosa by means of the sucking disk, a series of even five or six stool samples may be examined without recovering the organisms. The organisms also tend to be passed in the stool on a cyclical basis. The Entero-Test capsule can be helpful in recovering the organisms, as can the duodenal aspirate. Although cysts can often be identified on the wet stool preparation, many infections may be missed without the examination of a permanent stained smear (27). If material from the string test (Entero-Test) or mucus from a duodenal aspirate is submitted, it should be examined as a wet preparation for motility; however, motility may be represented by nothing more than a slight flutter of the flagella because the organism is caught up in the mucus. After diagnosis, the rest of the positive material can be preserved as a permanent stain.

Fluoroscopy may reveal hypermotility at the duodenal and jejunal levels, and X rays may reveal mucosal defects. If the cause is *Giardia*, the organisms may be recovered in a series of stool examinations. However, because giardiasis may not produce any symptoms at all, demonstration of the organism in symptomatic patients may not rule out other possibilities such as peptic ulcer, celiac disease of some other etiology, strongyloidiasis, and possibly carcinoma. Refer to Algorithm 22.1 for detailed information.

Antigen Detection. The development of fecal immunoassays for the detection of *Giardia* and/or *Cryptosporidium*

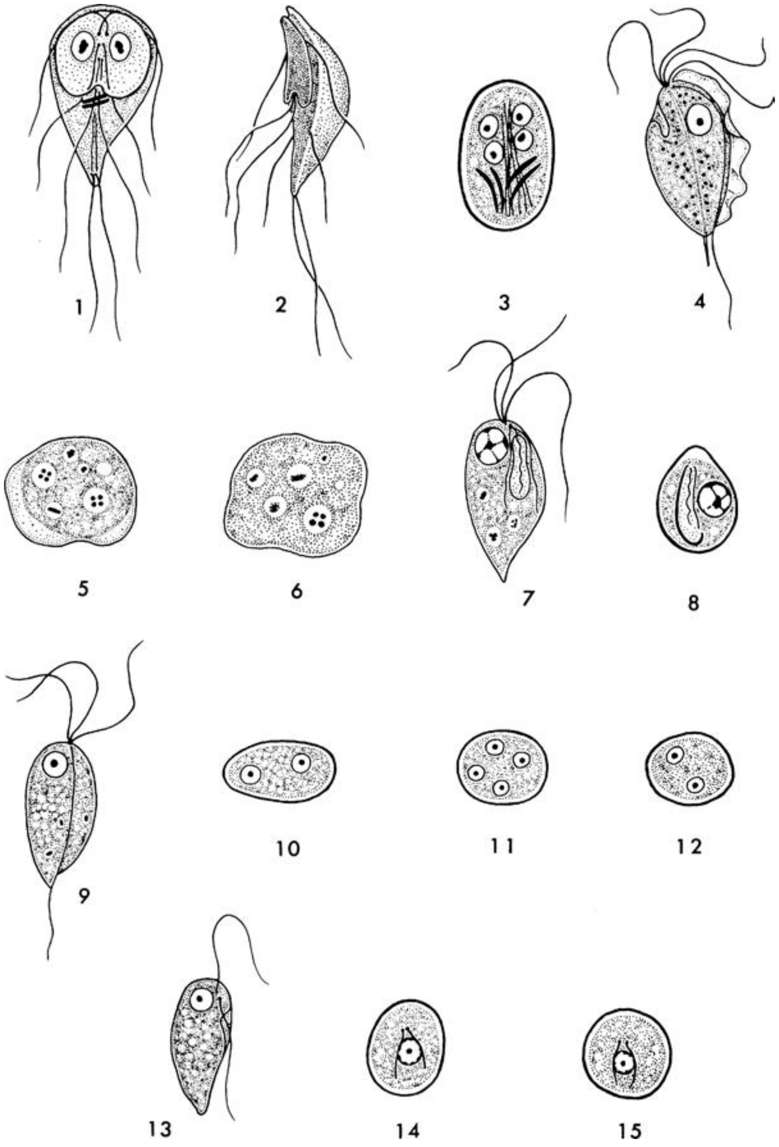

Figure 22.3 (1) Trophozoite of *Giardia lamblia* (front view); (2) trophozoite of *G. lamblia* (side view); (3) cyst of *G. lamblia*; (4) trophozoite of *Pentatrichomonas hominis*; (5) trophozoite of *Dientamoeba fragilis* (two fragmented nuclei); (6) trophozoite of *D. fragilis* (one fragmented nucleus); (7) trophozoite of *Chilomastix mesnili*; (8) cyst of *C. mesnili*; (9) trophozoite of *Enteromonas hominis*; (10–12) cysts of *E. hominis*; (13) trophozoite of *Retortamonas intestinalis*; (14 and 15) cysts of *R. intestinalis*.
doi:10.1128/9781555819002.ch22.f3

antigen in stool has dramatically improved the sensitivity over that seen with the routine ova and parasite examination and/or modified acid-fast stains (Table 22.5). Procedures involving the enzyme-linked immunosorbent assay (ELISA) have been developed to detect *Giardia* antigen in feces. The ELISA is at least as sensitive as microscopic wet examinations (28–30). Fluorescent methods with monoclonal antibodies have also proven to be extremely sensitive and specific in detecting *G. lamblia* in fecal specimens (31–34). A number of studies have compared the immunoassay products, with excellent and comparable results (28–34). Other products are available as a cartridge format that uses an immunochromatographic strip-based detection system for *G. lamblia* and/or *Cryptosporidium* spp. (35–37). Another cartridge format is used to test for the *Entamoeba histolytica/Entamoeba dispar* group, *Giardia lamblia*, and *Cryptosporidium* spp. This commercially available reagent kit requires fresh or frozen stools, since formalin interferes with the *Entamoeba* reagents (34). Any available antigen detection system should always be reviewed for compatibility with stools submitted in preservatives rather than fresh specimens. There are limitations when using kits that include organisms in the genus *Entamoeba*. However, commercial reagent kits for the detection of *Giardia* and *Cryptosporidium* can be used with formalin-based stool preservatives, the single-vial system (no mercury, PVA, or formalin), as well as fresh or frozen specimens. Many of these cartridge format tests are now available that detect both *Giardia* and *Cryptosporidium*, provide an answer within 10 min, and are equal to or better than other immunoassays in their sensitivity and specificity. Many of these newer methods are being used to test patients suspected of having giardiasis or those who may be involved in an outbreak

(Bottom) Cysts of *Giardia* (left, iron-hematoxylin; right, Wheatley's trichrome).
doi:10.1128/9781555819002.ch22.f4

situation. The detection of antigen in stool or visual identification of organisms by using monoclonal antibody reagents indicates current infection. With the increase in *Giardia* infections and awareness of particular situations such as nursery school settings, these detection assays are rapid and reliable immunodiagnostic procedures. However, it has been well documented that the use of a fecal immunoassay does not eliminate the need to analyze multiple stool specimens for sensitive detection of *Giardia* (38).

Antibody Detection. Unfortunately, serodiagnostic procedures for giardiasis do not yet fulfill the criteria necessary for wide clinical use, particularly since they may indicate either past or present infection (25). Studies comparing serum antibody responses to giardiasis in symptomatic and asymptomatic patients revealed that antigen recognition by anti-parasite IgM, IgA, IgG1, and IgG3 of these patients, determined by immunoblotting, was heterogeneous and revealed only minor differences in the responses of the two groups (25, 39). In a study investigating the secretory immune response to membrane antigens during giardiasis in humans, saliva samples showed a heterogeneous response to the membrane fraction when they were assayed by immunoblotting. Among the antigens recognized by patient saliva samples, those of 170, 105, 92, 66, 32, 29, and 14 kDa stood out since they were not recognized by saliva samples from healthy individuals. These findings may become more relevant in future studies of protection from or diagnosis of *Giardia* infections (40). Since *Giardia* trophozoites rarely invade the tissues or stimulate the systemic immune response, serodiagnostic assays fail to show differences in serum antibody responses between symptomatic and asymptomatic patients and are not recommended.

Histology. Trophozoites are detectable in the duodenum and proximal jejunum of infected patients. Although there has been some suggestion of mucosal invasion by this parasite, mucosal invasion has generally been found in areas where necrosis or mechanical trauma was present. In reviewing descriptions of general mucosal appearances, there can be a spectrum of change from normal to almost complete villous atrophy, with a greater density of inflammatory infiltrate in the lamina propria when villous atrophy is present. Apparently, patients with giardiasis also have reduced mucosal surface areas compared with controls, and the degree of abnormality correlates with indices of malabsorption. Enumeration of lamina propria plasma cells of different immunoglobulin classes reveals no clear patterns, however, suggesting that *Giardia* infection initially provokes IgM and IgE synthesis, with relative suppression of local IgA production.

Histologic changes in the mucosal architecture in immunodeficient patients with giardiasis also range from

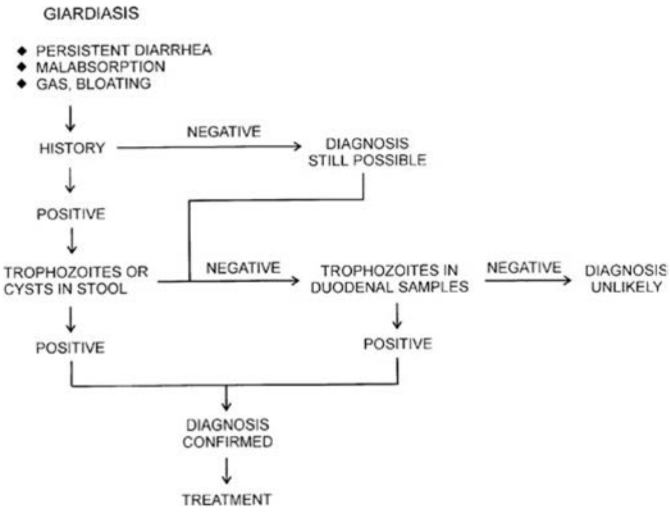
TABLE 22.4 Intestinal protozoa: cysts of flagellates

Species	Size	Shape	No. of nuclei	Other features
Pentatrichomonas hominis (*Trichomonas hominis*), *Trichomonas tenax*	No cyst stage			
Dientamoeba fragilis	~5–8 μm; inner organism about 5 μm; inner, outer cyst walls; very few cysts seen; trophozoites more common	Oval to round	1 or 2	Distinct cyst wall; inner cyst wall irregular, located directly adjacent to encysted parasite; peritrophic space exists between outer cyst wall and encysted parasite. Koch's postulates fulfilled with mice/rats; fecal-oral cycle established; confirmed in human fecal specimens
Giardia lamblia (*G. duodenalis*, *G. intestinalis*)	Length, 8–19 μm (usual range, 11–14 μm); width, 7–10 μm	Oval, ellipsoidal, or may appear round	4; not distinct in unstained preparations; usually located at one end	Longitudinal fibers in cysts may be visible in unstained preparations; deep-staining median bodies usually lie across the longitudinal fibers; there is often shrinkage, and the cytoplasm pulls away from the cyst wall; there may also be a halo effect around the outside of the cyst wall because of shrinkage caused by dehydrating reagents
Chilomastix mesnili	Length, 6–10 μm (usual range, 7–9 μm); width, 4–6 μm	Lemon-shaped with anterior hyaline knob	1; not distinct in unstained preparations	Cytostome with supporting fibrils, usually visible in stained preparation; curved fibril along side of cytostome usually referred to as "shepherd's crook"
Enteromonas hominis	Length, 4–10 μm (usual range, 6–8 μm); width, 4–6 μm	Elongate or oval	1 to 4; usually 2 lying at opposite ends of cyst; not visible in unstained mounts	Resembles *E. nana* cyst; fibrils or flagella usually not seen
Retortamonas intestinalis	Length, 4–9 μm (usual range, 4–7 μm); width, 5 μm	Pear shaped or slightly lemon shaped	1; not visible in unstained mounts	Resembles *Chilomastix* cyst; shadow outline of cytostome with supporting fibrils extends above nucleus; "bird beak" fibril arrangement

mild to severe villous atrophy. Nodular lymphoid hyperplasia has been reported, as well as mixed lesions. Again, the amount of villous damage seems to correlate with the degree of malabsorption. It appears that giardiasis produces a more severe degree of villous damage in patients with hypogammaglobulinemia. Giardiasis does not appear to be an important pathogen in patients with AIDS, although the infection has certainly been found in this group and in homosexual men.

In a study of 567 patients with giardiasis, a retrospective analysis of cases reported between 1988 and 1994 was performed. On histologic slides, trophozoites were found in duodenal (82.5%) and jejunal (2.1%) mucosa and also in gastric antral (8.7%) and ileal (12.1%) mucosa but rarely in the colon (0.4%). An entirely normal light-microscopic appearance of the duodenal mucosa was found in 462 patients (93.6%). Mild villous shortening and mild inflammation of the lamina propria were observed in the duodenal mucosa in 3.7% of the patients. Since the histology of the small-bowel mucosa is inconspicuous in the majority of patients with giardiasis, careful review of biopsy specimens must be performed (41).

Molecular Testing. In January 2013, the FDA approved the first test that can simultaneously detect 11 common viral, bacterial, and parasitic (*Cryptosporidium*, *Giardia*, *E. histolytica*) causes of infectious gastroenteritis from a single patient sample (xTAG Gastrointestinal Pathogen Panel; Luminex, Inc., Austin, TX) (42).



Algorithm 22.1 Giardiasis. Fecal immunoassay kits can be used on human stool specimens to confirm the presence of *Giardia* spp. Currently available reagents can be used with fresh, frozen, or preserved specimens (not those containing polyvinyl alcohol). If fluorescent testing is performed, the specimen should not be frozen (the actual organisms are disrupted during the freeze-thaw cycle); however, fresh or preserved specimens are acceptable. Check with each manufacturer for compatibility of the fixative with the proposed test; not all fixatives are compatible with all types of fecal immunoassays.

KEY POINTS—LABORATORY DIAGNOSIS

Giardia lamblia (*G. duodenalis*, *G. intestinalis*)

1. Even if a series of three stool specimens is submitted and examined correctly using the ova and parasite examination, the organisms may not be recovered and identified, particularly in a light infection.
2. Motility on wet preparations may be difficult to see because the organisms may be caught up in mucus. The only hint that *Giardia* is present may be the slight flutter of the flagella under reduced light. Do not use the ethyl acetate step in the concentration procedure if the specimen contains a lot of mucus.
3. Any examination for parasites in stool specimens must include the use of a permanent stained smear (even on formed stool).
4. Duodenal drainage (centrifuge and examine sediment; do not use the ethyl acetate step) and/or the use of the Entero-Test capsule may be very helpful in organism recovery. However, this technique does not take the place of the ova and parasite examination.
5. It has been well documented that the use of a fecal immunoassay (enzyme immunoassay, fluorescent-antibody assay, or rapid cartridge) does not eliminate the need to analyze multiple stool specimens for sensitive detection of *Giardia*; two different stool samples are recommended unless the first specimen is positive.
6. When performing the enzyme immunoassay, make sure that the wells are washed thoroughly according to directions; in order to avoid false-positive results, do not skip any wash steps. Make sure that the stream of buffer goes directly into the wells. Also, make sure that you use a wash bottle with a small opening, so that you have to squeeze the bottle to get the fluid to squirt directly into the wells.
7. When the directions tell you to “slap” the tray down onto some paper towels to remove all the fluid, make sure you slap it several times. Don’t be too gentle; the cups will not fall out of the holder. If they become loose, just push them back into the holder.
8. It is recommended that the fluorescent-antibody assay procedures be performed using centrifuged stool (500 × *g* for 10 min); prepare thin (rather than thick) smears and *perform the rinse step gently*. Remember that not all clinical specimens will provide the 3+ to 4+ fluorescence that we often see in the positive control. Also, from time to time, you may see fluorescing bacteria and/or some yeast in certain patient specimens. This is not particularly common, but the shapes can be distinguished from *Giardia* cysts and/or *Cryptosporidium* oocysts. Occasionally you may see the outline of a fluorescing trophozoite (some antigenic sites are shared between cysts and trophozoites); however, the fluorescence is often no more than a 1+ or maybe 2+. This finding can be interpreted as a positive test for *Giardia*. Normally, one can see cysts, even if a few trophozoites are present.
9. When using the cartridge (lateral-flow) test, if the stool is too thick, addition of reagents will not thin it out enough. If the specimen poured into the well remains too thick, the fluid will not flow up the membrane. If your specimens arrive in fixative and there is no fluid at the top of the vial overlaying the stool, this means that the vial may have been overfilled with stool. These specimens will have to be diluted with the appropriate diluent before being tested. It is always important to see the control line indicated as positive all the way across the membrane, not just at the edges. *A positive test result may be much lighter than the control line; this is normal.* At the cutoff time to read the result, any color visible in the test area should be interpreted as a positive. Do not read/interpret the results after the time indicated in the directions; you may get a false-positive result.

Treatment

The incidence of giardiasis worldwide may be as high as 1 billion cases. If giardiasis is diagnosed, the patient should

be treated (Table 22.6); more complete dosage information can be found in chapter 36. Current recommended treatments include the nitroheterocyclic drugs tinidazole, metronidazole, and furazolidone, the substituted acridine quinacrine, and the benzimidazole albendazole. Paromomycin is also used, as is nitazoxanide. Treatment failures have been reported with all the common antigiardial agents, and resistance to these drugs has been demonstrated in the laboratory. Clinical resistance has been reported, and includes situations in which patients have failed to respond to both metronidazole and albendazole treatments (43, 44). However, albendazole may be of similar effectiveness to metronidazole, may have fewer side effects, and has the advantage of a simplified regimen. Metronidazole is not recommended for pregnant women; although not well absorbed and not highly effective, paromomycin may be used to treat giardiasis in pregnancy (43). Tinidazole has also been used and has proven more effective than metronidazole as a single dose (43, 45). Less effective and/or less well-tolerated drugs for the treatment of giardiasis include albendazole, quinacrine, and furazolidone; the use of these agents should be reserved for giardi-

TABLE 22.6 Recommendations for therapy for giardiasis[a]

Clinical picture	Drug and duration of treatment	Side effects
Symptomatic infection, U.S.		
Adult and pediatric	Metronidazole, 5–7 days	Headache, vertigo, nausea, metallic taste, urticaria; disulfiram-like reaction with alcohol ingestion; rare side effects include pancreatitis, central nervous system toxicity, reversible neutropenia, peripheral neuropathy, T-wave flattening with prolonged use; mutagenic, carcinogenic?
Adult and pediatric	Nitazoxanide, single dose	Generally well tolerated
Alternatives	Furazolidone, 7–10 days	Nausea, vomiting, diarrhea; brown discoloration of urine; disulfiram-like reaction with alcohol ingestion; reacts unfavorably with monoamine oxidase inhibitors; mild hemolysis in glucose 6-phosphate dehydrogenase deficiency; carcinogenic?
	or quinacrine, 5–7 days	Nausea and vomiting, dizziness, headache; yellow/orange discoloration of skin, mucous membranes; rare side effects include toxic psychosis
	or albendazole, 5–7 days or single dose	Anorexia, constipation; rare side effects include reversible neutropenia and elevated liver function tests; teratogenic?
Symptomatic infection, non-U.S.		
Adult and pediatric	Tinidazole (single dose)	As for metronidazole
	or ornidazole (single dose)	As for metronidazole
Pregnancy		
First trimester	Paromomycin, 5–10 days	Ototoxicity and nephrotoxicity with systemic administration
Second and third trimesters	Paromomycin, 5–10 days, or metronidazole, 5–7 days	
Resistant infection or relapse	Drug of different class or combination nitroimidazole plus quinacrine, 2 wk or more	See above
Resistant infection (metronidazole)	Auranofin	Awaiting clinical trials to validate clinical efficacy in animals.

[a]Adapted from references 1, 15, 42, and 46.

asis refractory to treatment with the first-line agents (46). Auranofin, used for many years in treating rheumatoid arthritis, has been shown to be active against divergent *Giardia* strains with different forms of resistance against metronidazole, suggesting that auranofin could be a treatment alternative if patients fail standard metronidazole therapy (47). The ability of auranofin to override metronidazole resistance suggests that this drug has a mechanism of action different from that of metronidazole.

A simple colorimetric method has been determined for determining *in vitro* activity against *Giardia*. The microtiter plate assay is based on the nucleoside hydrolase activity released from the organism by lysis. Action of the nucleoside hydrolase on the substrate analog, 4-nitrophenyl β-D-ribofuranoside, gives rise to a colored product which can be determined by the change in absorbance. Values obtained using this method for metronidazole, tinidazole, and furazolidone were consistent with published values. This simple method, which does not involve radioisotopes or complex instrumentation, provided a convenient method for screening potential antigiardial agents (48).

Wheat germ (WG) agglutinin inhibits excystation and trophozoite growth *in vitro*, as well as reducing cyst passage in mice. In a double-masked, placebo-controlled study of dietary supplementation with WG, there appeared to be no clinically important differences between the two groups. However, symptoms appear to have resolved more rapidly in those taking WG in addition to metronidazole, and the WG was well tolerated in both the symptomatic and asymptomatic groups. Thus, in combination with antiprotozoal drugs, WG may be able to modify symptomatic giardiasis (49).

In the absence of a parasitologic diagnosis, the treatment of suspected giardiasis is a common question with no clear-cut answer. The approach depends on the alternatives and the degree of suspicion of giardiasis, both of which vary among patients and physicians. However, it is not recommended that treatment be given without a good parasitologic workup, particularly since relief of symptoms does not allow a retrospective diagnosis of giardiasis; the most commonly used drug, metronidazole, targets other organisms besides *Giardia*.

Another question involves treatment of asymptomatic patients. Generally, it is recommended that all cases of proven giardiasis be treated because the infection may cause subclinical malabsorption, symptoms are often periodic and may appear later, and a carrier is a potential source of infection for others. Certainly, in areas of the world where infection rates, as well as the prospect of reinfection, are extremely high, the benefit-per-cost ratio would also have to be examined.

Epidemiology and Prevention

Transmission is by ingestion of viable cysts. Although contaminated food or drink may be the source, intimate contact with an infected individual may also provide the infection mechanism. This organism tends to be found more frequently in children or in groups that live in close quarters. Often, there are outbreaks due to poor sanitation facilities or breakdowns as evidenced by infections of travelers and campers. There is also an increase in the prevalence of giardiasis in the male homosexual population, probably because of anal and/or oral sexual practices (43).

Although seasonal patterns have been identified for some infectious diseases, limited information is available for giardiasis. Some data suggest an association with the cooler, wetter months of the year; this is not surprising if one considers the issue of environmental conditions advantageous to cyst survival.

It has been documented that certain occupations may place an individual at risk for infection; such at-risk individuals include sewage and irrigation workers, who may become exposed to infective cysts. In situations where young children are grouped together, such as nursery schools, there may be an increased incidence of exposure and subsequent infection of both children and staff.

Most experts agree that the single most effective practice that prevents the spread of infection in the child care setting is thorough hand washing by the children, staff, and visitors. Specific guidelines can be found in Table 22.7. Rubbing the hands together under running water is the most important part of washing away infectious organisms. Premoistened towelettes or wipes and waterless hand cleaners should not be used as a substitute for washing hands with soap and running water. These guidelines are not limited to giardiasis but include all potentially infectious organisms.

TABLE 22.7 Guidelines for hand washing

- Children
  - When they arrive at the child care setting
  - Immediately before and after eating
  - After using the toilet or having their diapers changed
  - Before using water tables
  - After playing on the playground
  - After handling pets, pet cages, or other pet objects such as toys
  - Whenever hands are visibly dirty
  - Before going home
- Staff, visitors
  - When they arrive at the child care setting
  - Immediately before handling food, preparing bottles, or feeding children
  - After using the toilet, assisting a child in using the toilet, or changing diapers
  - After contact with a child's body fluids, including wet or soiled diapers, runny noses, spit, and vomit
  - After handling pets, pet cages, or other pet objects such as toys
  - Whenever hands are visibly dirty or after cleaning up a child, the room, bathroom items, or toys
  - After removing gloves for any purpose (if gloves are worn, hands should be washed immediately after the gloves are removed, even if the hands appear to be clean; use of gloves alone will not prevent contamination of hands or spread of organisms and should not be considered a substitute for hand washing)
  - Before giving or applying medication or ointment to a child or self
  - Before going home

The possible association between gastric acidity and giardiasis has been debated for some time. Evidence indicates that decreased gastric acid production may predispose people to *Giardia* infection. It is thought that normal gastric acidity acts as a barrier to the establishment of an infection; patients who have had a gastrectomy are prone to *Giardia* infection. Although achlorhydria is associated with blood group A and some evidence suggests that members of this group are more susceptible to giardiasis, subsequent evidence has not confirmed this information. Since reduction in gastric acid also occurs as a result of malnutrition, these factors may be linked and, as a group, increase the susceptibility to infection with this organism. This link between malnutrition and giardiasis may also be explained by the impairment of the host immune system.

The issue of whether breast milk modifies *Giardia* infection has also been discussed in terms of different interpretations of the results. A lower incidence of giardiasis in children younger than 6 months may be related to an association with breast-feeding and some protection against infection via secretory IgA; however, the lower incidence may also be related to decreased exposure to *Giardia* organisms in breast-fed infants.

Giardiasis is one of the more common causes of traveler's diarrhea and has been recorded in all parts of the world. It has also been speculated that visitors in areas where *Giardia* infections are endemic are more likely to present with symptoms than are individuals who live in the area; this difference is most probably due to the development of immunity of residents from prior and possibly continued exposure to the organism.

There have been a number of outbreaks attributed to either resort or municipal water supplies in Oregon, Colorado, Utah, Washington, New Hampshire, and New York (50–53). High rates of infection were also reported for hikers and campers who drank stream water. Because some of these areas were remote from human habitation, infected wild animals, especially beaver, are suspected (51).

During the past few years, this infection has received much publicity. With increased travel, there has been a definite increase in symptomatic giardiasis within the United States (53). Various surveys show infection rates of 2 to 15% in various parts of the world.

Because of the potential for wild-animal and possibly domestic-animal reservoir hosts, measures in addition to personal hygiene and improved sanitary measures have to be considered. Iodine has been recommended as an effective disinfectant for drinking water, but it must be used as directed. Filtration systems have also been recommended, although they have certain drawbacks such as clogging.

Water Testing. Over the past few years, concern over safe drinking water has increased, and these issues have led to the development of a more complex industry related to water treatment and testing. Untreated surface water is more likely than groundwater to contain organisms, because of the possibility of direct contamination with animal feces, treated and untreated human sewage, or fecal runoff from adjacent land after heavy rain or snow melt. Wells that have been poorly located, constructed, or damaged have also been implicated in outbreaks. Specific points to consider when testing well water are listed in Table 22.8; because specific testing for *Giardia* is difficult and expensive, the well water can also be tested for fecal coliforms as an indicator of fecal contamination. In some areas of the world, the percent positivity for water supplies can be very high for both *Cryptosporidium* and *Giardia* in both raw water and treated water samples.

The conventional filtration process used by most surface water treatment plants usually includes several steps: coagulation-flocculation, sedimentation, and filtration. During the first step, a chemical coagulant is added to the water to cause small suspended particles to stick together to form larger particles (flocculation), which either settle to the bottom (sedimentation) or are removed by filtration, primarily through fine sand. The coagulation-flocculation step is critical for successful removal of chlorine-resistant protozoa (1 to 20 µm in size), which could slip through the 50- to 70-µm spaces between grains of sand in a water treatment filter. Unfortunately, there are a number of variables that influence adequate filtration (amount of coagulant added, degree of mixing of coagulant with water, and changes in raw water pH, temperature, or turbidity). Conventional water filtration should trap nearly all protozoan parasites, including *Giardia* and *Cryptosporidium*, if appropriate procedures are followed (54).

TABLE 22.8 Questions for consideration when testing well water

1. Are other members of your family or users of your well water ill?
   (If yes, the well water may be a source of infection.)
2. Is your well located at the bottom of a hill, or is it considered shallow?
   (If either of these is true, runoff from rainwater or floodwater may be draining into the well, causing contamination.)
3. Is your well in a rural area where animals graze?
   (Well water can be contaminated with animal waste seepage contaminating the groundwater. This can occur if the well has cracked casings, is poorly constructed, or is too shallow.)

Environmental sampling methods were originally developed to assist in the investigation of suspected waterborne outbreaks of infection. The sample volumes generally recommended are 100 liters for source water and 1,000 liters or more for finished water. The usual procedure involves filtration through 1-µm polypropylene filter cartridges or fiberglass-resin cartridges. The filters are then eluted in a laboratory with detergent solutions, and recovered particulates are concentrated by centrifugation. A flotation purification step using density gradients is then used to separate the organisms from inorganic materials and debris. Currently, the most commonly used method for examining purified material for protozoa is an antibody-based immunofluorescence assay. This approach has several limitations, including the lack of information on the infectivity or viability of cysts or oocysts; the lack of indication of the host species or origin of the organisms; the chance of false identification of algal or other protozoal species; poor recovery efficiency; the labor-intensive procedures; and the need for skilled microscopists. It also appears that different organism numbers from the same water source can be attributed to method artifact rather than true differences in counts. Another method for the determination of *Giardia* cyst viability in environmental and fecal samples involves fluorogenic dye staining and differential interference contrast microscopy (55). This method has proved significantly better than the routine counting methods being used.

Newer methods that have been tried include a portable differential continuous-flow centrifuge for concentration of *Cryptosporidium* oocysts and *Giardia* cysts from large volumes of water (56). The effect of electroporation (very short pulses of high-voltage electricity) alone and in combination with various chemicals has been examined. While electroporation had a minor effect on oocyst and cyst survival, the combination of electrical and chemical treatment produced superior inactivation, particularly when chlorine, hydrogen peroxide, or potassium permanganate was used. Additional kinetic and optimum treatment combinations continue to be developed. The use of immunomagnetic beads to separate *Giardia* cysts from complex matrixes of environmental surface waters followed by DNA release and PCR amplification of the target giardin gene has improved the reliability of detection of *Giardia* with increased sensitivity (57). Water monitoring has undergone tremendous transition, with new molecular tools beginning to offer rapid, high-throughput, sensitive, and specific detection of a number of pathogens. High-density microarrays, quantitative real-time PCR (qPCR), and pyrosequencing are emerging rapidly as tools of pathogen detection and discovery (58).

Studies of the epidemic and endemic seroprevalence of antibodies to *Cryptosporidium* and *Giardia* in residents of three communities with different drinking water supplies were undertaken to review possible differences or similarities (59). The findings were consistent with a lower risk of exposure from drinking water obtained from deep well sources and increased seropositivity associated with an outbreak situation. Although intriguing associations were found among seroprevalence, outbreak-related serologic data, and patterns of parasite contamination of drinking water, further studies are required to validate this approach to risk assessment of waterborne parasitic infections at the community level.

Phagocytosis of *Giardia* cysts by hemocytes of the Asian freshwater clam, *Corbicula fluminea*, has been documented, and the mean number of cysts ingested per hemocyte increased significantly over time. These findings may result in this biological system being used to serve as an indication of contamination of wastewaters and agricultural drainage with *Giardia* cysts (60). Also, it is well known that rotifers thrive in environments such as wastewater and domestic sewage; they have been found to ingest *Giardia* cysts in an artificial setting. If this finding is consistent with results from natural environmental studies, perhaps the information will further explain the environmental dispersion of the cysts and suggest how this dispersion could be curtailed (61). Another study of blue mussels in Canada revealed *Giardia* (18%) and *Cryptosporidium* (73%) were found in the samples tested (62).

Characterization of *Giardia* Isolates. Isoenzyme studies, designed primarily to assist in organism identification and classification, have also provided additional information regarding pathogenicity, implication in waterborne outbreaks, and human disease. In one study in which isoenzyme patterns of 32 *Giardia* isolates obtained from both humans and animals were examined, there was no obvious correlation between clinical symptoms and isoenzyme patterns. Isolates from asymptomatic individuals were found in the same zymodemes (isoenzyme groups) as were isolates from symptomatic hosts. This study also confirmed previous observations regarding genetic heterogeneity and demonstrated significant differences between isolates from within a single region and other widely separated geographic locations (2). Australian data on two *Giardia* demes indicated that both appeared to be pathogenic and were derived from children with similar chronic symptoms (13).

Various studies have published data suggesting that zoonotic transmission between humans and animals is, at times, more likely or less likely to occur (5, 51, 63, 64).

Dientamoeba fragilis

Dientamoeba fragilis was first seen in 1909 but was not described until 1918. In 1940, Dobell recognized the close morphologic similarities between *D. fragilis* and *Histomonas meleagridis*, the ameboflagellate parasite of turkeys. A key scientific advance was made in 1934 when Tyzzer reported that *H. meleagridis* is transmitted in the eggs of *Heterakis*, the cecal worm of chickens and turkeys, a fact that has relevance to the life cycle of *D. fragilis* (1, 65). On the basis of electron microscopy studies, *D. fragilis* has been reclassified as an ameboflagellate rather than an ameba and is closely related to *Histomonas* and *Trichomonas* spp. (66). It has a cosmopolitan distribution, and past surveys demonstrate incidence rates of 1.4 to 19%. Much higher incidence figures have been reported for mental institution inmates, missionaries, and Native Americans in Arizona. *D. fragilis* tends to be common in some pediatric populations, and incidence figures are higher for patients younger than 20 years in some studies. Currently, it is in the phylum Parabasala, class Trichomonadea, family *Trichomonadidae*, and possibly the subfamily *Trichrichomonidinae*. This classification will probably undergo change in the future.

Life Cycle and Morphology

The life cycle and mode of transmission of *D. fragilis* were always speculative; however, newer information has clarified these issues. Transmission via helminth eggs such as those of *Ascaris* and *Enterobius* spp. has been postulated (65, 66) (Fig. 22.5). The cyst stage has recently been confirmed, thus also confirming fecal-oral transmission of *D. fragilis* (67–70, 82) (Tables 22.3 and 22.4).

Trophozoite. The trophozoite is characterized as having one (20 to 40%) or two (60 to 80%) nuclei. The nuclear chromatin is usually fragmented into three to five granules, and there is normally no peripheral chromatin on the nuclear membrane (Fig. 22.6 and 22.7). In some organisms, the nuclear chromatin tends to mimic that of *Endolimax nana*, *Entamoeba hartmanni*, or even *Chilomastix mesnili*, particularly if the organisms are overstained. The cytoplasm is usually vacuolated and may contain ingested de-

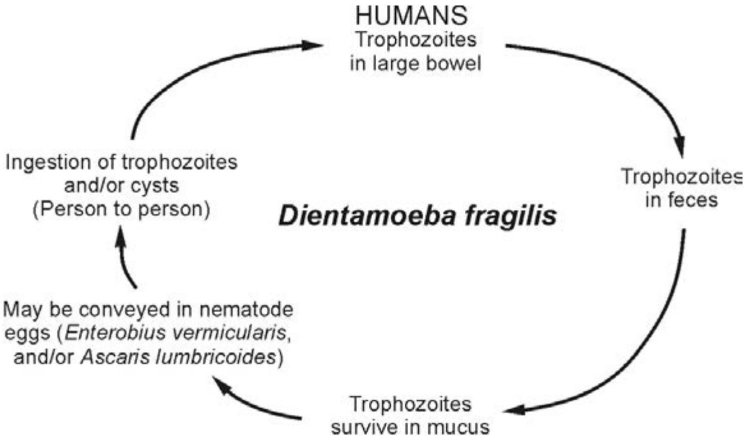

Figure 22.5 Life cycle of *Dientamoeba fragilis*. doi:10.1128/9781555819002.ch22.f5

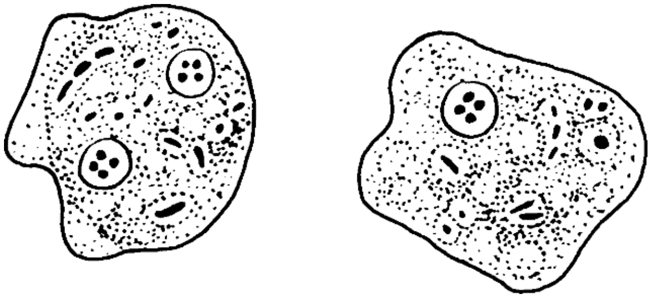
bris as well as some large, uniform granules. The cytoplasm can also appear uniform and clean with few inclusions. There can also be considerable size and shape variation among organisms, even on a single smear.

Cyst. Electron microscopy reveals various organelles within the cyst, including an axostyle, flagellar axonemes, and a costa. External flagella are absent. Observation of flagella components only within the cyst and not in the trophozoite stage provides support for the suggestion that *D. fragilis* has adapted to life in the gut by losing the flagella and adopting an amebic appearance and style of locomotion in the gut (68, 69). Precysts and cysts are extremely difficult to identify and tend to be quite rare when compared with cyst numbers of other protozoa. The cysts have a distinct cyst wall (~5 µm in diameter) with a clear zone around the cyst. A space is present between the cyst wall and the organism enclosed within the cyst wall. The nuclear structure is morphologically identical to that found in *D. fragilis* trophozoites. All cysts seen contain two nuclei, with each nucleus containing a large central karyosome with a delicate nuclear membrane. No chromatin is visible on the nuclear membrane and the nucleus is often fragmented into distinct granules of chromatin. These "true" cysts are rarely encountered in clinical samples, which probably accounts for the limited number of descriptive reports. In contrast, the precystic forms of *D. fragilis* are more frequently seen with a prevalence of up to 5% in clinical samples. This precystic stage is characterized by a compact spherical shape with a reduction in size of up to 50% from "normal" trophozoites. These forms range in size from 4 to 5 µm. The cytoplasm is darkly staining, indicating a denser structure than what is found in normal trophozoites. The cytoplasm is homogeneous and rarely contains any inclusions (70) (Fig. 22.7).

Figure 22.6 Trophozoites of *Dientamoeba fragilis*. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch22.f6



Clinical Disease

D. fragilis has been associated with a wide range of symptoms (66, 68, 69). The development of a rodent model, the fulfilling of Koch's postulates, and the discovery of a cyst stage in the life cycle have dramatically clarified possible transmission routes, including fecal-oral transmission (67–70). Case reports of children infected with *D. fragilis* reveal a number of symptoms, including intermittent diarrhea, abdominal pain, nausea, anorexia, malaise, fatigue, poor weight gain, and unexplained eosinophilia. Eosinophilia has been reported in up to 50% of pediatric and 10% of adult patients. The most common symptoms in patients infected with this parasite appear to be intermittent diarrhea and fatigue. In some patients, both the organism and the symptoms persist or reappear until appropriate treatment is initiated. Chronic symptoms are common, with up to a third of patients exhibiting persistent diarrhea.

Eleven pediatric patients, seven of whom had peripheral eosinophilia and a history of recent travel, were diagnosed with *D. fragilis* infection and reported symptoms of anorexia, intermittent vomiting, abdominal pain, and diarrhea. Based on findings in these patients, including bovine protein allergy and eosinophilic colitis, *D. fragilis* should be included in the differential diagnosis of chronic diarrhea and eosinophilic colitis. The identification of this pathogen requires clinical awareness of epidemiologic risk factors and presenting complaints, as well as proper laboratory permanent staining procedures essential to proper identification. Long-term parasite carriage by rodents and prolonged shedding of cysts, together with elevated levels of calprotectin in the stool, confirms the capacity of this organism to cause disease. An increase in fecal calprotectin has been reported in patients suffering from intestinal disorders such as inflammatory bowel disease (71). This new information definitely indicates that dientamoebiasis should be considered in the differential diagnosis of gastrointestinal diseases, including inflammatory bowel disease.

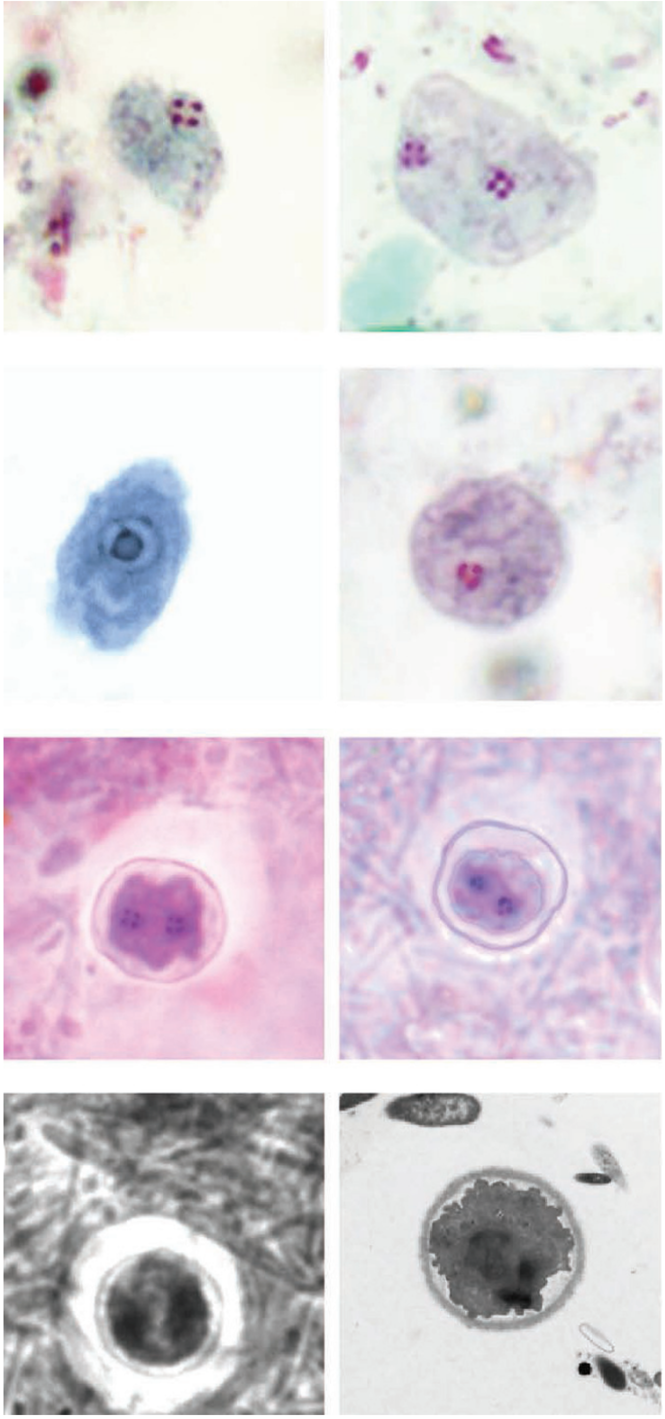


Figure 22.7 (Top) Trophozoites of *Dientamoeba fragilis*: (left) the trophozoite contains a single nucleus fragmented into four parts; (right) the trophozoite contains two nuclei, both of which are also fragmented. (Row 2, left) Trophozoite with a single nucleus that has not yet fragmented—can be confused with *Endolimax nana*; (right) trophozoite with a single nucleus that has begun to fragment. (Row 3, left and right) Cysts of *Dientamoeba fragilis*; note the space between the cyst wall and organism, also the two nuclei with fragmented chromatin. (Bottom, left) Cyst from rat feces; (right) transverse section across cyst showing the outer fibrillar cyst wall, peritrophic space, and the enclosed parasite. (Bottom row from reference 67 with permission).
doi:10.1128/9781555819002.ch22.f7

Diagnosis

Routine Diagnostic Procedures. Clinicians should include infection with *D. fragilis* in their differential diagnosis of patients presenting with abdominal pain, diarrhea, unexplained flatulence, nausea, vomiting, and/or eosinophilia. Diagnosis of *D. fragilis* infections depends on proper collection and processing techniques (a minimum of three fecal specimens) (27). Although the survival time for this parasite has been reported as 24 to 48 h, the survival time in terms of morphology is limited, and stool specimens must be examined immediately or preserved in a suitable fixative soon after defecation. It is particularly important that stained stained smears of stool material (trichrome, iron-hematoxylin) be examined with an oil immersion lens (100×). These organisms have been recovered in formed stool; therefore, a permanent stained smear must be prepared for every stool sample submitted for a parasite examination. Organisms seen in direct wet mounts may appear as refractile, round forms; the nuclear structure cannot be seen without examination of the permanent stained smear. With the recent confirmation of the cyst stage, one needs to take into account the more shrunken appearance of this form when compared with the trophozoite (Fig. 22.7).

Antigen Detection. Although fecal immunoassays for antigen detection are not yet available commercially, they have been developed using the immunofluorescence format (72). Studies using the enzyme immunoassay method are also under way. It is hoped that these assays may become available commercially, since preliminary results look very promising. The potential for detection of DNA from feces is also being investigated; certainly the development of rapid, specific, and sensitive tests would be extremely helpful within the diagnostic laboratory setting.

Antibody Detection. Using an indirect immunofluorescence assay, Chan et al. (73) found that serum samples from patients with confirmed *D. fragilis* infections had positive titers of 80, and all 12 matched controls had positive titers ranging from 20 to 160. The specificity of this assay was reinforced by immunoblotting 20 representative serum samples against *D. fragilis*; in all 17 indirect immunofluorescence-positive serum samples, a 39-kDa protein band of *D. fragilis* was identified.

Molecular Testing. The performance of a multiplex real-time PCR for the detection of *Blastocystis*, *D. fragilis*, *G. lamblia*, *Cryptosporidium* spp., and *Entamoeba* spp. in fecal samples was evaluated in an observational prospective study. Based on symptoms and clinical findings, pediatric patients suspected of having gastrointestinal parasitic disease were tested. Out of 163 patients, 114 (70%) had a fecal PCR-positive test. *D. fragilis* was detected most often, followed by *Blastocystis* (74).

Another study used a multiplex tandem PCR (MT-PCR) assay for the detection and identification of four common pathogenic protozoan parasites, *Cryptosporidium* spp., *D. fragilis*, *E. histolytica*, and *Giardia intestinalis*, from human clinical samples. In this study, *Giardia* ranked first, with *D. fragilis* being second in terms of positives. The MT-PCR assay provided rapid, sensitive, and specific simultaneous detection and identification of the four organisms. This study also emphasized the lack of sensitivity demonstrated by microscopy, and thus, molecular methods such as MT-PCR must be considered the diagnostic methods of choice for enteric protozoan parasites (75).

Since 2007, Statens Serum Institut (Denmark) has used real-time PCR for *D. fragilis* as the routine diagnostic work-up for intestinal parasitosis, testing more than 22,000 samples from 2008 through 2011. They demonstrated a very high proportion (43%) of investigated patients positive for *D. fragilis*, ranging from 12 to 71% depending on the age group, with a bimodal age distribution peaking in children and adults of parental age, as well as a clear association between exposure to children and risk of *D. fragilis* infection (76).

Recently, the EasyScreen Enteric Parasite Detection Kit (Genetic Signatures, Sydney, Australia) was evaluated for the detection and identification of five common enteric parasites—*Blastocystis* spp., *Cryptosporidium* spp., *D. fragilis*, *Entamoeba* complex, and *G. intestinalis*—in human clinical samples. This enteric parasite detection kit exhibited 92 to 100% sensitivity and 100% specificity and detected all commonly found genotypes and subtypes of these clinically important human parasites. No cross-reactivity was detected in stool samples containing various other bacterial, viral, and/or protozoan species (77).

KEY POINTS—LABORATORY DIAGNOSIS

Dientamoeba fragilis

1. A minimum of three specimens (stool) should be submitted for the diagnosis of *Dientamoeba* infections.
2. Although a cyst stage has been confirmed, these organisms will still be difficult to see on a wet preparation. Consequently, it is mandatory that a permanent stained smear be included in the ova and parasite examination. Trophozoites with either one or two nuclei can be found in the same specimen; there may also be tremendous size variation among the organisms seen in a single smear.
3. The trophozoite forms have been recovered from formed stool, hence the need to perform the permanent stained smear on specimens other than liquid or soft stools.
4. Remember, the cyst form will appear shrunken with two cyst walls; often there will be a large clear area surrounding the cyst (permanent stain). This is evidence of shrinkage during dehydration and is commonly seen with other protozoa as well.
5. Organisms with a single nucleus can easily be confused with *Endolimax nana* or *Entamoeba hartmanni*, both of which are considered nonpathogens.

Treatment

Clinical improvement has been observed in adults receiving tetracycline; symptomatic relief has been observed in children receiving either diiodohydroxyquin, metronidazole, or tetracycline. Current recommendations include iodoquinol, paromomycin, tetracycline, metronidazole, or combination therapy (78). Since symptomatic relief has been observed to follow appropriate therapy, *D. fragilis* is probably pathogenic in infected individuals who are symptomatic. Although limited studies have been undertaken regarding the efficacy of various therapies, information continues to support the fact that the elimination of this organism from symptomatic patients leads to clinical improvement. Additional information can be found in chapter 36.

Epidemiology and Prevention

As reported for many of the intestinal protozoa, *D. fragilis* is worldwide in distribution. It is suspected that the true incidence of this infection is considerably higher than reported, particularly since many laboratories do not yet emphasize diagnostic methods such as the permanent stained smear that would confirm the diagnosis (27, 69). Infection with *D. fragilis* is particularly common in Canada. This parasite has been associated with diarrhea and abdominal pain in some patients. In looking at seroprevalence data for a large group of randomly selected patients aged from 6 months to 19 years, 172 (91%) of 189 gave positive results at titers of 1:10 or higher. The specificity of the indirect immunofluorescence assay was reinforced by immunoblotting of 20 representative serum samples against *D. fragilis*. Findings over a 5-year period indicate that *D. fragilis* was the most common protozoan, followed closely by *G. lamblia* and more distantly by *Cryptosporidium parvum*. Previous data reported 85.6% for *G. lamblia* and 86% for *C. parvum* (72).

Since fecal-oral transmission has now been documented, preventive measures would tend to be those related to other intestinal pathogenic protozoa. With transmission occurring from the ingestion of certain helminth eggs and/or cyst forms, the use of hygiene and sanitary measures to prevent contamination with fecal material would be appropriate. There is speculation that *D. fragilis* may be infrequently recovered and identified; low incidence or absence from survey studies may be due to poor laboratory techniques and a general lack of knowledge about the organism (27, 66, 69).

Pentatrichomonas hominis (*Trichomonas hominis*)

It is generally thought that *Pentatrichomonas hominis* was first observed by Davaine in 1854 and described by him with the species name *hominis*. Although other protozoologists doubt that he actually saw this organism, the species name has been accepted. The genus name, *Pentatrichomonas*, is based on the five anterior flagella and a granular parabasal body. Although most readers are familiar with the generic term *Trichomonas*, this name will be changed to *Pentatrichomonas* for this edition of the book.

P. hominis has been recovered from all parts of the world, in both warm and temperate climates. It is considered to be nonpathogenic, although it is often recovered from diarrheic stools (Tables 22.3 and 22.4). Statistics generated over the years include college students (0.16%); rural Georgia (0.3%); New Orleans clinic population in 1935 (1.2%); Peking, China, clinic patients (3.5%); and a Cali, Colombia, survey (1956 to 1961) (2.0 to 13.5%) (2).

Life Cycle and Morphology

There is no known cyst stage (Fig. 22.8). The trophozoites live in the cecal area of the large intestine and feed on bacteria. The organism is not considered to be invasive. The trophozoite measures 5 to 15 µm in length and 7 to 10 µm in width. It has a pyriform shape and has both an axostyle and undulating membrane, which help in the identification (Fig. 22.3). The undulating membrane extends the entire length of the body, in contrast to that seen in *Trichomonas vaginalis* (Fig. 22.9).

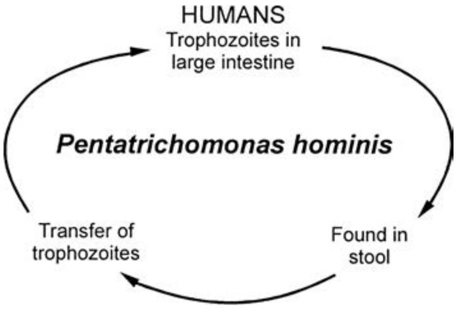

Figure 22.8 Life cycle of *Pentatrichomonas hominis*. doi:10.1128/9781555819002.ch22.f8

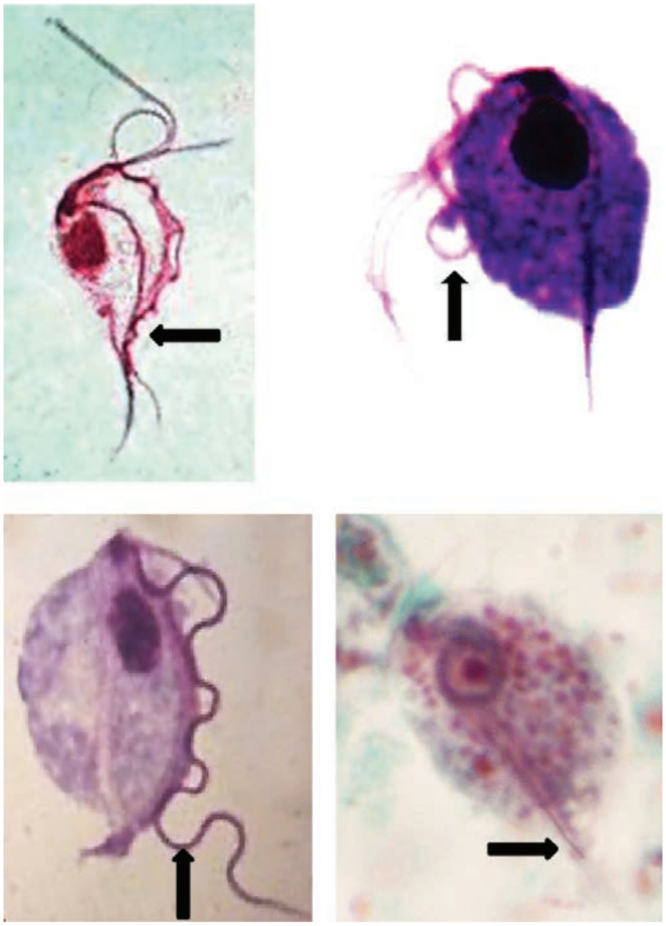
Figure 22.9 (Upper, left) *Pentatrichomonas hominis*, note undulating membrane extends the entire length of the body (arrow) (courtesy of http://umvf.univ-nantes.fr/parasitologie/enseignement/trichomonose/site/html/3.html); (right) *Trichomonas vaginalis*, note the undulating membrane extends about half the length of the body (arrow). (Lower, left) *P. hominis*, note undulating membrane extends the entire length of the body (arrow); (right) *P. hominis*, note the axostyle (supporting rod) protruding from the bottom (arrow). In this example, no undulating membrane or flagella are visible (Wheatley's trichrome stain). doi:10.1128/9781555819002.ch22.f9



Diagnosis

In freshly passed stool specimens, particularly in unformed stool, motility may be visible. In a wet preparation, one specifically looks for the flagellar movement from the undulating membrane and the presence of the axostyle. These small flagellates are difficult to stain and may even be missed on a permanent stained smear, especially if the stain is pale. In more formed stools, the trophozoites may round up (not encysted) and may not exhibit the characteristic motility seen in more active forms. When preserved fecal specimens are received in the laboratory, the permanent stained smear is the most sensitive method for finding and identifying *P. hominis*.

Misdiagnosis in Urinalysis

It is important to remember that *Trichomonas vaginalis* is often diagnosed in urine via the organism motility. Since the finding of *T. vaginalis* in the urine of children can imply the possibility of a sexual transmission, it is very important to keep in mind the possibility of fecal contamination within a child's urine due to collection issues. Thus *P. hominis* (nonpathogen in stool) could accidentally be misdiagnosed as *T. vaginalis* (pathogen/sexually transmitted flagellate) in urine. ANY DIAGNOSIS OF *T. VAGINALIS* IN A CHILD'S OR INFANT'S URINE SHOULD ALWAYS BE CONFIRMED; the misdiagnosis of *P. hominis* as *T. vaginalis* could be misinterpreted as a possible child abuse case.

Epidemiology and Prevention

Since there is no known cyst stage, transmission probably occurs in the trophic form. If ingested in a protecting substance such as milk, these organisms can apparently survive passage through the stomach and small intestine in patients with achlorhydria. *P. hominis* cannot be transplanted into the vagina, the natural habitat of *T. vaginalis*. Based on diagnostic test results, the incidence of this organism is relatively low, but it tends to be recovered more often than *Enteromonas hominis* or *Retortamonas intestinalis*. However, without the use of the permanent stained smear, the presence of *P. hominis* may be missed. The infection is diagnosed more often in warm climates and in children rather than adults. Because of the fecal-oral transmission route, preventive measures should emphasize improved hygienic and sanitary conditions. Although *P. hominis* is commonly found in dogs, puppies, and cats, there is no documented information related to possible transmission to humans.

Trichomonas tenax

Trichomonas tenax was first recovered from the mouth, specifically in tartar from the teeth. It is worldwide in distribution. There is no known cyst stage (Tables 22.3 and 22.4; Fig. 22.10). The trophozoite has a pyriform shape and is smaller and more slender than that of *P. hominis*. The undulating membrane extends almost the entire length of the body, similar to that seen in *P. hominis* (Fig. 22.11). There is also the typical axostyle and a single nucleus. *T. tenax* cannot survive passage through the stomach and cannot be established in the vagina. Although the exact mode of transmission is not known, it is assumed to be by direct contact or use of contaminated dishes and glasses. Prevalence rates vary from 0 to 25%, depending on opportunities for exposure and on oral hygiene.

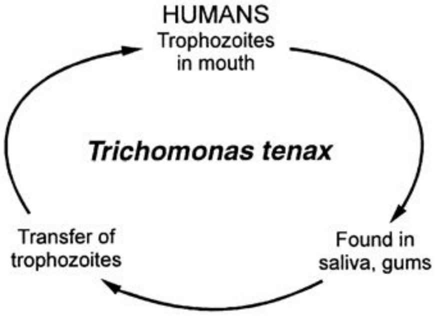


Figure 22.10 Life cycle of *Trichomonas tenax*. doi:10.1128/9781555819002.ch22.f10

Although *T. tenax* was considered a harmless commensal in the mouth, there are reports of periodontal disease, as well as respiratory infections and thoracic abscesses, particularly in patients with underlying cancers or other lung diseases. Studies have reported *T. tenax* as a cause of pleuropulmonary infections in humans. In a study from the Philippines using 18S rRNA amplification and sequencing, *T.*

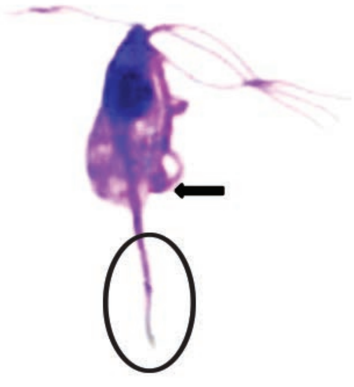

Figure 22.11 *Trichomonas tenax*, specimen from the mouth, Giemsa stain. Note the undulating membrane extends almost the entire length of the body (arrow). Also note the axostyle protruding from the posterior end (oval). In this example, the flagella are clearly visible. doi:10.1128/9781555819002.ch22.f11

tenax was found in 14 sputum specimens, thus confirming the presence of this organism in the respiratory tract of humans (79). Other cases were reported from western Europe. Diagnosis is based on recovery of the organisms from the teeth, gums, tonsillar crypts, or pulmonary specimens, and therapy may or may not be indicated. Better oral hygiene will rapidly eliminate the infection from the mouth.

In another recent study, pleural infection was confirmed with *T. tenax* and a new *Tetratrichomonas* species was also detected in the oral cavity. The name *Tetratrichomonas empyemagena* as been proposed for this species (80).

Chilomastix mesnili

Chilomastix mesnili tends to have a cosmopolitan distribution, although it is found more frequently in warm climates. It has both trophozoite and cyst stages and is somewhat more easily identified than are some of the smaller flagellates such as *E. hominis* and *R. intestinalis* (Tables 22.3 and 22.4; Fig. 22.12). The trophozoite is described as being oval, measuring 6 to 24 µm in length and 4 to 8 µm in width. However, if the more elongate posterior end is not visible, the shape can be almost round. There is a single nucleus and a distinct oral groove or cytostome close to the nucleus (Fig. 22.3 and 22.13). Flagella are difficult to see unless there is obvious motility in a wet preparation. The morphology can be confirmed by using a permanent stained smear, particularly when the cytostome is visible. The cysts are pear or lemon shaped, and they range from 6 to 10 µm in length and 4 to 6 µm in width (Fig. 22.13). There is also a single nucleus in the cyst and the typical curved cytostomal fibril, which is called the shepherd's crook. Again, more definitive morphology can be seen on a permanent stain.

C. mesnili normally lives in the cecal region of the large intestine, where the organisms feed on bacteria and debris. It is considered to be a nonpathogen, and no treatment is recommended. However, as with all nonpathogenic protozoa, they should be reported to the physician; nonpathogens and pathogens are transmitted and acquired the same way. Thus, the result report indicates the patient has acquired something contaminated with fecal material (fecal/oral transmission). Particularly if the patient is symptomatic, additional fecal specimens should be examined for possible pathogens. Since transmission is through ingestion of infective cysts, prevention depends on improved personal hygiene and upgraded sanitary conditions.

Chilomastix mesnili
Enteromonas hominis
Retortamonas intestinalis

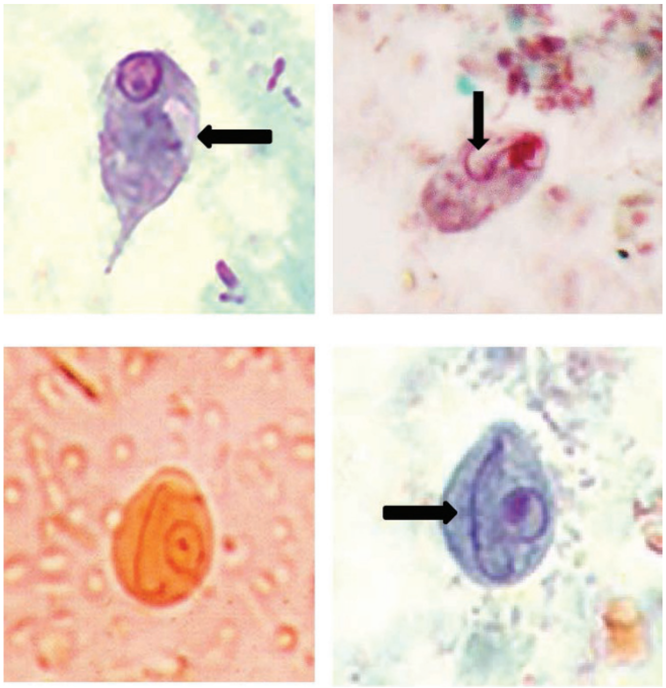

Figure 22.13 *Chilomastix mesnili*. (Upper, left and right) Trophozoites of *Chilomastix mesnili* (note the feeding groove; flagella are not visible) (arrows). (Bottom, left) *C. mesnili* cyst (iodine wet mount; nucleus and curved fibril are visible, as is the lemon shape); (right) *C. mesnili* cyst (note the "lemon or pear" shape and the curved fibril, the shepherd's crook) (arrow).
doi:10.1128/9781555819002.ch22.f13

Enteromonas hominis

The flagellate *E. hominis* is considered to be nonpathogenic and has been reported from both warm and temperate climates (0.2–0.8%) (Tables 22.3 and 22.4; Fig. 22.12). The trophozoites are somewhat pear shaped, measuring approximately 4 to 10 µm by 3 to 6 µm (Fig. 22.3). There is no cytostome, and the flagella are rarely visible unless motile organisms are seen. The cyst measures approximately 6 to 10 µm by 4 to 6 µm and tends to be oval. There are two nuclei, and the cyst may mimic a two-nucleated *E. nana* cyst. However, *E. nana* cysts containing two nuclei are quite rare in most clinical specimens. Also, *E. hominis* is not often reported, perhaps in part because of the small size of the organism and the difficulties in identification. Even on a permanent stained smear, this organism is often difficult to identify accurately. Infection is considered to be caused by ingestion of the infective cysts. No symptoms have been attributed to this infection, and therapy is not indicated.

Retortamonas intestinalis

Retortamonas intestinalis has been recovered from both warm and temperate areas of the world (Fig. 22.12). It has also been found in certain groups such as mental hospital patients. Like *E. hominis*, it is not commonly found in patient stools (Tables 22.3 and 22.4). *R. intestinalis* is also a small flagellate with trophozoites that are elongate pyriform or ovoidal (Fig. 22.3). They measure 4 to 9 µm in length by 3 to 4 µm in width. This flagellate does have a cytostome, which may be difficult to see, even in a permanent stained smear. The cysts are somewhat pear shaped, measuring 4 to 9 µm in length and 4 to 6 µm in width (Fig. 22.3). Both the trophozoite and the cyst have a single nucleus. This organism is rarely found in clinical specimens, possibly in part because of the difficulties in accurate identification of this and other smaller flagellates, even when the permanent stain technique is used. Infection is through ingestion of the cysts, and improved hygienic conditions would certainly prevent spread of the infection. *R. intestinalis* is considered a nonpathogen; thus, no therapy is indicated.

Balantidium coli

Balantidium coli was first isolated by Malmsten in 1857 from the dysenteric stools of two patients and was soon also observed by Leuckart in 1861 and Stein in 1862, who transferred the species to the genus *Balantidium* (prior genera were *Paramoecium*, *Leukophyra*, and *Holophyra*) (1).

B. coli is widely distributed in hogs, particularly in warm and temperate climates, and in monkeys in the tropics. Human infection is found in warmer climates, sporadically in cooler areas, and in institutionalized groups with low levels of personal hygiene. It is rarely recovered in clinical specimens within the United States.

Morphologically similar organisms have been found in a number of mammals, including rats, chimpanzees, orangutans, and, infrequently, dogs or cats. The species found in pigs, *Balantidium suis*, is probably identical to *B. coli* from humans. Other species have been isolated from guinea pigs (*Balantidium caviae*), cockroaches (*Balantidium blattarum*), fish, birds, and amphibia. In all, about 50 species have been described.

Life Cycle and Morphology

B. coli is the only pathogenic ciliate and is the largest of the protozoa that parasitize humans (Tables 22.9 and 22.10; Fig. 22.14). Both the trophozoite and cyst forms are found (81).

Trophozoite. The trophozoite is quite large, oval, and covered with short cilia; it measures approximately 50 to 100 µm in length and 40 to 70 µm in width (Fig. 22.15 and 22.16). The organism can easily be seen in a wet preparation on lower power (10× objective). The anterior end is somewhat pointed and has a cytostome present; in contrast, the posterior end is broadly rounded. The cytoplasm contains many vacuoles with ingested bacteria and debris. There are two nuclei within the trophozoite, a very large bean-shaped macronucleus and a smaller round micronucleus (more difficult to see). The organisms normally live in the large intestine. The motile trophozoite exhibits a rotary-type motion by means of its somatic cilia that may facilitate movement through the contents of the colon.

Cyst. The cyst is formed as the trophozoite moves down the intestine. The process of encystment begins in the colon and rectum of the host, and cysts are generally found in

TABLE 22.9 Intestinal protozoa: ciliate

Balantidium coli	Shape and size	Motility	No. of nuclei	Other features
Trophozoite	Ovoid with tapering anterior end; 50–100 µm in length; 40–70 µm in width (usual range, 40–50 µm)	Ciliates: rotary, boring; may be rapid	1 large kidney-shaped macronucleus; 1 small, round micronucleus, which is difficult to see even in the stained smear; macronucleus may be visible in unstained preparation	Body covered with cilia, which tend to be longer near cytostome; cytoplasm may be vacuolated
Cyst	Spherical or oval; 50–70 µm (usual range, 50–55 µm)		1 large macronucleus visible in unstained preparation; micronucleus difficult to see	Macronucleus and contractile vacuole are visible in young cysts; in older cysts, internal structure appears granular; cilia difficult to see within the cyst wall

TABLE 22.10 Intestinal flagellates and ciliates: recommended diagnostic procedures

Organism	Specimen	Diagnostic procedure
Giardia lamblia (*G. duodenalis*, *G. intestinalis*)	Stool	Complete ova and parasite exam, fluorescent antibody, enzyme and immunochromatographic immunoassays; approved molecular tests/instruments
	Duodenal contents	Wet preparation and permanent stains
	Entero-Test	Wet preparation and permanent stains
	Aspirate	Wet preparation and permanent stains
	Biopsy	Routine histology
Dientamoeba fragilis	Stool	Complete ova and parasite exam
Enteromonas hominis	Stool	Complete ova and parasite exam
Retortamonas intestinalis	Stool	Complete ova and parasite exam
Chilomastix mesnili	Stool	Complete ova and parasite exam
Pentatrichomonas hominis (*Trichomonas hominis*)	Stool	Complete ova and parasite exam
Trichomonas tenax	Gingival scrapings	Wet preparation and permanent stains
	Pyorrheal material	Wet preparation and permanent stains
	Pulmonary specimens	Wet preparations and permanent stains
Balantidium coli	Stool	Complete ova and parasite exam
	Pulmonary specimens[a]	Wet preparations and permanent stains
	Biopsy	Routine histology

[a] It is very important to differentiate between ciliated epithelial cells and trophozoites of *B. coli*. Bronchoalveolar wash fluid often contains these ciliated human cells, which can easily be confused with ciliates in wet preparations.

formed feces. Nuclear division does not occur in the cyst; therefore, only two nuclei are present, the macronucleus and the micronucleus (Fig. 22.15 and 22.16). The cysts measure from 50 to 70 μm in diameter.

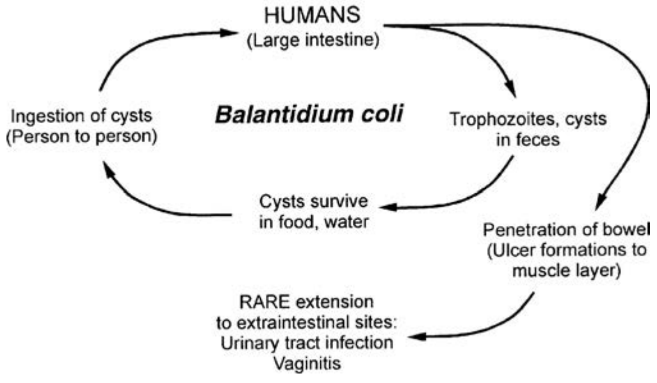
Clinical Disease

Some individuals with *B. coli* infections are totally asymptomatic, whereas others have symptoms of severe dysentery similar to those seen in patients with amebiasis. Although many patients are asymptomatic, malnutrition, alcoholism, or a compromised immune system can favor the parasite.

Symptoms usually include diarrhea or dysentery, tenesmus, nausea, vomiting, anorexia, and headache. Insomnia, muscular weakness, and weight loss have also been reported. The diarrhea may persist for weeks to months prior to the development of dysentery. There may be tremendous fluid loss, with a type of diarrhea similar to that seen in cholera or in some coccidial or microsporidial infections. Following ingestion, excystation releases trophozoites that invade the colonic mucosa, multiply, and form colonies. Within the tissue, *B. coli* propagates and may produce ulcers and abscesses that extend to the muscular layer. The symptoms of *B. coli*-induced colitis may be confused with amebic colitis. If extensive damage occurs in the wall of the colon, red blood cells may be seen within the trophozoites, as well as in the stool. *B. coli* produces no known toxins, but the ability to produce colonic ulcers is attributed to hyaluronidase, which is an enzyme that digests hyaluronic acid, a component of the "glue" holding mucosal epithelial cells together.

On contact with the mucosa, *B. coli* may penetrate the mucosa with cellular infiltration in the area of the developing ulcer (Fig. 22.17). Some of the abscess formations may extend to the muscular layer. The ulcers may

Figure 22.14 Life cycle of *Balantidium coli*.
doi:10.1128/9781555819002.ch22.f14



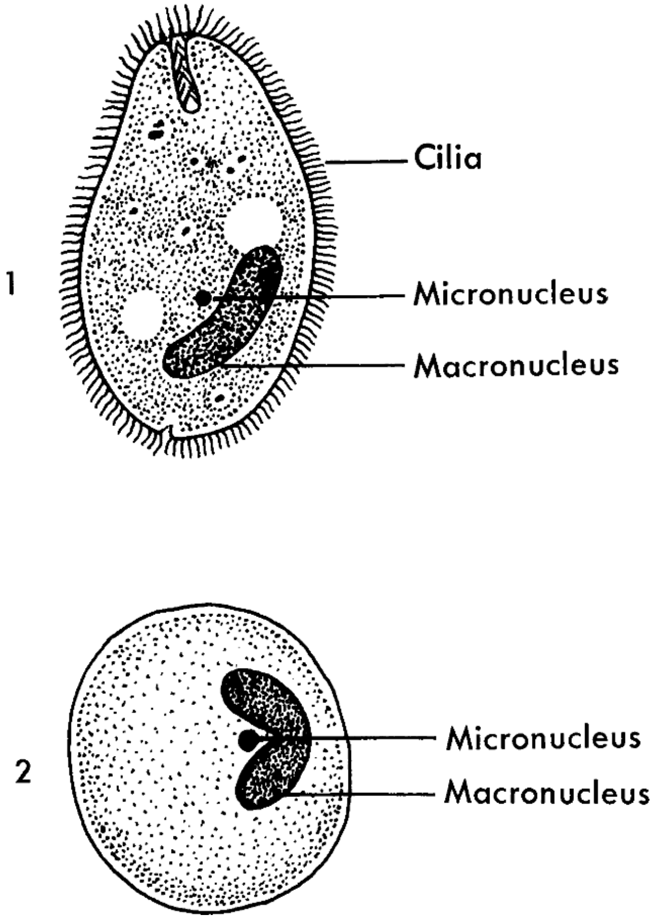


Figure 22.15 (1) Trophozoite of *Balantidium coli*; (2) cyst of *B. coli*. doi:10.1128/9781555819002.ch22.f15

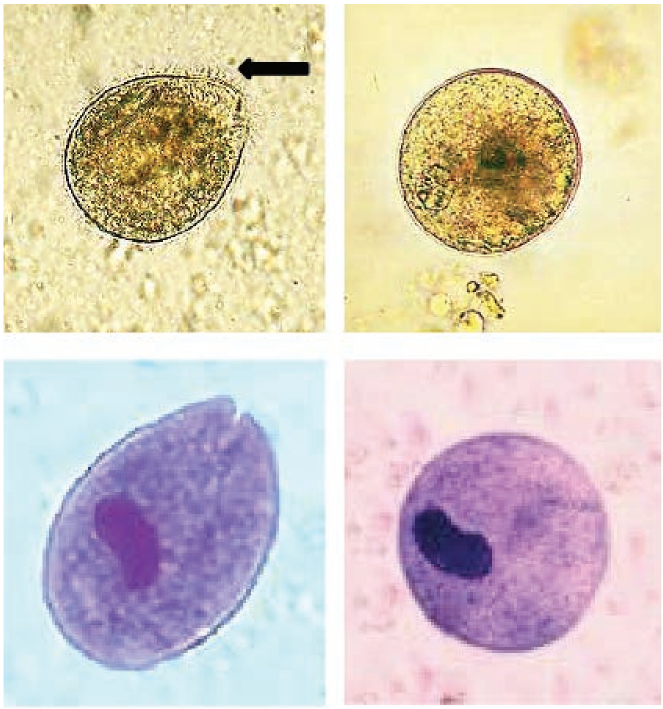

Figure 22.16 *Balantidium coli.* (Upper, left) Trophozoite in wet mount (note surrounding cilia shadows) (arrow); (right) cyst in wet mount (note the macronucleus is visible, but no cilia are visible within the cyst wall). (Lower, left) Trophozoite, stained, note the large macronucleus (in some permanent stained smears, the organism stains so dark, it will mimic a helminth egg); (right) cyst, stained (note very dark macronucleus, micronucleus is usually not visible within the trophozoite or cyst). doi:10.1128/9781555819002.ch22.f16

vary in shape, and the ulcer bed may be full of pus and necrotic debris. Although the number of cases is small, extraintestinal disease has been reported (peritonitis, urinary tract infection, inflammatory vaginitis, pulmonary hemorrhage and respiratory failure, and vertebral osteomyelitis and myelopathy).

Immunocompromised individuals have developed balantidiosis without any direct contact with pigs, perhaps with rats or contaminated produce as a possible source of infection. For the clinician, this infection should be included in the differential diagnosis for persistent diarrhea in travelers to or from Southeast Asia, the Western Pacific islands, rural South America, or communities where close contact with domestic swine occurs.

Death rarely occurs, but in developing countries with undernourished and overparasitized populations, this infection can make the difference between a healthy life and chronic debilitation. It has been suggested that there may be virulent and avirulent stains of *B. coli*; however, no solid evidence of this fact has been documented.

Diagnosis

Routine Stool Examination. Routine stool examinations, particularly wet-preparation examinations of fresh and concentrated material, will demonstrate the organisms. Organism recognition and identification on a permanent stained smear may be very difficult. These protozoa are so large that they tend to stain very darkly, thus obscuring any internal morphology. *B. coli* organisms may even be confused with helminth eggs because of their size, particularly when the cilia are not visible. The recovery of *B. coli* from specimens within the United States is rare. Nonetheless, laboratories are expected to be able to identify these organisms and are called upon to do so with proficiency-testing specimens.

Pulmonary Specimen Wet Preparations. Diagnosing lung infections with *B. coli* can be difficult due to possible confusion between ciliated epithelial cells and ciliate trophozoites. Bronchoalveolar wash fluid containing *Balantidium* may

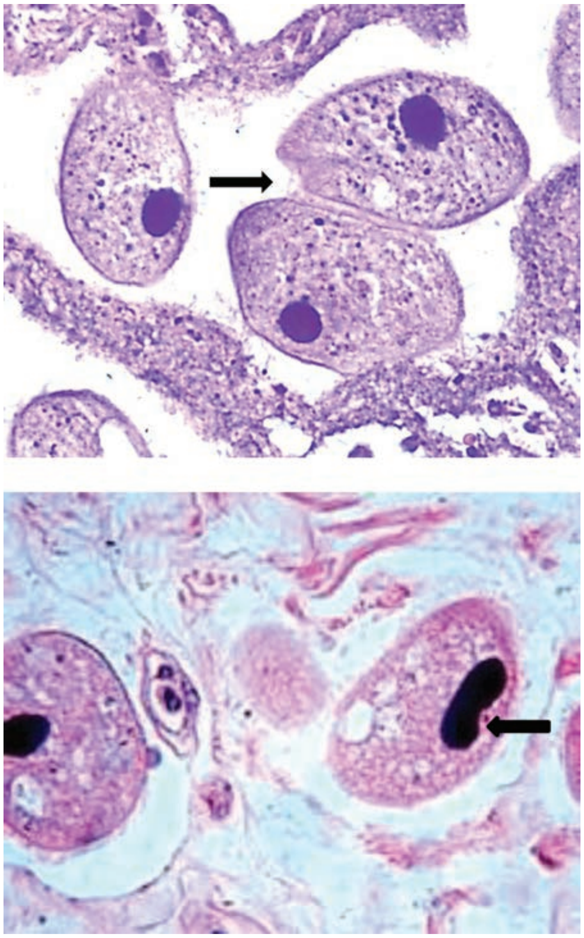

Figure 22.17 Trophozoites of *Balantidium coli*. (Upper) Tissue of pig large intestine. The cilia are visible surrounding the trophozoites; also note the oral groove (arrow). (Image courtesy of Dr. Forey, Veterinary Medicine, Washington State University/Pullman.) (Lower) Trophozoite in human colon (note large macronucleus; some cilia are visible on the lower trophozoite [arrow]). (Image courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch22.f17

also contain motile ciliated human cells from the trachea that can be mistaken for ciliates in wet mounts. A ciliated epithelial cell has few cilia on the surface compared to the uniformly ciliated surface of a *B. coli* trophozoite. Also, the cilia may be clumped in the case of columnar epithelial cells. Ciliated human cells generally measure <30 µm, while *B. coli* measures 150 to 200 µm, is elongated rather than ovoid, and is more likely to swim aimlessly in circles, unlike the pronounced spiraling movements of ciliates (81).

KEY POINTS—LABORATORY DIAGNOSIS

Balantidium coli

1. Since the organisms are so large, they can frequently be seen under low power (100×, 10× objective), particularly in a concentration sediment wet mount.
2. If fecal specimen wet mounts are examined using high dry power (400×, 40× high dry objective), the organisms may be confused with vegetable cells (both cells and parasites are larger than other intestinal protozoa). The cilia tend to be short and can be missed on microscopic examination.
3. Although this infection is very rare within the United States, all laboratories may receive positive specimens for proficiency testing; generally the specimens are designed to be examined as wet mounts only.
4. These organisms do not stain well (too large and thick) on the permanent stained smear (particularly if the smear is thick) and can be confused with fecal debris (including helminth eggs), hence the need to make the diagnosis by using wet smears (from direct mounts or concentrate sediment).
5. If pulmonary specimens are received, it is very important to differentiate between ciliated epithelial cells and true *B. coli* trophozoites.

Treatment

For treatment of *B. coli*, tetracycline is the drug of choice, although it is considered investigational for this infection. Iodoquinol or metronidazole may be used as alternatives. Additional information can be found in chapter 36.

Epidemiology and Prevention

Although *B. coli* has been found in many different simian hosts, domestic hogs probably serve as the most important reservoir host for human infection. In areas where pigs are the main domestic animal, the incidence of human infection can be quite high. Particularly susceptible to infection are persons working as pig farmers or in slaughterhouses (28% infection in New Guinea). Human infection is fairly rare in temperate areas, although once the infection is established, it can develop into an epidemic, particularly in areas with poor environmental sanitation and personal hygiene. This situation has been seen in mental hospitals in the United States. Preventive measures involve increased attention to personal hygiene and sanitation measures, since the mode of transmission is ingestion of infective cysts through contaminated food or water.

Intestinal Protozoa (Coccidia), Microsporidia, and Algae

Coccidia
Cryptosporidium spp.
Cyclospora cayetanensis
Cystoisospora (*Isospora*) *belli*
Sarcocystis spp.
Microsporidia
Algae (*Prototheca*)

Coccidia

Although most readers understand the main categories related to parasitology classification, the coccidia and microsporidia can be somewhat confusing; a few comments as review may be helpful. The major phyla of protozoa include Sarcomastigophora (includes the amebae and flagellates), the Apicomplexa (malaria parasites, coccidia, and *Babesia*), and the Ciliophora (*Balantidium coli*). Several protozoan genera are included in the phylum Apicomplexa and are referred to as coccidia. All organisms included in the Apicomplexa are unicellular, with an apical complex typically composed of polar rings, rhoptries, micronemes, and usually a conoid; subpellicular microtubules and micropores are common. These structures can be seen in electron microscopy (EM) studies and are used to help classify the various coccidia. Genera that develop in the gastrointestinal tract of vertebrates throughout their entire life cycle include *Eimeria*, *Cystoisospora*, *Cyclospora*, and *Cryptosporidium*. Those that are capable of or require extraintestinal development are referred to as cyst-forming coccidia and include *Besnoitia*, *Caryospora*, *Frenkelia*, *Hammondia*, *Neospora*, *Sarcocystis*, and *Toxoplasma*. The coccidian genera that cause disease in humans include *Cryptosporidium*, *Cyclospora*, *Cystoisospora*, *Sarcocystis*, and *Toxoplasma* (see chapter 25 for a discussion of *Toxoplasma*).

Cryptosporidium spp.

The first reported description of *Cryptosporidium parvum* was in 1907 in the gastric crypts of a laboratory mouse (Tyzzer). Subsequently, it has been found in chickens, turkeys, mice, rats, guinea pigs, horses, pigs, calves, sheep, rhesus monkeys, dogs, cats, kangaroos, lizards, snakes, and humans (Table 23.1) (1–4). Information also supports previous suggestions that cryptosporidiosis is a zoonosis, is not host specific, and is transmitted via the fecal-oral route (4). What was previously called *Cryptosporidium parvum* and was thought to be the primary *Cryptosporidium* species infecting humans is now classified as two separate species, *C. parvum* (mammals, including humans) and *Cryptosporidium hominis* (primarily humans) (3) (Table 23.1). Differentiation of these two species based on oocyst morphology is not possible using routine stains.

doi:10.1128/9781555819002.ch23

TABLE 23.1 Current species names within the genus *Cryptosporidium*[a]

Species	Main host(s)	Less common host(s)
C. andersoni	Cattle, Bactrian camels	Sheep
C. baileyi	Chicken, turkeys	Cockatiels, quails, ostriches, ducks
C. bovis	Cattle	
C. canis	Dogs	Humans
C. fayeri	Kangaroos (red kangaroo)	
C. felis	Cats	Humans, cattle
C. fragile	Asian toad	
C. galli	Finches, chicken, capercaillies, grosbeaks	
C. hominis	Humans, monkeys	Dugongs, sheep
C. macropodum	Kangaroos (grey kangaroo)	
C. meleagridis	Turkeys, humans	Parrots
C. molnari	Fish	
C. muris	Rodents, Bactrian camels	Humans, rock hyrax, mountain goats
C. parvum	Cattle, sheep, goats, humans	Deer, mice, pigs
C. pestis	Cattle	
C. ryanae	Cattle	
C. saurophilum	Lizards	Snakes
C. scophthalmi	Fish	
C. serpentis	Snakes, lizards	
C. suis	Pigs	
C. waranii	Monitor lizards	
C. wrairi	Guinea pigs	

[a] Adapted from references 1–4.

Cryptosporidium infection is now well recognized as causing disease in humans, particularly in those who are in some way immunosuppressed or immunodeficient. *Cryptosporidium* has been implicated as one of the more important opportunistic agents seen in patients with AIDS (3–5). Also, reports of respiratory tract and biliary tree infections confirm that the developmental stages of this organism are not always confined to the gastrointestinal tract.

Unfortunately, at the time of this writing, no totally effective therapy for cryptosporidiosis has been identified, despite the testing of over 100 drugs. In the 25 years since the emergence of cryptosporidiosis as a significant disease, particularly in individuals with HIV/AIDS and other immunodeficient individuals, little progress has been made with the development of effective treatments. However, the sequencing of the genomes of *C. parvum* and *C. hominis* has led to the identification of new molecular targets for possible drug development. Currently, the literature contains over 4,500 published papers related to cryptosporidiosis, including information on nosocomial transmission, day care center outbreaks, and a number of waterborne outbreaks. This is remarkable, since fewer than 30 publications were available prior to 1980. In response to this rapidly expanding area of parasitology, there have been definite improvements in diagnostic procedures, particularly those involving the newer immunoassay detection kits (4, 6, 7).

The pathogenesis of cryptosporidial diarrhea, even in patients with AIDS, is not fully understood. However, patients with no intestinal symptoms who are passing formed stool containing few oocysts contrast sharply with those who are symptomatic with watery diarrhea and are passing large numbers of oocysts. These findings imply a relationship between intestinal dysfunction and injury and the number of organisms infecting the intestinal mucosa.

Age and immune status at the time of primary exposure to *Cryptosporidium* do not appear to be primary factors influencing the susceptibility of humans to infection. Symptomatic intestinal and respiratory cryptosporidiosis has been seen in both immunocompetent and immunodeficient patients of all ages. However, once the primary infection has been established, the immune status of the host plays a very important role in determining the length and severity of the illness. People who are immunocompetent usually develop a short-term, self-limited diarrhea lasting approximately 2 weeks.

In contrast, those who are immunocompromised initially develop the same type of illness; however, it becomes more severe with time and results in a prolonged, life-threatening, cholera-like illness. These severe infections have been seen in patients undergoing immunosuppressive chemotherapy with drugs that affect both T- and B-lymphocyte function, in patients with hypogammaglobulinemia, and in those with AIDS. From many observations of these types of patients, the difference in outcome can probably be explained by the development, in the immunocompetent host, of an immune response sufficient to eradicate the parasite from the infected individual. This explanation is also supported by the fact that individuals whose immunosuppressive therapy has been discontinued will rapidly clear the body of *Cryptosporidium* once their immune system function is restored. Studies also suggest that the overall immune response to cryptosporidiosis is probably an antibody-dependent, cell-mediated, cytotoxic effect of unknown mechanism. Patients with $CD4^+$ counts of less than 50 cells/mm^3 can develop persistent or intractable diarrhea, thus emphasizing the importance of the host immune response in controlling the disease.

Life Cycle and Morphology

Cryptosporidium differs from other coccidia infecting warm-blooded vertebrates in that its developmental stages do not occur deep within host cells but are confined to

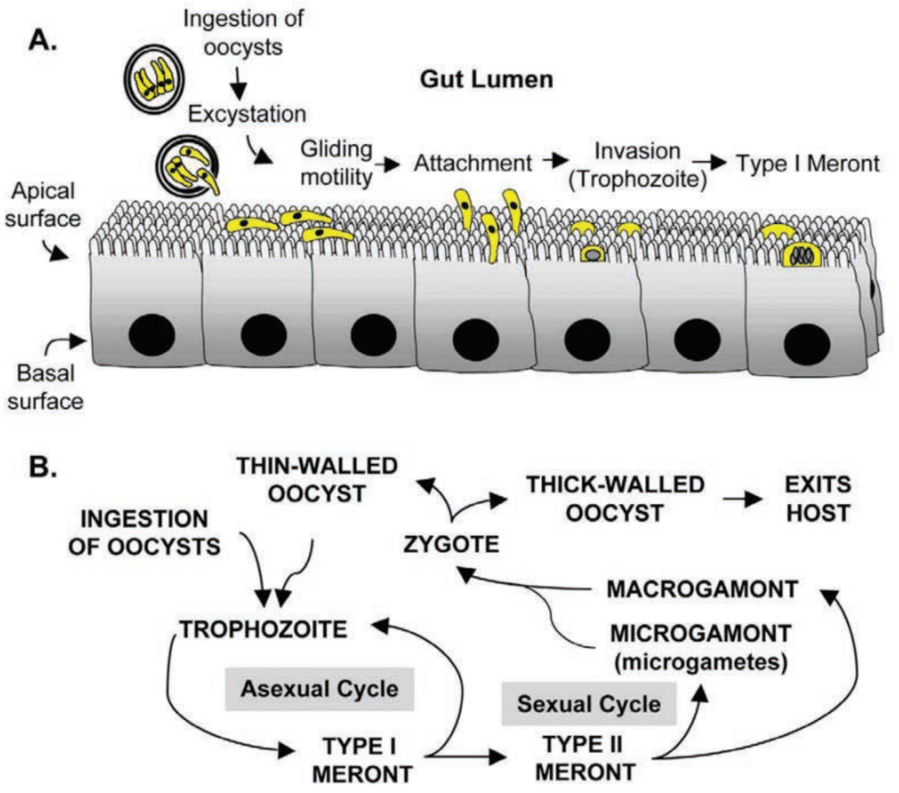

Figure 23.1 Life cycle of *Cryptosporidium* spp. illustrating various stages. (Illustration by Sharon Belkin.)
doi:10.1128/9781555819002.ch23.f1

an intracellular, extracytoplasmic location. Each stage is within a parasitophorous vacuole of host cell origin; however, the vacuole containing the organism is located at the microvillous surface of the host cell. Details of the life cycle can be seen in Fig. 23.1 and 23.2 (8).

The presence of a thin-walled, autoinfective oocyst may explain why a small inoculum can lead to an overwhelming infection in a susceptible host and why immunosuppressed patients may have persistent, life-threatening infections in the absence of documentation of repeated exposure to oocysts (Fig. 23.2). The stages found on the microvillous surface measure 1 μm, and the oocysts recovered in stool specimens measure 4 to 6 μm (Table 23.2; Fig. 23.3).

Each intracellular stage of *Cryptosporidium* resides within a parasitophorous vacuole within the microvillous region of the host cell. Oocysts undergo sporogony while they are in the host cells and are immediately infective when passed in the stool. This is in contrast to the oocysts of *Cystoisospora* (*Isospora*) *belli*, which do not sporulate until they are passed from the host and are exposed to oxygen and temperatures below 37°C. Approximately 20% of the oocysts of *Cryptosporidium* do not form the thick, two-layered, environmentally resistant oocyst wall. The four sporozoites within this autoinfective stage are surrounded by a single-unit membrane. After being released from a host cell, this membrane ruptures and the invasive sporozoites penetrate the microvillous region of other cells within the intestine and reinitiate the life cycle. As mentioned above, these thin-walled oocysts that can recycle are thought to be responsible for the development of severe, life-threatening disease in immunocompromised patients, even those who are no longer exposed to the environmentally resistant oocysts.

The prepatent period from the time of ingestion of as few as 10 infective oocysts to completion of the life cycle with excretion of newly developed oocysts in the human is approximately 4 to 22 days. The patent period during excretion of oocysts can range from 1 to 20 days in humans. Previous studies have suggested that persons infected with *Cryptosporidium* develop antibody responses to several antigens. Results now suggest that characteristic antibody responses develop following infection and that persons with preexisting antibodies may be less likely to develop illness, particularly when infected with low oocyst doses (4, 5).

Oocysts recovered in clinical specimens are difficult to see without special staining techniques, such as the modified acid-fast, Kinyoun, and Giemsa methods, or the fecal immunoassay methods. The four sporozoites may be seen within the oocyst wall in some of the organisms, although they are not always visible in freshly passed specimens (Fig. 23.4). The oocysts are immediately infective, regardless of whether or not the sporozoites are seen within every oocyst.

Figure 23.2 Life cycle of *Cryptosporidium* spp. (Adapted from Current WL, Garcia LS. *Clin Microbiol Rev* **4**:325–358, 1991.) doi:10.1128/9781555819002.ch23.f2

Information Based on EM. The oocyst wall has distinct inner and outer layers and is unique in having a suture at one end; the suture dissolves during excystation, opening the wall, through which the sporozoites leave the oocyst. Excystation of sporozoites is enhanced by exposure to reducing conditions followed by exposure to pancreatic enzymes and/or bile salts. Data suggest that a novel parasite protein, CP47, may play an important role in attachment of sporozoites to the host cell; this protein exhibits significant binding affinity for the surfaces of both human and animal ileal cells. Both sporozoites and merozoites appear similar to those of other coccidia, with organelles such as the pellicle, rhoptries, micronemes, electron-dense granules, nucleus, ribosomes, subpellicular microtubules, and apical rings. Once they are inside the parasitophorous vacuole, changes in the apex of the host cell and the parasite result in an attachment or feeder organelle. The fertilized macrogamont, or zygote, develops into an oocyst with either a thick wall (80%, which are passed in the stool) or a thin wall (20%, which remain internal, causing internal autoinfection). The zygotes that develop into thin-walled oocysts do not contain the characteristic wall-forming bodies. The thick-walled oocysts are characterized by having a thin, moderately coarse outer layer and a finely granular inner layer. Between these two layers of the oocyst wall is an electron-lucent zone that consists of the two oocyst membranes sandwiched between the outer and inner layers of the oocyst wall. The outer layer of the wall is continuous and of a uniform thickness, while the inner layer contains a suture at one pole.

Clinical Disease

Immunocompetent Individuals. Clinical symptoms include nausea, low-grade fever, abdominal cramps, anorexia, and 5 to 10 watery, frothy bowel movements per day, which may be followed by constipation. Some patients may present with diarrhea as described above, and others may have relatively few symptoms, particularly later in the course of the infection. In patients with the typical watery diarrhea, the stool specimen contains very little fecal material but consists mainly of water and mucus flecks. Often the organisms are entrapped in the mucus, and diagnostic procedures are performed accordingly. Generally, a patient with a normal immune system has a self-limited infection; however, patients who are compromised may have a chronic infection with a wide range of symptoms (asymptomatic to severe).

Occasionally, these patients require fluid replacement and the diarrhea persists for more than 2 weeks. This is particularly true of infants, in whom excessive fluid loss

TABLE 23.2 Coccidia

Species	Shape and size	Other features
Cryptosporidium spp.	Oocyst generally round, 4–6 μm, each mature oocyst containing sporozoites	Oocyst usual diagnostic stage in stool; various other stages in life cycle can be seen in biopsy specimens taken from gastrointestinal tract (brush border of epithelial cells, intestinal tract) and other tissues (respiratory tract, biliary tract)
Cyclospora cayetanensis	Organisms generally round, 8–10 μm; they mimic *Cryptosporidium* spp. (acid fast) but are larger	In wet smears they look like nonrefractile spheres; they will also autofluoresce with epifluorescence; are acid-fast variable from no color to light pink to deep red; those that do not stain may appear wrinkled; in a trichrome-stained stool smear, they will appear as clear, round, somewhat wrinkled objects; they cause diarrhea in both immunocompetent and immunosuppressed patients
Cystoisospora (*Isospora*) *belli*	Ellipsoidal oocyst; usual range, 20–30 μm long and 10–19 μm wide; sporocysts rarely seen broken out of oocysts but measure 9–11 μm	Mature oocyst contains 2 sporocysts with 4 sporozoites each; usual diagnostic stage in feces is immature oocyst containing spherical mass of protoplasm (diarrhea, intestinal tract)
Sarcocystis hominis, *S. suihominis*, *S. bovihominis*	Oocyst thin-walled and contains 2 mature sporocysts, each containing 4 sporozoites; thin oocyst wall frequently ruptures; ovoid sporocysts each measure 9–16 μm long and 7.5–12 μm wide	Thin-walled oocyst or ovoid sporocysts occur in stool (intestinal tract)
S. "lindemanni"	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary considerably	Sarcocysts contain several hundred to several thousand trophozoites, each of which measures 4–9 μm in width and 12–16 μm in length; the sarcocysts may also be divided into compartments by septa, not seen in *Toxoplasma* cysts (tissue/muscle)

may last for over 3 weeks. In general, when CD4$^+$ cells are present at levels greater than 200/μl, infections are acute and resolve in approximately 2 weeks; however, when the CD4$^+$ cell count drops below 200/μl, the infection may be chronic and may not resolve.

Based on questions that arose from the 1993 Milwaukee outbreak, regarding appropriate management and prognosis of patients with inflammatory bowel disease who are infected with *Cryptosporidium*, it is clear that cryptosporidiosis may present as an acute relapse of inflammatory bowel disease and responds to standard therapy. Antibiotics confer no benefit. It appears that immunosuppressive therapy does not predispose to chronic or severe illness in these patients. Cryptosporidiosis may present with acute findings initially mimicking Crohn's disease. The total cost of outbreak-associated illness during the Milwaukee outbreak was $96.2 million: $31.7 million in medical costs and $64.6 million in productivity losses. The average total costs for persons with mild, moderate, and severe illness were $116, $475, and $7,808, respectively. The authors also comment that these cost-of-illness estimates are conservative (10).

Failure to thrive has also been attributed to chronic cryptosporidiosis in infants. Since diarrheal illness is a major cause of morbidity and mortality in young children living in developing countries, it is likely that cryptosporidiosis plays a major role in the overall health status of these children. Apparently, cryptosporidiosis has a lasting adverse effect on linear growth (height), especially when acquired during infancy and when children are stunted before they become infected. It has also been suggested that *Cryptosporidium* may be implicated in the respiratory disease that often accompanies diarrheal illness in malnourished children. Those with respiratory infections tend to have coughing, wheezing, croup, hoarseness, and shortness of breath.

Histologically, enteric infections are characterized by villous atrophy, enlarged crypts, and infiltration of the lamina propria by inflammatory cells. Respiratory infections have been characterized by infiltration of the lamina propria by inflammatory cells, loss of cilia, hyperplasia, and hypertrophy of epithelial cells. Similar inflammatory cell infiltration has also been reported for infections involving other organs.

Immunocompromised Individuals. *AIDS (intestinal disease).* The duration and severity of diarrheal illness depend on the immune status of the patient. Most severely immunocompromised patients cannot overcome the infection, the illness becomes progressively worse with time, and the sequelae may be a major factor leading to death. The length and severity of illness may also depend on the ability to reverse the immunosuppression. In these patients, *Cryptosporidium* infections are not always confined to the gastroin-

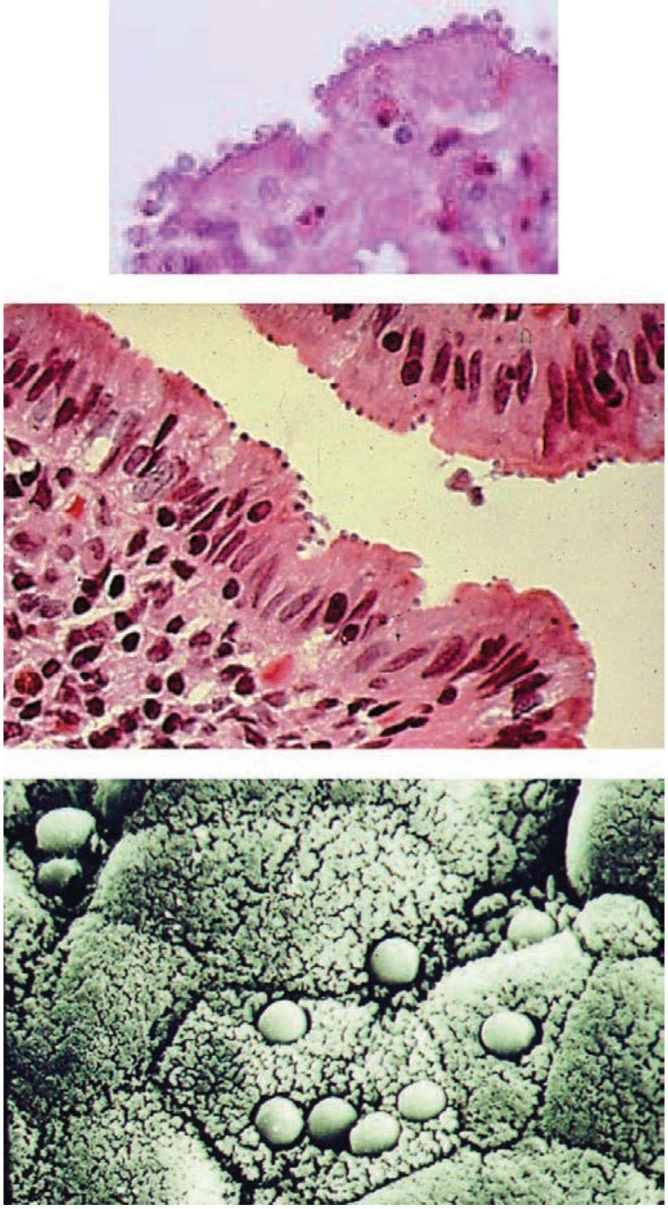

Figure 23.3 *Cryptosporidium* spp. (Top) Organisms on the brush border of the mucosal surface (courtesy of Armed Forces Institute of Pathology). (Middle) Organisms on the brush border of the mucosal surface. (Bottom) Organisms on the mucosal surface, human tissue (scanning electron micrograph, ×4,000). (Courtesy of Marietta Voge.) doi:10.1128/9781555819002.ch23.f3

testinal tract; additional symptoms (respiratory problems, cholecystitis, hepatitis, and pancreatitis) have been associated with extraintestinal infections. While the clinical features of sclerosing cholangitis secondary to opportunistic infections of the biliary tree in patients with AIDS are well known, the mechanisms by which pathogens such as *Cryptosporidium* actually cause disease are unclear.

In reviewing data from patients with gastric cryptosporidiosis, no clear correlation was found between endoscopy and histologic findings; however, a close correlation between the intensity of the infection and the degree of histologic alterations was observed (5). These findings suggest that in patients with AIDS, cryptosporidiosis, and severe immunodepression, upper endoscopy with random gastric biopsies should be performed, even in the absence of endoscopically identified lesions. The diagnosis of gastric cryptosporidiosis relies on histologic findings; pathologists need to be aware that *Cryptosporidium* organisms are found mainly in areas showing reactive hyperplasia.

When reviewing data from AIDS patients with four clinical syndromes, i.e., chronic diarrhea (36%), cholera-like disease (33%), transient diarrhea (15%), and relapsing illness (15%), there is no statistically significant correlation between the histologic intensity of infection and the clinical severity of illness. However, infected patients had a much shorter survival time than did *Cryptosporidium*-negative AIDS patients, and survival was independent of sex, race, or injection drug use (5).

Patients with CD4 counts of 180/µl or greater can usually clear the infection with *Cryptosporidium* over a period of 7 days to 1 month. These data are important in predicting the natural progression of the infection and in designing therapeutic trials. Frequent diagnosis of *Cryptosporidium* infection in patients with neoplasia and diarrhea who are undergoing chemotherapy suggests that for this patient group it is appropriate to routinely submit fecal specimens for examination for oocysts and that the cost of laboratory testing is justified.

AIDS (biliary tract disease). Sclerosing cholangitis is well known as a complication of AIDS. Direct cytopathic effects are noted in infected monolayers (human biliary epithelial cell line) and are associated with widespread programmed cell death (apoptosis) beginning within hours after exposure to the organism. This finding of specific cytopathic invasion of biliary epithelia by *Cryptosporidium* may be relevant to the pathogenesis and possible therapy of secondary sclerosing cholangitis seen in AIDS patients with biliary cryptosporidiosis. It appears that more severely immunocompromised individuals are more likely to exhibit biliary tract disease.

AIDS (pancreatitis). In AIDS patients with pancreatitis, cellular changes are generally not severe, and these patients exhibit hyperplastic squamous metaplasia. The patients usually present with abdominal pain resistant to analgesics, elevated serum amylase levels, and abnormalities on sonography and computed tomography. It is difficult to clarify the impact of cryptosporidiosis-related pancreatic disease, and this disease complication is apparently not linked to significant morbidity.

AIDS (respiratory tract disease). Because many patients with respiratory cryptosporidiosis also have other pathogens present, it is difficult to determine the significance of this complication in AIDS patients. Certainly for patients with respiratory symptoms, it is important to examine sputum as well as stool specimens to confirm the diagnosis.

Primary immunodeficiency diseases. Many different primary immunodeficiency diseases have been described; ingeneral, they can be categorized as follows: combined immunodeficiencies (which impact both T and B lymphocytes); antibody deficiencies; complement deficiencies; and defects in phagocytes (decreased number and function). In general, the number of these cases reported in relation to cryptosporidiosis is few; however, the most serious immunodeficiency in terms of risk is severe combined immunodeficiency syndrome. These patients are at risk for disseminated disease; often the prognosis is poor.

Malignant disease. Although cryptosporidiosis can be seen in patients with malignant disease, infection with *Cryptosporidium* spp. does not appear to pose a special risk. Exceptions to this general statement seem to involve leukemia and other hematologic malignancies (5). Certainly there is more interest in patients who are candidates for bone marrow transplantation, particularly when assessing possible risks related to cryptosporidiosis.

Solid-organ transplant patients. Cryptosporidiosis has been found in liver, kidney, lung, and cardiac transplant recipients, as well as following small bowel transplantation (5, 11–13). In most cases the cryptosporidiosis was not unusually severe and did not involve dissemination to extraintestinal sites. However, in children, the symptoms may be more severe; after therapy with nitazoxanide for a maximum of 21 days, all patients recovered (12).

Diagnosis

Routine. Previously, many human cases were diagnosed after examination of small or large bowel biopsy material, often under both light microscopy and EM (Fig. 23.3). However, because biopsies may miss the infected area of the mucosa, cases have recently been diagnosed by recovering oocysts from fecal material by a flotation method; several other previously reported cases were also diagnosed by using fecal concentrates (Table 23.3). Fresh fecal specimens can be concentrated by using Sheather's sugar solu-

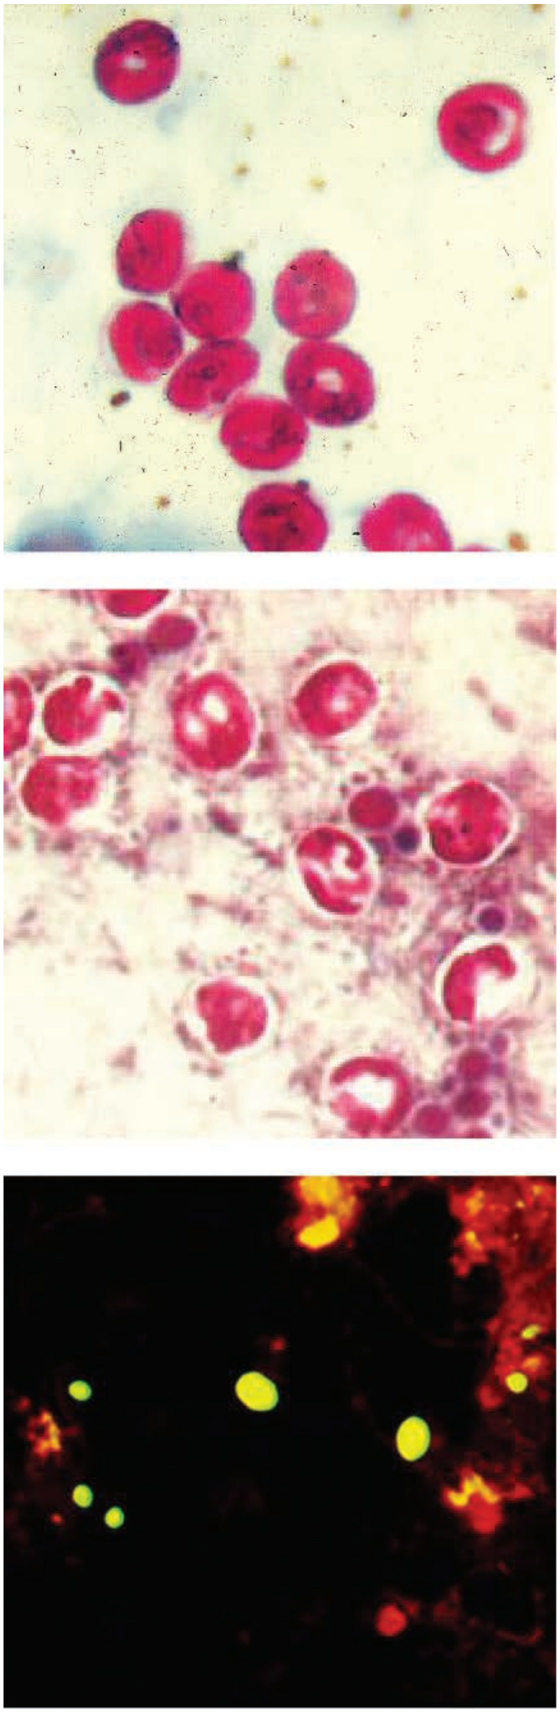

Figure 23.4 *Cryptosporidium.* (Top, middle) Oocysts from stool, stained with modified acid-fast stain. Note that in the middle image some of the sporozoites are visible within the oocyst wall. Although the sporozoites are not always seen, the oocysts are immediately infectious when passed. (Bottom) *Cryptosporidium* and *Giardia* with combination FA reagent (large organisms are *Giardia*, small organisms are *Cryptosporidium*).

TABLE 23.3 Intestinal coccidia: recommended diagnostic procedures[a]

Organism	Specimen	Diagnostic procedure
Cryptosporidium spp.	Stool	Modified acid-fast stains, fluorescent stains, immunoassays; molecular test or instrumentation
	Sputum	Immunoassays, modified acid-fast stains
	Scraping	Modified acid-fast stains or routine histology
	Biopsy specimen	Routine histology
Cyclospora cayetanensis	Stool	Modified acid-fast stains, autofluorescence
	Biopsy specimen	Routine histology
Cystoisospora belli	Stool	Concentration sedimentation and modified acid-fast stains
	Biopsy specimen	Routine histology
Sarcocystis spp.	Stool	Concentration sedimentation and special stains
	Biopsy	Routine histology

[a] When using immunoassay reagents (FA) or modified acid-fast stains for organism detection, these procedures should be performed with centrifuged stool (500 × *g* for 10 min). When using immunoassay reagents for antigen detection (EIA, rapids), centrifugation of the fecal specimen is not required. Procedure directions must be checked, and compatibility issues between the kit reagents and stool preservatives must be kept in mind.

tion, and coverslip preparations can be examined by both phase-contrast and bright-field microscopy. The oocysts will float, and one must focus directly under the glass coverslip. Most laboratories no longer use this approach and have switched to modified acid-fast stains performed on concentrated stool sediment or the newer immunoassays (14, 16–19). For the diagnosis of cryptosporidiosis, stool and other body fluid specimens should be submitted as fresh material in 5 or 10% formalin, sodium acetate-acetic acid-formalin, or one of the newer single-vial stool collection systems. Fixed specimens are recommended because of potential biohazard considerations. Some research laboratories routinely use potassium dichromate solution (2 to 3% [wt/vol] in water) as a storage medium to preserve oocyst viability; this solution is not a fixative and is not recommended for the routine clinical laboratory. Either fresh or preserved specimens can be examined using the routine stool formalin-ethyl acetate concentration and one of the modified acid-fast stains, the fecal immunoassay tests (Table 23.4), or molecular tests (20).

Phase-Contrast Microscopy. Although examination of unpreserved flotation material by phase-contrast microscopy has proven to be an excellent procedure for the recovery and identification of *Cryptosporidium* oocysts, many laboratories have neither access to such equipment nor experience with phase-contrast microscopy. Also, since the organism is considered to be infectious to laboratory personnel, fixed specimens can be processed by using several modified acid-fast stains, many of which are very satisfactory in demonstrating the organisms in stool material (Fig. 23.4 and 23.5). The more formed and normal the specimen, the better the chance for artifact material that can be confused with *Cryptosporidium* spp. It is important to remember that the number of oocysts is directly correlated with the consistency of the stool; the more diarrheic the stool, the more oocysts are present.

Antigen Detection. The use of immunoassays has proven to be very helpful in providing a more sensitive method of detecting organisms in stool specimens. A direct fluorescent antibody (FA) procedure with excellent specificity and sensitivity has been developed and results in a significantly increased detection rate over conventional staining methods. Enzyme immunoassay (EIA) also provides excellent specificity and sensitivity for laboratories using this approach (6, 7). Some of these reagents, particularly the combination direct-FA product used to identify both *Giardia* cysts and *Cryptosporidium* oocysts, are being widely used in water testing and outbreak situations (21–27).

It is recommended that the stool specimen be centrifuged at 500 × *g* for 10 min prior to use of any of the special stains or FA immunoassay reagents; centrifugation under these conditions ensures maximum recovery of the oocysts. Centrifugation at lower speeds and for shorter times (often mentioned in some procedures) may not guarantee recovery of the oocysts. Uncentrifuged fresh, frozen, or fixed fecal material can be used for the antigen detection immunoassays; these procedures do not rely on visual identification of the oocysts (FA) but instead rely on antigen detection. The selection of fresh or frozen stool rather than fixed specimens depends on testing parameters; currently, if the test reagents or kit format includes *Entamoeba histolytica*/*E. dispar* or *E. histolytica* alone, the test format

requires fresh or frozen stool. If the test format includes *Cryptosporidium* and/or *Giardia*, fresh, frozen, *or* preserved stools can be used. *However, it is always important to check with the manufacturer to confirm that the particular stool fixative you are currently using will be compatible with the immunoassay test reagents.* It is also important to review laboratory workflow and test request numbers prior to making test method selections (EIA, FA, rapid cartridge). Multiple stool specimens may have to be examined to diagnose the infection; this is particularly true when dealing with formed stool specimens, which may have low organism numbers.

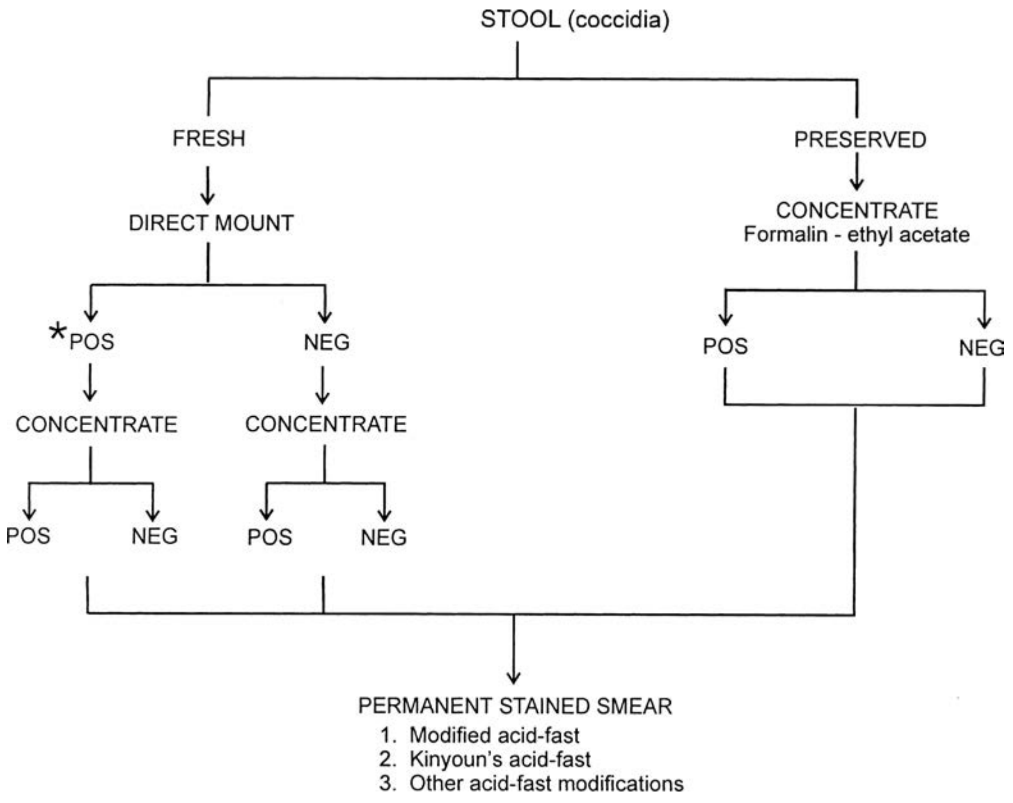

Figure 23.5 Diagnostic work flow diagram leading from submission of stool specimen to final permanent-stained smear for *Cryptosporidium* spp. and *Cyclospora cayetanensis*. *, Identification of coccidia may be difficult in a direct wet mount unless there are numerous oocysts present. In many laboratories, the use of fecal immunoassays has replaced acid-fast staining techniques for *Cryptosporidium* spp. The immunoassays can be performed on unconcentrated material (EIA, lateral-flow rapid cartridge) or concentrated material (FA assay). doi:10.1128/9781555819002.ch23.f5

Ordering/Testing Options. Various screening approaches have been used, and the approach varies from testing all specimens submitted for a routine stool examination to testing limited risk groups or testing only on request. There are numerous pros and cons to each approach; each laboratory will have to select its own approach on the basis of the patient base, client preferences, single versus batch testing, opportunity for in-service education for clients, availability of personnel, level of personnel training and expertise, clinical relevance, and cost. Prevalence data tend to be low unless specific risk groups are screened. A comprehensive approach would be to screen all symptomatic patients; however, even this approach often results in the identification of very few positive patients and is certainly not particularly cost-effective. A selective approach involving all compromised patients or compromised patients with diarrhea might be more reasonable. However, this assumes that the laboratory will always have access to this type of patient information, an assumption that is not realistic. Many laboratories have elected to provide in-service education to their physician clients and will perform these procedures only on request. Options for test ordering can be seen in Table 23.5. Although there is evidence for regional and seasonal variability of cryptosporidiosis, these possibilities will probably have little impact on the laboratory's overall approach to diagnostic testing.

Respiratory Cryptosporidiosis. Respiratory cryptosporidiosis has been found in AIDS patients. Sputum specimens from immunodeficient patients with undiagnosed respiratory illness should be submitted in 10% formalin and examined for *Cryptosporidium* oocysts by the same techniques as used for stool samples. Infection of the gallbladder and biliary tree should result in oocysts being passed in the stool.

Antibody Detection. Preliminary results from serologic methods for the diagnosis of cryptosporidiosis appear promising; however, additional patients must be studied

TABLE 23.5 Testing options for the diagnosis of cryptosporidiosis[a]

History	Pros	Cons
No travel outside United States		
Test every stool		
Modified acid-fast stain	Identifies infected patients	May not detect carriers or patients with small number of organisms
Immunoassay	Is more sensitive than the modified acid-fast stains and may identify patients who are carriers with low parasite numbers	High cost; may not be clinically relevant to screen all patients, particularly if there are small numbers in the patient base
Test on order only (after appropriate education of the physician client base)		
Geographic area with little to no reported cases	Is clinically relevant and more cost-effective	Still necessary to set up linkages with public health, water companies, etc., so that appropriate communication can serve as a link and notice of possible early outbreak situation
Geographic area with reported cases and history of outbreak situations	Education of the physician client base targets potential patient risk groups and potential problem situations	Still necessary to continue linkages with public health, water companies, etc., so that appropriate communication can serve as a link and notice of possible early outbreak situation
Travel outside United States		
Order routine ova and parasite examinations (minimum of two; must include the concentration and permanent stained smear)	Facilitates detection and identification of possible other relevant pathogens. If patient has become asymptomatic by the time the ova and parasite examination results are available (negative results), no additional testing is required.	Routine ova and parasite exam will not reveal the presence of *Cryptosporidium* (with rare exceptions based on organism numbers and method selection). If the patient remains symptomatic after the ova and parasite examination results (negative results) are available, more sensitive immunoassay procedures can be performed.
Order routine ova and parasite examinations and immunoassay for *Cryptosporidium*	This approach may be more clinically relevant in terms of turnaround time issues.	May result in excess testing

[a] It is important to remember that laboratories in different geographic regions may approach this testing differently. The important point is to ensure that physicians and laboratory personnel communicate regarding the pros and cons of each approach. Preliminary education, selection of the most clinically relevant approach, client education and communication, and periodic review of testing options and approaches will result in more cost-effective and better patient care.

before the actual diagnostic potential of these methods can be evaluated. Serologic tests have been very useful in estimating the prevalence of the infection in different parts of the world. Some of the data reveal very interesting associations between seroprevalence, outbreak-related laboratory serologic data, and patterns of parasite contamination of drinking water (21).

Flow Cytometry. Flow cytometry methods for the quantitation of *Cryptosporidium* oocysts in stool specimens have been developed as an alternative approach. Studies indicate that the results are approximately 10 times more sensitive than those of conventional immunofluorescence assays. However, this approach is somewhat impractical for most clinical laboratories.

Molecular Testing. PCR technology also offers alternatives for the diagnosis of *Cryptosporidium* in both clinical and environmental samples. Compared with microscopic examination by conventional acid-fast staining procedures, PCR is more sensitive and easier to interpret but requires more "hands-on" time and expertise, as well as being more expensive. An important advantage of PCR is the ability to directly differentiate between different *Cryptosporidium* genotypes, which is important in outbreak situations. Sensitivity, specificity, ability to genotype, ease of use, and adaptability to batch testing make PCR a useful tool for future diagnostic and molecular epidemiologic studies.

A 19plex laboratory-developed gastrointestinal pathogen panel using Luminex xTAG analyte-specific reagents has been validated, which simultaneously screens directly in fecal specimens for diarrhea-causing pathogens, including bacteria, viruses, and parasites (*Giardia lamblia*, *Cryptosporidium* spp., and *Entamoeba histolytica*). Overall sensitivity was 94.5% with a specificity of 99.8% (20).

KEY POINTS—LABORATORY DIAGNOSIS

***Cryptosporidium* spp.**

1. If the specimen represents the typically watery diarrhea, numerous organisms should be caught up in mucus.
2. The more normal the stool (semiformed, formed), the fewer the organisms and the more artifact material that will be present. It is unlikely that the oocysts will be seen in a wet preparation unless the parasite load is quite heavy; in this case, suspicious objects seen in the wet mount may be suggestive of coccidian oocysts.
3. Several concentrates and at least five or six modified acid-fast smears should be examined before a patient is considered negative, especially if the patient has been receiving experimental medications.
4. The normal permanent stains (trichrome, iron hematoxylin) do not adequately stain *Cryptosporidium* spp., although oocysts are occasionally seen in these preparations, especially those from patients with heavy infections.
5. Although the organisms can be stained with auramine-rhodamine stains, they should be confirmed by using acid-fast stains or the immunoassay reagents (most sensitive). This is particularly true if the stool contains other cells or a lot of artifact material (more normal stool consistency).
6. When using immunoassay reagents, it is important to remember that the stool specimen fixative and immunoassay reagents must be compatible. Concentrated stool sediment (500 × *g* for 10 min) should always be used for staining tests (modified acid-fast, etc.) and FA immunoassay because the tests are detecting the oocysts. However, when immunoassay reagents are used to detect *Cryptosporidium* antigen, the specimen does not have to be concentrated before being tested. Check specific kit directions and chapter 33.
7. Sputum specimens should be submitted in 5 or 10% formalin and processed in the same way as a stool sample.
8. It is important to remember that microsporidia are also present in approximately 30% of severely immunocompromised patients (<100 CD4$^+$ cells) who have cryptosporidiosis. The diagnostic procedures for the identification of *Cryptosporidium* spp. are not appropriate for the identification of microsporidial spores. Modified trichrome stains and optical brightening agents (calcofluor white) can be used for that purpose (17).

Histology. When examining histology preparations, developmental stages in the life cycle of *Cryptosporidium* spp. can be found at all levels of the intestinal tract, with the jejunum being the most heavily infected site. Routine hematoxylin and eosin staining is sufficient to demonstrate these parasites. Under regular light microscopy, the organisms are visible as small (~1 to 3 μm), round structures aligned along the brush border. They are intracellular but extracytoplasmic and are found in parasitophorous vacuoles. Developmental stages are more difficult to identify without using transmission EM. It is also important to remember that *Cryptosporidium* spp. have been found in other body sites, primarily the lungs, as a disseminated infection in severely immunocompromised patients. Within tissue, confusion with *Cyclospora cayetanensis* is unlikely, because the oocysts of this coccidian are approximately 8 to 10 μm and the developmental stages occur within a vacuole at the luminal end of the enterocyte, rather than at the brush border. Developmental stages of *Cystoisospora belli* also occur within the enterocyte and so should not be confused with *Cryptosporidium* spp.

Newer methods involving PCR have also been used to detect *Cryptosporidium* DNA in fixed, paraffin-embedded tissue. This approach could provide a sensitive and specific method for detection of parasite material in paraffin-embedded tissues and could be very valuable in retrospective studies of archival material. PCR has also been used to detect viable *Cryptosporidium* oocysts. Using PCR, confirmation of the presence of *Cryptosporidium* spp. in environmental studies has become more widely used (27–32).

Water Quality and Testing. During the past few years, the issues of water quality and water testing have become more important and controversial. Since the late 1980s, most of the water utilities have either set up in-house water quality testing laboratories or contracted with commercial water laboratories for the recovery and identification of *Cryptosporidium* and *Giardia* species. In a recent study, two methods were evaluated for the recovery of *Cryptosporidium* and *Giardia* species. The American Society for Testing and Materials method involves sampling a minimum of 100 liters of water through a polypropylene yard cartridge filter, extracting the particulates, flotation-concentrating the extracted particulates on a Percoll-sucrose gradient with the commercially available *Cryptosporidium*/*Giardia* combination FA reagent, and reviewing the slides for the presence of *Cryptosporidium* oocysts and/or *Giardia* cysts. This method tends to be labor-intensive, complex, and lengthy and depends on the skill and experience of the personnel and the quality control measures in use within the laboratory. Recovery rates tend to be low with this approach. The second method uses sampling by membrane filtration, Percoll-Percoll step gradient, and immunofluorescent staining; this method was characterized by higher recovery rates in all three types of waters tested: raw surface water, partially treated water from a flocculation basin, and filtered water. When seeded specimens were used, much higher recovery rates were obtained when the flotation step was eliminated from the protocol. Oocyst and cyst recovery rates decreased in both methods as the turbidity of the water increased. When smaller tubes were used for flotation, the membrane filter method was less time-consuming and cheaper. However, the lack of a confirmatory step might be a problem, particularly if cross-reacting algae are present in water samples. A number of other test options, including PCR, are currently being used (22–32). Unfortunately, these procedures emphasize organism detection; the issues of organism viability and infectivity have not yet been totally resolved.

Treatment

Cryptosporidiosis tends to be self-limiting in patients who have an intact immune system. For patients who are receiving immunosuppressive agents, one method of therapy would be to discontinue such a regimen. Other approaches with specific therapeutic drugs have been tried, but to date the results are still somewhat controversial (Table 23.6). Tissue culture systems with cell lines such as human ileocecal adenocarcinoma (HCT-8) cells and animal models that support the entire life cycle have been developed, and these may provide excellent opportunities for *in vitro* drug studies.

Immunocompetent Patients. Currently, the drug of choice for immunocompetent individuals is nitazoxanide. Studies indicate a statistically significant reduction in median oocyst excretion after 2 weeks of therapy with paromomycin. Several studies have reported success for a combination of paromomycin (1 g twice daily) and azithromycin (600 mg daily) for 4 weeks followed by paromomycin monotherapy for an additional 8 weeks. Recommended dosages can be found in chapter 36 (33).

Immunocompromised Patients. No drug has proven to be effective in this patient population. Ongoing studies with immunologic intervention hold promise, but this approach is still being evaluated in clinical trials. One approach that has had a dramatic impact on cryptosporidiosis in AIDS patients is highly active antiretroviral therapy (HAART) leading to an increased CD4 count. Resolution of the diarrhea resulting from cryptosporidiosis is apparently related to the enhanced CD4 count rather than to any change in the viral load or any therapeutic impact of the drugs themselves. Thus, it appears that cellular immunity is critical in clearing *Cryptosporidium* infection in these patients. Nitazoxanide (treatment duration of 5 to 21 days), paromomycin, or a combination of paromomycin and azithromycin may be tried to decrease diarrhea and continued malabsorption of antimicrobial drugs, which can occur with chronic cryptosporidiosis.

Treatment Summary. Although over 100 therapeutic agents have been evaluated, nitazoxanide is the only drug that has been approved by the FDA for treatment of cryptosporidiosis in immunocompetent persons in the United States. However, this drug is not effective in immunocompromised individuals. In patients with HIV/AIDS, the mainstay of treatment is immune reconstitution with HAART, which results in clearance or abrogation of infection (33). There is no vaccine available for cryptosporidiosis.

Epidemiology and Prevention

Epidemiology. Information on the epidemiology of *Cryptosporidium* continues to expand, since its potential pathogenicity in humans is now well documented (Tables 23.7 to 23.9; Fig. 23.6 to 23.8). The organism is transmitted

TABLE 23.6 Chemotherapeutic agents and supportive therapy for the treatment of human cryptosporidiosis[a]

Chemotherapeutic agent[b]	Comments
Recommended agents	
Nitazoxanide	This is a nitrothiazole benzamide with a wide spectrum of activity against coccidia, amebae, nematodes, cestodes, and trematodes. Preliminary data appear promising, with suggested activity against cryptosporidial infection in AIDS patients. The agent appears to be well tolerated. Additional trials are under way. Nitazoxanide is FDA-approved only for treatment of diarrhea caused by *Giardia* or *Cryptosporidium*[c]. It is available in 500-mg tablets and an oral suspension and should be taken with food.
Paromomycin (Humatin)	Paromomycin is synonymous with aminosidine (marketed outside the United States). It is an oligosaccharide aminoglycoside related to kanamycin; it achieves high concentrations in the colon but is poorly absorbed. Studies indicate that the drug effect is probably static rather than cidal for *Cryptosporidium*. Although decreased bowel movements and oocyst shedding have been reported, a small number of patients developed biliary tract disease and some of these required cholecystectomy. Despite conflicting results, paromomycin currently is used as the first-line drug in treating cryptosporidiosis. Since patients enter treatment trials after paromomycin failure, the question of delay and possible spread to the biliary tree has been raised.
Macrolides	
Spiramycin (oral)	Although a number of studies have been reported, divergent results are seen. Placebo results were often comparable to those obtained from patients receiving the drug. Absorption seems to be decreased in the presence of food. Decrease in diarrhea and oocyst excretion was seen in immunocompetent infants randomized to receive spiramycin (100 mg/kg/day) or placebo. A positive clinical response, as well as organism eradication, has also been reported in a group of AIDS patients.
Spiramycin (intravenous)	This approach was taken to circumvent absorption problems. Data revealed a statistically significant drop in oocyst count compared to placebo; however, administration of intravenous spiramycin was associated with paresthesias, taste perversion, nausea, and vomiting. At doses of >75 mg/kg/day there were cases of severe colitis due to intestinal injury.
Azithromycin	This drug has a long half-life (6 to 8 h) and achieves high concentrations in tissue, particularly in the biliary tree and gallbladder. Although decreased oocyst counts have been obtained from patients with high drug levels in serum, marginal improvement has been seen in other patients. A lactose-free form of azithromycin in 300-mg tablets is available through Pfizer's compassionate-use program. There may be a therapeutic effect on biliary tree infection, particularly in patients receiving intravenous azithromycin. Intravenous azithromycin at doses up to 2 g daily for 2 weeks is well tolerated.
Clarithromycin	Little information is available on other macrolides, including clarithromycin, roxithromycin, and dirithromycin; however, studies are in progress.
Benzeneacetonitrile derivatives	
Diclazuril	Interest stems from its efficacy for *Eimeria*; however, reports indicate that doses ranging from 50 to 800 mg were no more efficacious than placebo. This may have been due to poor drug bioavailability.
Letrazuril	Poor absorption of diclazuril led to the development of letrazuril. Although bioavailability was improved, patient clinical improvement was minimal. Data also suggest that this drug may interfere with modified acid-fast staining methods.
Miscellaneous agents	
Difluoromethylornithine (DFMO) (Eflornithine)	Although some success with this agent against *Cryptosporidium* in AIDS patients has been reported, serious toxicity has been documented (bone marrow suppression, gastrointestinal intolerance, and hearing impairment).
Atovaquone (Mepron)	This drug is an antimalarial that has been evaluated against *Pneumocystis jirovecii*, *Toxoplasma gondii*, and *Cryptosporidium* in AIDS patients. Preliminary results do not look promising.
Supportive therapeutic agents	
Nonspecific antidiarrheal agents (Kaopectate, Imodium, Lomotil, Pepto-Bismol, opiates)	These agents are often helpful, but individual regimens need to be developed for each patient; safety in patients with cryptosporidiosis is not known.
Octreotide (Sandostatin)	This is a synthetic cyclic octapeptide analog of somatostatin; anecdotal reports indicate some success in treating AIDS-related diarrhea. However, most patients had neither cryptosporidial diarrhea nor other identifiable pathogens.

[a] Adapted from Blagburn BL, Soave R, *in* Fayer R (ed), Cryptosporidium *and Cryptosporidiosis*, ASM Press, Washington, DC, 1997, and reference 33.

[b] Although other agents have been tried (zidovudine, recombinant interleukin-2), any improvement is most probably due to increased patient immune function rather than to the antiparasitic activity of the drug.

[c] *Med Lett Drugs Ther* **45**:29, 2003.

TABLE 23.7 Biological factors which impact the epidemiology of *Cryptosporidium*[a]

- Small (4–6 µm), environmentally resistant, and fully sporulated/infectious oocysts when passed; although sporozoites may not be seen in every oocyst, they are immediately infectious when passed
- Large livestock animal and human reservoir host populations
- Ubiquitous, able to cross-infect multiple host species (not species specific)
- Low infective dose (≤10–100 oocysts)
- Large multiplication capability ($>10^{10}$) in a single host
- Resistance to disinfectants
- Lack of effective therapy; resistance to available drugs

[a] Adapted from Casemore DP et al., *in* Fayer R (ed), Cryptosporidium *and Cryptosporidiosis*, ASM Press, Washington, DC, 1997.

by oocysts that are normally fully sporulated and infective at the time they are passed in stool. The oocysts are resistant to some of the disinfectants that are routinely used in medical care facilities. Exactly which of the oocyst layers is primarily responsible for the mechanical rigidity and resistance to disruption exhibited by the intact oocyst is not known. However, it has been suggested that the central glycolipid/lipoprotein layer and the inner filamentous layer may provide rigidity and elasticity to the wall.

TABLE 23.8 Risk factors for acquisition of cryptosporidiosis

Risk factor	Examples
Deficient immunity	AIDS, other acquired or congenital immunodepression syndromes (e.g., boys with mutation of the CD154 gene, congenital X-linked immunodeficiency with hyper-IgM), immunosuppression, malnutrition
Zoonotic contact	Leisure activities such as camping, backpacking, farm visits
Occupational exposure	Veterinary, agricultural, nursing or medical, laboratory, day care centers
Poor sanitary conditions	Drinking water and food, inadequate sewage or waste disposal, inadequate fly control
Exposure to untreated water (surface or recreational)	Leisure activities
Exposure to inadequately treated water supply	Inadequate treatment or breakdown in treatment process
Consumption of raw foods	Unpasteurized milk, raw meat
Travel	Travel from developed to underdeveloped countries and from urban to rural areas
Age (infants, young children)	Weaning, teething, pica, finger sucking, wearing diapers; poor infection control
Contact with case of diarrhea	Day care, household, parents

TABLE 23.9 Factors related to potential outbreaks of cryptosporidiosis

Factor	Examples
Factors unrelated to water	Sufficient number of parasites (viability, infectivity, virulence) Sufficient number of susceptible individuals for ingestion of oocysts leading to primary infection Sufficient number of susceptible individuals for whom contact with primary case leads to secondary transmission Adequate epidemiologic and laboratory surveillance and reporting
Water-related factors	Abnormal weather conditions (heavy rainfall); increased load for water treatment facilities High turbidity of surface water; increased challenge for water treatment facilities Breakdown in integrity of groundwater aquifers (prolonged rain after drought) Suboptimal water treatment functions Problems with finished-water distribution

Studies have shown that calves and perhaps other animals serve as potential sources of human infections. Contact with these animals may be an unrecognized cause of gastroenteritis in humans in both rural and urban settings. Direct person-to-person transmission is also likely and may occur through direct or indirect contact with stool material. Direct transmission may occur during sexual practices involving oral-anal contact. Indirect transmission may occur through exposure to positive specimens in a laboratory setting or from contaminated surfaces or food or water (10, 14, 21–29, 30–32, 37, 39).

Agricultural wastewater and runoff, particularly from lambs and calves, is also now recognized as an important potential source of infective *Cryptosporidium* oocysts (27). It has been shown that in healthy adults with no serologic

evidence of past infection with *Cryptosporidium*, a low dose of oocysts is sufficient to cause infection. With healthy human volunteers, the median infective dose was 132 oocysts, and one-fifth of the volunteers became infected with a dose as low as 30 oocysts. Specific guidelines are available for the prevention of cryptosporidiosis, particularly where drinking water is involved. Information can be seen in Tables 23.9 to 23.16.

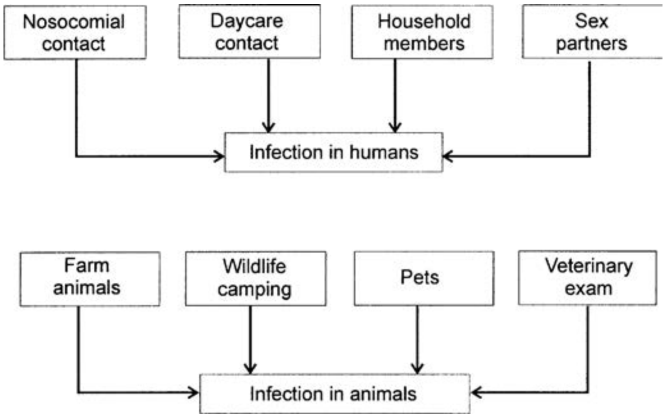
	Air dried, 4 h	100% reduced (excystation, dyes)
	Air dried in feces, 1–4 days	Noninfectious (*in vivo*, mice)

[a]Adapted from Fayer R et al *in* Fayer R (ed), Cryptosporidium *and Cryptosporidiosis,* ASM Press, Washington, DC, 1997.

Various surveys indicate prevalence rates of 1 to 2% in Europe, 0.6 to 4.3% in North America, and 3 to 20% in other areas of the world (Asia, Australia, Africa, and Central and South America). It has been suggested that the infection rate for individuals with diarrheal illness is 2.2% for persons living in industrialized countries and 8.5% for those residing in developing countries. Available data indicate that there are 250 million to 500 million *Cryptosporidium* infections annually among persons living in Asia, Africa, and Latin America. Generally, young children tend to have higher infection rates and all patients appear to have symptoms. Available serologic data support the prevalence rates, with figures from Europe and North America normally between 25 and 35% and those from South America indicating rates of up to 64%.

Figure 23.8 Flow diagram demonstrating sources of close-contact transmission of *Cryptosporidium* oocysts.
doi:10.1128/9781555819002.ch23.f8



The epidemiologic considerations for cryptosporidiosis emphasize transmission by environmentally resistant oocysts, numerous potential reservoir hosts for zoonotic transmission, documentation of person-to-person transmission in day care centers, nosocomial transmission within the health care setting, occurrence of asymptomatic infections (infective, carrier state), widespread environmental distribution resulting in the probability of waterborne transmission, and the link between cryptosporidiosis and severe, life-threatening disease in individuals with impaired immune function. Prevalence data from the Centers for Disease Control and Prevention for patients with AIDS are thought to be an underestimate of the actual prevalence (2 to 5%), particularly when other figures indicate percentages of 15% (National Institutes of Health, Bethesda, MD) and 11% (Great Britain). Surveillance systems currently under discussion can be seen in Table 23.15.

As our understanding of the epidemiology of cryptosporidiosis expands, it is obvious that there are numerous

[a] Data from the *CDC Surveillance for Waterborne-Disease Outbreaks—United States* (usually provided on a 2-year cycle with a 2- to 4-year delay).

[b] In June/July 2004, approximately 50 people were infected with *C. cayetanensis* from the ingestion of snow peas (7). In 2000, there were 1,368 cases of cryptosporidiosis with 13 outbreaks associated with recreational water (data from *CDC Surveillance for Waterborne-Disease Outbreaks—United States [1999–2000]* **51:**SS-8, 2002). In 2009–2010, there were 27 outbreaks with 436 cases of cryptosporidiosis associated with recreational water (data from *CDC Recreational Water-Associated Disease Outbreaks—United States [2009–2010]* **63:**6–10, 2014).

ways for the resistant oocysts to become disseminated. Some of these recent examples have generated enhanced interest in and concern about additional sources of infectious oocysts and the potential for accidental human consumption through contaminated food and/or water. Specific examples can be seen in Table 23.16 and Fig. 23.6, 23.7, and 23.8.

Prevention. Oocysts are susceptible to ammonia, 10% formalin in saline, freeze-drying, and exposure to temperatures above 65°C for 30 min. Commercial bleach in a 50% solution is also effective (Table 23.10). For most of the chemicals that have been tried for disinfection, effective concentrations are not practical outside the laboratory and high concentrations that significantly reduce oocyst infec-

TABLE 23.12 Prevention of cryptosporidiosis: recommendations (particularly important for patients who are immunocompromised)[a]

Preventive measure	Comments
Handwashing	Prior to eating and food preparation; after touching children in diapers; after touching clothing, bedding, toilets, bed pans from anyone with diarrhea; after gardening; after touching pets or other animals; after touching or coming in contact with anything contaminated with human or animal stool (includes dirt); after removing gloves to perform any of the above activities.
Practicing safe sex	Always wash hands after touching partner's anal or rectal area.
Avoiding touching farm animals	Particularly important for contact with young animals; wash hands thoroughly; avoid touching stool of any animal; after potential exposure, clean shoes (HIV-infected persons should not perform this task).
Avoiding pets' stools	If HIV infected, avoid cleaning litter boxes or cages or stool disposal (very important if animals are younger than 6 months); have puppies or kittens (if younger than 6 months) tested for presence of *Cryptosporidium* before bringing them home; have any pet tested that has diarrhea.
Swimming	Avoid swallowing water when in lakes, rivers, pools, or hot tubs; organisms are not killed by routine chlorination; avoid swimming in polluted ocean water, since oocysts can survive for several days in salt water.
Washing and cooking food	Thoroughly wash all fruits and vegetables if eating uncooked; use safe water (see below) for washing food; peel fruit; avoid unpasteurized milk or dairy products. Cooking kills *Cryptosporidium,* so cooked or packaged food is safe unless handled by someone infected with the organism.
Drinking water	Do not drink directly from lakes, rivers, streams, or springs; may want to avoid tap water (including refrigerator ice-maker ice and chilled water); boil water (rolling boil for 1 min is sufficient to kill organisms); filter with appropriate filters (look for "reverse osmosis," "absolute 1 micron," "Standard 53," and the words "cyst reduction" or "cyst removal"); a home distiller can be used. Store filtered water as for boiled water.
Bottled water	Bottled water labels reading "well water," "artesian well water," "spring water," or "mineral water" do not guarantee that the water does not contain *Cryptosporidium.* However, water that comes from protected well or spring water sources is less likely to be contaminated than bottled water from rivers and lakes.
Drinks	Canned or bottled soda, seltzer, fruit drinks, and steaming hot tea and coffee are safe; fountain drinks, fruit drinks from concentrate mixed with tap water, and iced tea or coffee may not be safe.

[b] Any of the four comments in this column on a package label will indicate that the filter should be able to remove *Cryptosporidium*.

tivity are either very expensive or quite toxic. Unfortunately, oocysts of *Cryptosporidium* have shown high levels of resistance to most commercial disinfectants, including iodine water purification tablets (34). Although chlorine and related compounds can dramatically reduce the ability of oocysts to excyst or infect, high concentrations and long exposure times are required, making this approach impractical. Although rarely used in routine clinical laboratories, stool specimens can be collected in potassium dichromate specifically for *Cryptosporidium* spp., and the oocysts remain viable in this solution for at least 12 months. In general, it is preferred that the oocysts be rendered noninfectious prior to submission to the laboratory for diagnostic testing.

TABLE 23.14 Bottled water: label information[a]

Almost all oocysts exposed to soils that are frozen at −10°C become inactivated within 50 days; inactivation occurs regardless of the presence or absence of freeze-thaw cycles (35). Although oocysts that are purified from fecal material prior to cryopreservation tend to lose viability and infectivity for tissue culture and mice, when the oocysts are cryopreserved in feces a certain number remain viable and maintain infectivity. Based on these studies, fecal material appears to protect the oocysts during cryopreservation stored at −20°C for at least 30 days (36).

Outbreaks. In January and February 1987, cryptosporidiosis was associated with an estimated 13,000 cases of gastroenteritis in Carroll County, GA. *Cryptosporidium* oocysts were identified in the stools of 39% of the persons examined during the outbreak; a randomized telephone survey indicated probable attack rates of 54% within the city of Carrollton and 40% overall for the county. The only significant risk factor associated with illness was exposure to the public water supply, which was filtered and chlorinated. It was interesting that, according to records kept during the outbreak, the treatment facility was operating within Environmental Protection Agency guidelines. Additional reports of waterborne outbreaks have appeared in the past few years (Table 23.11). Another massive waterborne outbreak was reported in Milwaukee, WI. Contamination of the public water supply during March and April 1993 resulted in approximately 300,000 infections. Infection during this outbreak appeared to be more severe than in previous reports of large case series. The risk of secondary infection in a household was low (5%) when the index case involved an adult. Also, the recurrence of watery diarrhea after apparent recovery was a frequent occurrence among visitors with laboratory-confirmed cryptosporidiosis (39%) and among visitors and residents with clinical infection (21%).

This increase in the number of reported waterborne disease outbreaks associated with *Cryptosporidium* spp. can be attributed to improved techniques for oocyst recovery and identification. The use of high-volume filters, immunofluorescence, and molecular detection methods has resulted in the demonstration of oocysts in surface and drinking waters and in sewage effluents from many geographic regions (21, 22, 24–27).

TABLE 23.15 Possible surveillance approaches for the establishment of baseline data on the occurrence of cryptosporidiosis

Surveillance approach	Comments
Make cryptosporidiosis reportable to CDC	Applies to each state or city; provides legal authority for collecting information
Monitor sales of antidiarrheal medications	Local pharmacy computerized databases (provide historical as well as current diarrheal illness information)
Monitor logs maintained by health maintenance organizations and hospitals (complaints of diarrheal illness)	May be particularly useful if keyed to ZIP codes, particularly in case of waterborne transmission
Monitor incidence of diarrheal illness in nursing homes	Can monitor differences between use of municipal and bottled water; could also serve to establish baseline data
Monitor laboratory data for *Cryptosporidium* spp.	More likely to provide information on AIDS (or other immunocompromised) patients; may not be best way to obtain information on general public (excessive cost)
Monitor tap water in selected cities or locations	Intensive surveillance might be recommended in approximately 10 cities known to have *Cryptosporidium* spp. in their finished water, again to establish some baseline data
Establish methods of rapid reporting and communication among relevant agencies	Education of physicians, public, etc., is vital to the understanding of epidemiology of cryptosporidiosis

Water Testing. The immunofluorescence method can be used to examine large volumes of water, is relatively specific for *Giardia* and *Cryptosporidium* spp., and permits examination of the specimen by epifluorescence and phase-contrast or differential interference contrast microscopy. However, disadvantages of the method include low recovery percentages (5 to 25%), long processing times (1–2 days to 1–2 weeks), the need for highly trained personnel, the high cost per sample (approximately $300), the inability to identify viable or virulent organisms, and cross-reactivity with non-human *Cryptosporidium* organisms. Unfortunately, the more the specimen or water sample is manipulated during processing, the more likely it is that organisms will be lost in the process, thus accounting for the low recovery percentages.

Incorporation of the use of fluorogenic vital dyes to determine oocyst viability appears to offer some improvements; however, the positive relationship between vital-dye reactions and excystation may not always correlate directly with viability or infectivity. A number of other methods have been used in an effort to improve organism recovery and to determine the viability and infectivity of the oocysts recovered. These include the use of a fluorescence *in situ* hybridization technique for labeling of *Cryptosporidium* oocysts in water samples, species- and strain-specific typing of parasites in clinical and environmental samples, use of PCR for the detection of *Cryptosporidium* oocysts in municipal water samples, use of cell culture to determine the infectivity of *Cryptosporidium* oocysts, immunomagnetic separation coupled with immunofluorescence microscopy for oocyst detection, a combination of immunomagnetic separation and integrated cell culture-PCR, and use of β-tubulin mRNA as a marker of *Cryptosporidium* oocyst viability.

Data indicate that viable *Cryptosporidium* oocysts exposed to chlorine or other oxidizing conditions may lack identifying epitopes. This finding may be important for the water industry, where naturally occurring oxidizing conditions or sanitizing treatments could produce viable oocysts that are undetectable by standard protocols. Detailed knowledge of the structure and stability of the *Cryptosporidium* oocyst wall may ultimately contribute to the development of water treatment options that will reduce the viability of the intact oocyst and thus the waterborne dissemination of the parasite.

Cyclospora cayetanensis

The first published report of *Cyclospora* infection in humans can probably be dated to 1979 when Ashford described coccidian organisms causing diarrhea in two children and a woman in Papua New Guinea and concluded that they could be *Cystoisospora*. In 1986, four travelers returning from Mexico and Haiti had flu-like symptoms and

TABLE 23.16 Potential sources for *Cryptosporidium* oocysts related to accidental human ingestion of contaminated food and/or water

Transmission agent	Comments
Eastern oysters (*Crassostrea virginica*)	Oysters collected from Maryland tributaries of the Chesapeake Bay contain infectious oocysts; 7 sites in Chesapeake Bay area are positive for infected oysters
Atlantic coast commercial shellfish	*Cryptosporidium* spp. found in commercial shellfish from 64.9% of sites examined along the Atlantic coast, using either microscopy or molecular testing
Clams (Italy, seawater)	Oocysts detected in 23 of 32 pools of clams
Clams (California, freshwater)	*C. parvum* DNA in clams from 3 different riverine ecosystems confirmed with PCR and DNA sequence analysis
Clams (*Tapes decussates*, Spain)	Oocysts found in siphons, gills, stomach, digestive diverticula, intestine; oocysts found in branchial mucus and in interfilamentary spaces suggest repeated filtrations and the possibility of infective oocysts
Bent mussels (*Ischadium recurvum*)	Mussels may be useful as biological indicator of water contamination with *Cryptosporidium* oocysts; found in same areas indicated above for oysters
Mussels (*Mytilus galloprovincialis*)	Oocysts survive in seawater for at least 1 year; filtered out by benthic mussels, retaining infectivity up to 14 days
Mussels (*Perna viridis*); Thailand	*Cryptosporidium* spp. oocysts indigenous in mussels from coast of Thailand (food source)
Canada geese (migrating birds)	Infectious oocysts disseminated by migrating waterfowl
House flies (*Musca domestica*)	Adult and larval stages of house flies can mechanically carry oocysts in their digestive tracts and deposit them on external surfaces
Filth flies (*Calliphoridae*, *Sarcophagidae*, *Muscidae*)	Wild-caught flies (>90%) harbored *Cryptosporidium* oocysts; oocysts carried internally and externally—potential for mechanical transmission of infectious oocysts
Filth flies (*Muscidae*, *Calliphoridae*, *Lauxaniidae*, *Anthomyiidae*)	80% of all *Cryptosporidium* oocysts viable; >69% of *Giardia lamblia* cysts viable; potential for mechanical transmission of infectious oocysts high
Dung beetles (*Anoplotrupes stercorosus*, *Aphodius rufus*, *Onthophagus fracticornis*)	Although many oocysts pass safely through mouthparts and gastrointestinal tracts of the beetles, most are destroyed; however, coprophagous insects are considered important as agents of both control and dissemination
Free-living soil nematode (*Caenorhabditis elegans*)	*C. elegans* can ingest and excrete oocysts; the role of free-living nematodes in contamination requires further study

it was suggested that the cause was a new pathogen. In subsequent reports, *Cyclospora* was described as a coccidian-like body (CLB), cyanobacterium-like body, blue-green alga, or large *Cryptosporidium*. In 1989, 53 cases of CLB infection in Peru were attributed to an unidentified flagellate. In 1989, similar structures were seen in the stool samples of an AIDS patient in Chicago with chronic diarrhea and with no history of recent travel. Then, in the early 1990s, blue-green algae were described as the causative agent of severe diarrhea in eight international travelers who had been to Mexico, South America, India, or Southeast Asia and also in expatriates living in Nepal. It was not until the early 1990s that these organisms were characterized as a new coccidian species capable of causing human infection (40).

In recent years, human cyclosporiasis has emerged as an important infection, with a number of outbreaks being reported in the United States and Canada. Prior to 1995, only one outbreak of cyclosporiasis had been reported in the United States; however, from May through August 1996, more than 1,400 cases were reported from 20 states, Washington, DC, and two Canadian provinces (5, 41, 42). Understanding of the biology and epidemiology of *C. cayetanensis* is limited and has been complicated by a lack of information about the parasite's origins, possible animal reservoir hosts, and relationship to other coccidia (40–43).

There have been a number of outbreaks of diarrhea associated with *C. cayetanensis*; the distribution is worldwide (United States, Caribbean, Central and South America, Southeast Asia, Eastern Europe, Australia, Nepal). These organisms are acid-fast variable and have been found in the feces of immunocompetent travelers to developing countries, immunocompetent subjects with no travel history, and patients with AIDS. Patients reported symptoms of a "flu-like" illness with nausea, vomiting, anorexia, weight loss, and explosive diarrhea lasting 1 to 3 weeks. Cumulative evidence suggests that outbreaks in the United States and Canada during the spring months of 1996 and 1997 were related to the importation and ingestion of Guatemalan raspberries. It is quite likely that the outbreak reported from Florida in 1995 was also attributable to contaminated food. The cases reported in all three outbreaks probably represented only a small fraction of those that occurred. Rapid transport of fresh fruits and produce from developing countries increases the chance that endemic parasites from other regions may come into contact with consumers from industrialized nations; *Cyclospora* represents an excellent example of this type of transmission.

Life Cycle and Morphology

The oocysts that had previously been recovered from human stool specimens were immature, so the structure of the mature oocyst was not seen in those specimens. It takes approximately 7 to 15 days for oocyst maturation, so the mature stage may not have been seen in human specimens. Evidence obtained from excystation experiments indicates that the oocyst contains two sporocysts, each containing two sporozoites, a pattern which places these organisms in the coccidian genus *Cyclospora*. EM confirmed the presence of characteristic organelles for coccidian organisms of the phylum Apicomplexa. The name *Cyclospora cayetanensis* sp. nov. was proposed for this newly described disease-producing coccidian organism from humans. The species name comes from the university where it was initially studied (Universidad Peruana Cayetano Heredia).

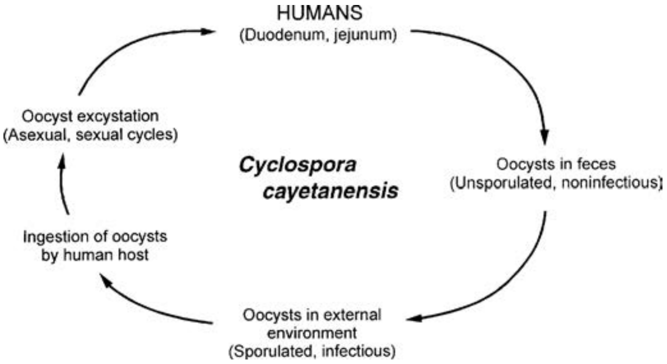
Two types of meronts and sexual stages have been seen in jejunal enterocytes in biopsy specimens from infected patients. These findings confirm that the entire life cycle can be completed within a single host (Fig. 23.9). Unsporulated oocysts are passed in the stool, and sporulation occurs within approximately 7 to 13 days. Complete sporulation produces two sporocysts that rupture to reveal two crescent-shaped sporozoites measuring 1.2 by 9.0 µm.

The transmission of *Cyclospora* is thought to be fecal-oral, although direct person-to-person transmission has not been well documented and may not be a factor, since sporulation takes a number of days. Outbreaks linked to contaminated water and various types of fresh produce (raspberries, basil, baby lettuce leaves, and snow peas) have been reported, and this organism is highly resistant to disinfectants commonly used in the food industry (Table 23.17, Fig. 23.10). The adhesins responsible for the strong attachment of *Cyclospora* to produce are unknown; however, it seems to be stronger than that of *Cryptosporidium* or *Giardia*. Also, information on potential reservoir hosts has yet to be defined; however, it appears that in some areas humans are the only host.

Clinical Disease

The clinical presentation varies throughout areas of endemicity, where asymptomatic infections are more frequent. Children tend to have more severe clinical symptoms. The infections cause fewer symptoms as children get older and as the duration of the infection decreases. As in young children, the elderly may also present with a more severe illness. In areas where *Cyclospora* is not endemic, infections almost always cause symptoms, and there may be serious sequelae; however, fatalities tend to be rare.

Figure 23.9 *Cyclospora cayetanensis* life cycle. doi:10.1128/9781555819002.ch23.f9



The incubation period is approximately 2 to 11 days after exposure. There is generally 1 day of malaise and low-grade fever, with rapid onset of diarrhea from 5 to 15 times per day. There may also be fatigue, anorexia, vomiting, myalgia, and weight loss with remission of self-limiting diarrhea in 3 to 4 days, followed by relapses lasting from 4 to 7 weeks.

In patients with AIDS, symptoms may persist for as long as 12 weeks; biliary disease has also been detected in this group. Diarrhea alternating with constipation has also been reported; this is not uncommon in a number of protozoal gastrointestinal infections. Clinical clues include unexplained prolonged diarrheal illness during the summer in any patient and in persons returning from tropical areas. The majority of infected individuals had intermittent diarrhea for 2 to 3 weeks, and many complained of intense fatigue, as well as anorexia and myalgia, during the illness. The clinical presentation of patients infected with this organism is similar to that of patients infected with *Cryptosporidium*.

Developmental stages of *C. cayetanensis* usually occur within epithelial cells of the jejunum and lower portion of the duodenum. *Cyclospora* infection reveals characteristics of a small bowel pathogen, including upper gastrointestinal symptoms, malabsorption of D-xylose, weight loss, and moderate to marked erythema of the distal duodenum. Alterations of the epithelial tissue include vacuolization at the tips of the villi of the surface epithelium, loss of the brush border, and alteration of cells from a columnar to cuboid shape. Histopathology in small bowel biopsy specimens reveals acute and chronic inflammation, partial villous atrophy, and crypt hyperplasia (Fig. 23.11).

Diagnosis

Electron Microscopy. When examined in formalin-preserved human stool specimens and by EM, these organisms exhibited characteristics of a cyanobacterium. The organisms stained orange with safranin and were modified acid-fast variable, with some organisms staining deep red with a mottled appearance but no internal organization (44). Preliminary EM revealed internal structures that resembled those of the cyanobacteria.

Autofluorescence. The oocysts autofluoresce strong green (450 to 490 DM excitation filter) or intense blue (365 DM excitation filter) under UV epifluorescence. It is strongly recommended that during concentration (formalin-ethyl

TABLE 23.17 Examples of outbreaks of *Cyclospora cayetanensis* infection, United States and Canada[a]

Outbreak	Implicated cause	Comments
July 1990 (11 cases), Chicago hospital	Tap water from the physicians' dormitory was probably the source of the outbreak	This is the first reported outbreak of diarrhea associated with *Cyclospora* in the United States.
1995 (14 cases), Florida	Fresh raspberries and strawberries	Given the cumulative evidence and the occurrence in 1996 and 1997 of outbreaks in North America associated with consumption of Guatemalan raspberries, food-borne transmission of *Cyclospora* was likely in 1995 in Florida as well.
23 May 1996 (38 cases), South Carolina	Fresh raspberries	Imported from Guatemala
26 June 1996 (48–54 possible cases), Virginia	Basil-pesto pasta salad	No raspberries or mesclun lettuce was served at the luncheon.
June and July 1996 (185 possible cases), 25 clusters in northern Virginia, Washington, DC, and Baltimore, MD	Food containing fresh basil	All basil was associated with the same company.
1996 (180 cases), Florida	Fresh raspberries	Imported from Guatemala
1996 (1,465 cases), 20 states	Fresh berries, berries with or without fresh raspberries	As few as five Guatemalan farms could have accounted for the 25 events; the raspberries could be traced to a single exporter per event.
April and May 1997 (80 cases), California, Florida, Nevada, New York, and Texas	Fresh raspberries, mesclun (baby lettuce leaves, known as spring mix, field greens, or baby greens)	These 80 cases a part of the next listing for 1997 of a total of 1,450 cases
1997 (1,450 cases), United States and Canada	Fresh raspberries, mesclun	Most cases were linked to ingestion of raspberries from Guatemala; exportation of fresh raspberries from Guatemala was voluntarily suspended at the end of May 1997.
1998 (94 cases), Boston, MA	Dessert containing raspberries, strawberries, blackberries, and blueberries	No specific commentary on source of fresh berries, but probably imported
July 1999 (62 cases), Missouri	Fresh basil	Chicken pasta salad and tomato basil salad; grown either in Mexico or United States
June 2000 (54 cases)	Fresh raspberries	Wedding cake, which had a cream filling that included raspberries imported from Guatemala
2001 (17 cases), British Columbia	Fresh Thai basil	Importation was traced from the United States.
June and July 2004 (96 cases), Pennsylvania	Pasta salad containing raw snow peas	Snow peas imported from Guatemala
April 2005 (592 cases), Florida	Fresh basil	Linked to a number of restaurants
April 2009 (160 cases), multiple countries	Unknown	Cruise ship
2012 (123 cases)	Possible cilantro	Restricted shipments from Puebla, Mexico (FDA, 2015)
August 2013 (631 cases), 22 states	Prepackaged salad mix	Lettuce grown in Mexico, restaurant salads, largest U.S. outbreak since 1997; 83% of cases from Iowa, Nebraska, Texas

[a] During this time frame, outbreaks were also being documented from many areas throughout the world (Canada, Germany, Mexico, Indonesia, Colombia, Peru, Turkey, Nigeria, India, China, Sweden).

acetate) of stool specimens, the centrifugation be carried out for 10 min at 500 × *g*.

Modified Acid-Fast and Safranin Stains. In clean wet mounts, the organisms are seen as nonrefractile spheres and are acid-fast variable with the modified acid-fast stain; those that are unstained appear as glassy, wrinkled spheres (Fig. 23.12 to 23.14). Modified acid-fast stains stain the oocysts light pink to deep red, and some will contain granules or have a bubbly appearance. It is very important to be aware of these organisms when the modified acid-fast stain is used, because *Cryptosporidium* spp. and other similar but larger structures (approximately twice the size of *Cryptosporidium* oocysts) are seen in the stained smear. It is important for laboratories to measure all acid-fast oocysts, particularly if they appear to be somewhat larger than those of *Cryptosporidium*. Although modified acid-fast stains are the most commonly used stains to identify the oocysts in stool, a safranin-based stain that tends to uniformly stain *Cyclospora* oocysts is also recommended (44).

Flow Cytometry. Another diagnostic option involves the use of flow cytometry. This approach appears to be a useful alternative to microscopy, particularly for screening large

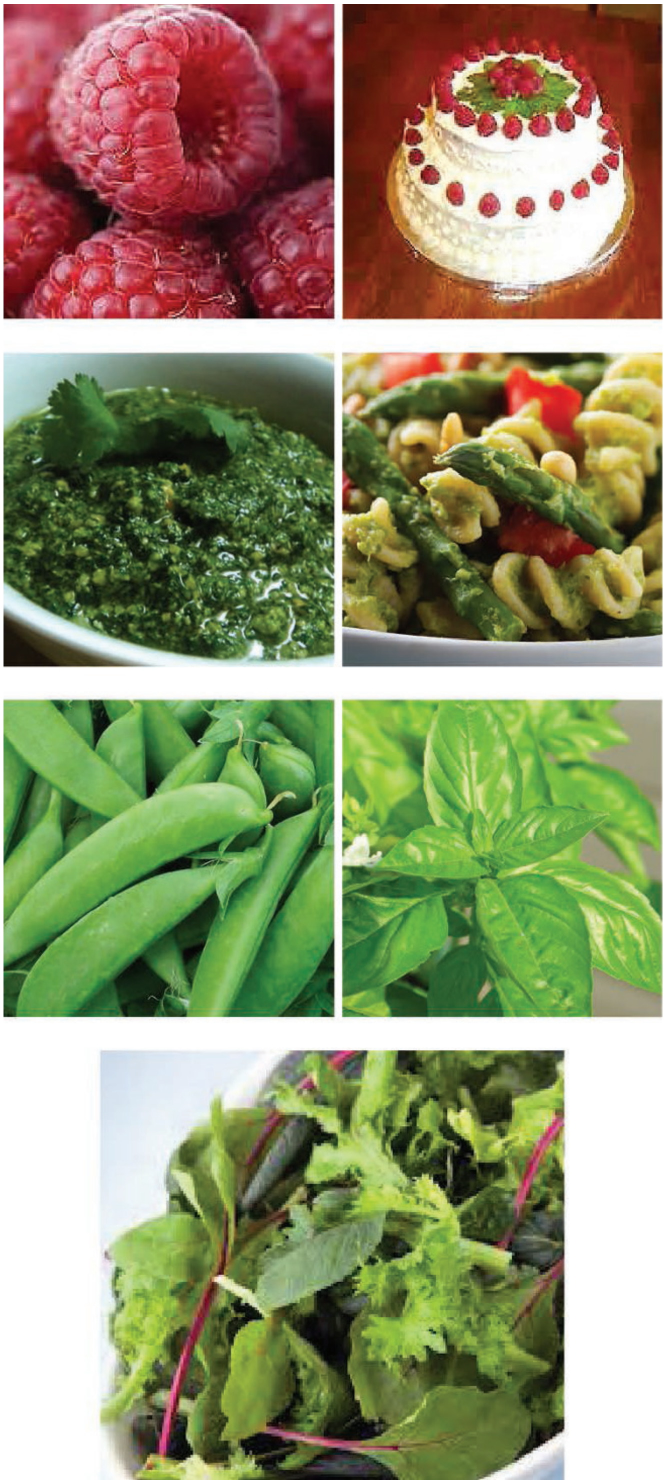


Figure 23.10 Foods associated with *Cyclospora cayetanensis* contamination and transmission. (Top) Raspberries, raspberry cake; (row 2) pesto, pesto salad; (row 3) snow peas, basil; (bottom) mesclun (baby lettuce leaves for salad).

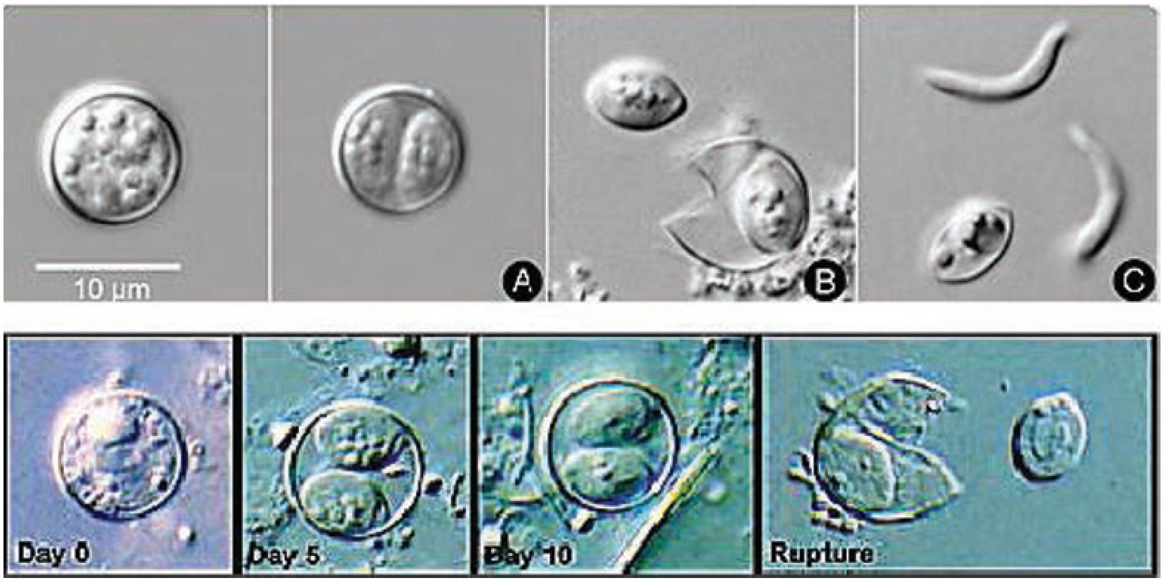

Figure 23.12 *Cyclospora cayetanensis* oocysts. (Upper) (far left) Unsporulated oocyst with undifferentiated cytoplasm; (A) sporulating oocyst that contains two immature sporocysts; (B) oocyst that was mechanically ruptured with one of its two sporocysts released; (C) one free sporocyst is seen, as well as two free sporozoites, the infective stage of the organism. (Lower) Sporulation of *Cyclospora* oocysts; Day 0, oocyst passed in fresh stool; Days 5 and 10, sporulated oocysts containing two sporocysts; Rupture, ruptured oocyst, one sporocyst outside, one remaining inside the oocyst wall. (Courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch23.f12

numbers of clinical specimens for *Cyclospora* oocysts in an outbreak situation (45).

Molecular Testing. *Cyclospora* DNA amplification by PCR has been used for diagnosis. Conventional PCR and nested PCR targeting small subunit rRNA for *Cyclospora* have a sensitivity of 62%. False positivity with some *Eimeria* species has been noted (40). The amplified product of about 300 bases cannot differentiate *Cyclospora* from *Eimeria* species. Digestion of the amplified products using the restriction enzyme MnlI (PCR-restriction fragment length polymorphism [PCR-RFLP]) followed by gel electrophoresis results in patterns that can discriminate these two genera. Recently, a 70-kDa heat shock protein (HSP70) gene-based nested PCR protocol for detection of *C. cayetanensis* has been developed (46). The BioFire Film Array Gastrointestinal Panel for bacterial, viral, and pathogenic pathogens is now available and includes *Cyclospora* (Table 23.4).

Antibody Testing. Serological assays to determine human exposure to *Cyclospora* are not yet available. Westerm blot can differentiate between acute and convalescent infection; however, this test is still in the research stages.

KEY POINTS—LABORATORY DIAGNOSIS

Cyclospora cayetanensis

1. *Cyclospora* oocysts may appear to be larger than normal *Cryptosporidium* oocysts; be sure to measure these organisms to confirm their size.
2. Fecal specimens should be concentrated prior to staining; centrifugation for 10 min at 500 × *g* is recommended.
3. On wet smears, the oocysts appear as nonrefractile spheres and, depending on the filters used, autofluoresce green to blue with epifluorescence. Autofluorescence may be 2+ to 4+.
4. On modified acid-stained smears, the oocysts stain from light pink to deep red, and some contain granules or have a bubbly appearance. Those that do not stain may appear wrinkled. A strong decolorizer should not be used; a 1% sulfuric acid solution is recommended and also works well for modified acid-fast stains for *Cryptosporidium* spp. and/or *Cystoisospora belli*. The original 3 to 5% sulfuric acid is usually too strong for *Cyclospora* and removes too much color. Even with the 1% acid decolorizer, some oocysts may appear clear or very pale.
5. If the oocysts are seen in a regular trichrome-stained smear of stool, they may appear as clear, round, some-

KEY POINTS—LABORATORY DIAGNOSIS

***Cyclospora cayetanensis* (continued)**

what wrinkled objects that are larger than *Cryptosporidium* spp. However, unless there are large numbers of these oocysts present, they look like "ghost cells" and will probably not be recognized as *Cyclospora* oocysts.

6. It is very important to measure these oocysts; *Cyclospora* oocysts measure 8 to 10 µm, and *Cryptosporidium* oocysts measure from 4 to 6 µm.
7. In the modified safranin technique, the oocysts uniformly stain a brilliant reddish orange if fecal smears are heated in a microwave oven during staining. The stained slide can also be examined by epifluorescence microscopy first, and suspect oocysts can be confirmed by bright-field microscopy.

Treatment

Apparently, patients do not respond to conventional antimicrobial therapies. Some patients have been treated symptomatically with antidiarrheal preparations and have obtained some relief; however, the disease appears to be self-limiting within a few weeks. Trimethroprim-sulfamethoxazole (TMP-SMX) is currently the drug of choice (adults: 760/800 mg given orally twice daily for 7 days; children: 5 mg of TMP/kg plus 25 mg of SMX/kg given orally twice daily for 7 days); relief of symptoms has been seen by 1 to 3 days posttreatment. Patients with AIDS may need higher doses and long-term maintenance treatment. However, symptoms recur within 1 to 3 months posttreatment in over 40% of patients. In a study with TMP-SMX in Nepal, shedding of oocysts and symptoms disappeared after 7 days of treatment (43).

Other antibiotics, such as azithromycin, norfloxacin, tinidazole, nalidixic acid, diloxanide fluorate, and quinacrine, have also been tested for *Cyclospora* treatment, all without success. Ciprofloxacin can be used as an alternative therapy in patients who are allergic to sulfa products; however, evidence of treatment failure with ciprofloxacin has also been seen.

Epidemiology and Prevention

Epidemiology. Epidemiological studies have shown that consumption of untreated water, lack of adequate sanitation, and the presence of animals in the household are associated with increased risk of *Cyclospora* infections. In industrialized nations, most people are susceptible to infections. However, susceptible populations in areas of endemicity are restricted to the very young and the very old. In developed nations, cyclosporiasis has been observed in tourists (0.6%) or expatriates visiting countries where the disease is endemic, in the immunocompromised, and in immunocompetent hosts with no foreign travel history. Published reports emphasize that individuals of all ages, including both those who are immunocompetent and those who are immunosuppressed, can become infected. Travelers to areas with endemic *Cyclospora* infection should be aware of the increased risk of infection during the late spring and summer. Preliminary data and extrapolation from what we currently know about cryptosporidiosis suggest that modes of transmission may be similar, particularly considering waterborne transmission (Table 23.11).

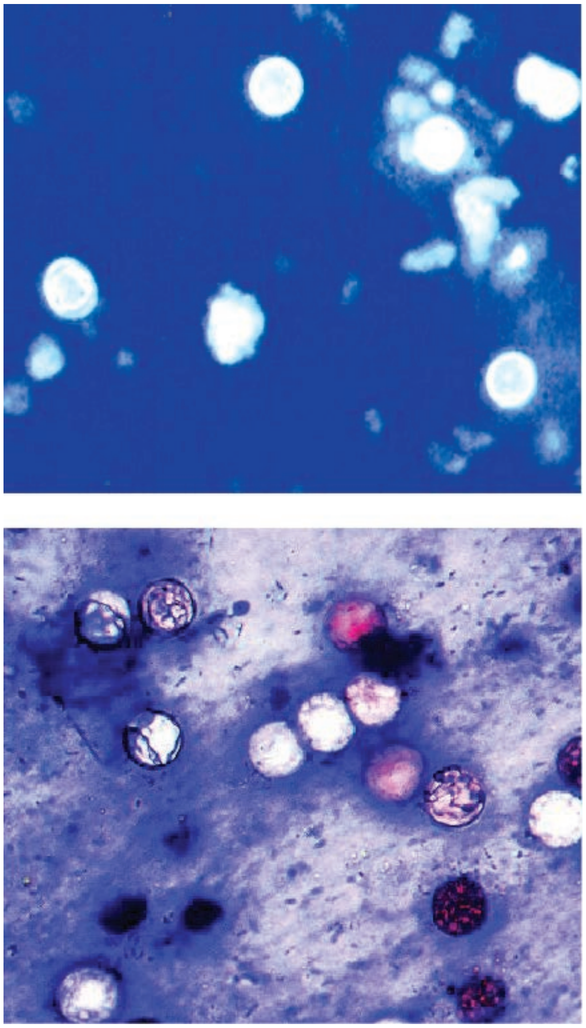

Figure 23.13 (Upper) *Cyclospora cayetanensis* autofluorescence using the same filter used for calcofluor white. (Lower) Modified acid-fast stain of *C. cayetanensis* (note that some oocysts stain quite dark, while some have not retained the stain; this is typical, and the organisms are described as "modified acid-fast variable"). The oocysts measure 8 to 10 µm. A 1% acid decolorizer is recommended—all coccidia will stain well using this approach. A stronger acid may decolorize *Cyclospora* too much. **Note** These images were photographed from concentrated, stained fecal material (500 × *g* for 10 min). doi:10.1128/9781555819002.ch23.f13

Oocyst detection methods for foods and environmental samples include phase-contrast, bright-field, and differen-

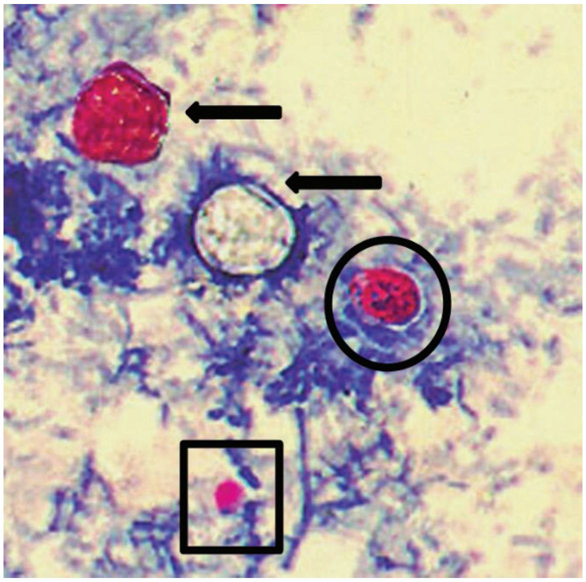

Figure 23.14 Modified acid-fast stain. Oocysts of *Cryptosporidium* (4–6 µm) (circle) and *Cyclospora cayetanensis* (8–10 µm) (arrows); one of the *Cyclospora* oocysts has not retained the stain. The smallest structure (square) is an artifact and measures approximately 1–2 µm.
doi:10.1128/9781555819002.ch23.f14

tial interference contrast microscopy. Epifluorescence microscopy has also been used. Other coccidian oocysts also autofluoresce and stain with acid-fast stain, so these procedures have to be used in combination with other diagnostic assays.

Molecular Epidemiology. Although current PCR protocols can detect *Cyclospora* in different samples, these methods cannot differentiate between sporulated and unsporulated oocysts, limiting their use in biological or epidemiological investigations. Therefore, there are no animal models or *in vitro* cultivation methods to determine the infectious potential of *Cyclospora*.

Prevention. Since this parasite, like *Cryptosporidium*, is not killed by routine chlorination, drinking water treated by halogenation may not be safe. Boiling is recommended. Hot drinks such as coffee or tea are recommended, rather than placing any reliance on iodine treatment of the water. Fresh fruits and vegetables should be thoroughly washed and/or peeled prior to eating. Although prophylaxis has not been adequately investigated and is not recommended, specific circumstances might warrant this approach (e.g., for HIV-positive individuals visiting these areas).

Improved agricultural practices would contribute to reducing the burden of parasite contamination at the farm level. These practices would involve the use of properly treated irrigation water and the use of pathogen-free water for washing produce.

As our understanding of the epidemiology of cyclosporiasis expands, it is obvious that there may be numerous ways for the resistant oocysts to become disseminated. Some of these recent examples identified for *Cryptosporidium* spp. have generated enhanced interest in and concern about additional sources of infectious oocysts and the potential for accidental human consumption through contaminated food and/or water. These examples may be just as relevant for *Cyclospora*. Specific examples for *Cryptosporidium* can be seen in Table 23.16. Recovery of waterborne oocysts of *C. cayetanensis* in Asian freshwater clams (*Corbicula fluminea*) has been reported (42, 43). It has been proposed that shellfish concentrate oocysts from contaminated waters. Controlled laboratory studies with *Corbicula fluminea* showed that 48 to 100% of the clams retained *Cyclospora* oocysts for up to 13 days.

Cystoisospora (*Isospora*) *belli*

Cystoisospora belli was first described by Virchow in 1860 but not named until 1923. Molecular biology studies have demonstrated that *Isospora* spp., particularly those from primates and carnivores, are more closely related to the *Sarcocystiidae* than to the *Eimeriidae*. This has required the transfer of the species into the family *Sarcocystiidae* and the genus *Cystoisospora*. Although infections have been found in various parts of the world, certain tropical areas in the Western Hemisphere appear to contain some well-defined locations of endemicity. These organisms can infect both adults and children, and intestinal involvement and symptoms are generally transient unless the patient is immunocompromised. *C. belli* has also been implicated in traveler's diarrhea (47). However, unlike *C. cayetanensis*, large outbreaks of cystoisosporiasis have not been reported.

Although oocysts of *Isospora natalensis* have been reported in patients from South Africa, the validity of this species requires further study and documentation.

Life Cycle and Morphology

Schizogonic and sporogonic stages in the life cycle of *C. belli* have been found in human intestinal mucosal biopsy specimens. Development in the intestine usually occurs within the epithelial cells of the distal duodenum and proximal jejunum. Eventually, oocysts are passed in the stool; they are long and oval and measure 20 to 33 µm by 10 to 19 µm (Table 23.2). Usually the oocyst contains only one immature sporont, but two may be present (Fig. 23.15 and 23.16). Continued development occurs outside the body with the development of two mature sporocysts, each containing four sporozoites, which can be recovered from the fecal specimen (Fig. 23.17, 23.18, 23.19, 23.20). The sporulated oocyst is the infective stage that will excyst in the small intes-

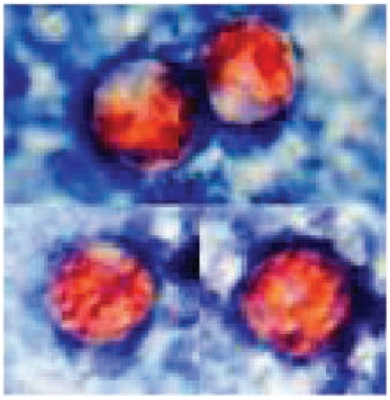

Figure 23.15 Hot safranin stain of *Cyclospora cayetanensis* oocysts (photographed at a high magnification). Note the oocysts are unsporulated. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch23.f15

tine, releasing the sporozoites, which penetrate the mucosal cells and initiate the life cycle. The life cycle stages, i.e., schizonts, merozoites, gametocytes, gametes, and oocysts, are structurally similar to those seen in the other coccidia.

The patent period is not known but may be as short as 15 days. Chronic infections develop in some patients, and oocysts can be shed for several months to years. In one particular case, an immunocompetent individual had symptoms for 26 years and *C. belli* was recovered in stool a number of times over a 10-year period. However, in such cases, one also has to take into account the possibility of reinfection.

Figure 23.16 Life cycle of *Cystoisospora belli*. (Illustration by Gwen Gloege.) doi:10.1128/9781555819002.ch23.f16

Clinical Disease

Risk factors for symptomatic *C. belli* infection may include a variety of conditions. In addition to immunocompromised states that include AIDS, adult T-cell leukemia, Hodgkin's lymphoma, non-Hodgkin's lymphoma, thy-

moma, transplantation, and corticosteroid-treated patients, immunocompetent conditions can also be the risk factors for symptomatic cystoisosporiasis. These factors include poor hygiene, malnutrition, chronic alcoholism, and debilitating infectious diseases.

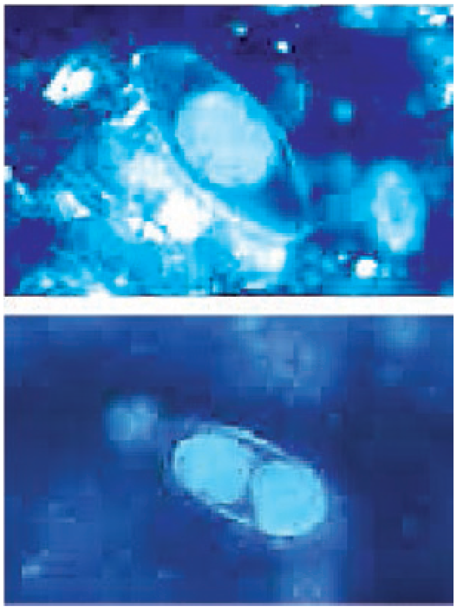
doi:10.1128/9781555819002.ch23.f20



Clinical symptoms include diarrhea, which may last for long periods (months to years), weight loss, abdominal colic, and fever; diarrhea is the main symptom. Bowel movements (usually 6 to 10 per day) are watery to soft, foamy, and offensive smelling, suggesting a malabsorption process. Eosinophilia is found in many patients, recurrences are quite common, and the disease is more severe in infants and young children. Charcot-Leyden crystals derived from eosinophils have also been found in the stools of patients with *C. belli* infection. The diarrhea and other symptoms may continue in compromised patients, even those on immunosuppressive therapy, when the regimen of therapy is discontinued. This infection has been found in homosexual men, all of whom were immunosuppressed and had several months of diarrhea.

Immunosuppressed Patients. Patients who are immunosuppressed, particularly those with AIDS, often present with profuse diarrhea associated with weakness, anorexia, and weight loss. In one patient with a well-documented infection of long standing, a series of biopsies showed a markedly abnormal mucosa with short villi, hypertrophied crypts, and infiltration of the lamina propria with eosinophils, neutrophils, and round cells. It has been recommended that physicians consider *C. belli* in AIDS patients with diarrhea who have immigrated from or traveled to Latin America, are Hispanics born in the United States, are young adults, or have not received prophylaxis with TMP-SMX for *Pneumocystis jirovecii*. It has also been recommended that AIDS patients traveling to Latin America and other developing countries be advised of the waterborne and foodborne transmission of *C. belli*, and they may want to consider chemoprophylaxis.

Chronic severe watery diarrhea due to *C. belli* has also been reported in other immunodeficiency states. These include HIV-negative renal transplant recipients, human T-cell leukemia virus 1-associated T-cell lymphoma, acute lymphoblastic leukemia, Hodgkin's lymphoma, and thymoma.

Extraintestinal Infections. Extraintestinal infections in AIDS patients have been reported. One patient was a 38-year-old man who presented with progressive dyspnea and fever; he also complained of dysphagia, nausea, vomiting, and brown watery diarrhea (eight or nine episodes daily) and had lost 20 lb in 2 months. He was diagnosed with *P. jirovecii* pneumonia and oropharyngeal candidiasis and was treated with TMP-SMX and pentamidine. His condition improved, and he was discharged; however, he was readmitted complaining of nausea, vomiting, and diarrhea; he was diagnosed with giardiasis and treated. Five months later he was diagnosed as having *C. belli* and *Entamoeba histolytica* infection and was treated. Three months later he presented with dyspnea, fever, diarrhea, and generalized wasting; he was diagnosed with cytomegalovirus pneumonia and died 2 weeks later. At autopsy, microscopic findings associated with *C. belli* infection were seen in the lymph nodes and walls of both the small and large intestines. Intracellular zoites were seen in the cytoplasm of histiocytes. Each organism was surrounded by a thick eosinophilic cyst wall in routine histologic preparations with hematoxylin and eosin, and the cyst wall was periodic acid-Schiff (PAS) positive. Examination of the intestinal tissues revealed intraepithelial asexual and sexual stages of *C. belli*, as well as some merozoites that appeared to be in cells of the lamina propria.

The second case involved a 30-year-old woman who was living in France but was originally from Burkina Faso. Initially she was symptomatic with fever, diarrhea, and weight loss. She was diagnosed with esophageal candidiasis and *C. belli* infection. She was treated with TMP-SMX and given maintenance therapy but suffered episodes of recurrent infection over the next 3 years. Examination of samples collected at autopsy revealed stages of *C. belli* in the intestine, mesenteric and mediastinal lymph nodes, liver, and spleen. The extraintestinal stages were always observed as single organisms that did not stain well with acid-fast stains. Massive infection with plasmacytosis and some eosinophils, but no granulomatous reaction, was observed.

In a third AIDS patient who presented with watery, nonbloody diarrhea and fever, examination of small intestine biopsy specimens revealed merozoites in the intestinal lumen, lamina propria, and lymphatic channels. Finding the merozoites within the lymphatic channels documents a means of dissemination to lymph nodes and other tissues. Additional studies of extraintestinal tissue cysts have identified early tissue cysts that lack a developed cyst wall, demonstrated that more than one tissue cyst can occupy a host cell, described the distribution of micronemes and the shedding of zoite membranes, and identified tubular structures in the inner tissue cyst wall and inner compartment.

In another AIDS patient who was sporadically treated for HIV, tuberculosis, and *C. belli* diarrhea over a period of years, autopsy findings confirmed the presence of macrogametocytes and microgametocytes within the epithelium of the gallbladder and unicellular cysts in the mesenteric lymph nodes, as well as in the esophagus, duodenum, ileum, colon, and appendix.

Diagnosis

HIV and intestinal parasitic infections are among the main health problems in developing countries. Coinfections of these diseases often enhance the progression of HIV to AIDS. Laboratory diagnosis and identification of opportunistic intestinal parasites should be emphasized for patients with lower CD4$^+$ T-cell counts, particularly those with ≤350 cells/mm^3 (48). Varying degrees of peripheral blood eosinophilia are often seen in patients with cystoisosporiasis. In patients with intestinal inflammatory diseases with diarrhea and peripheral blood eosinophilia, cystoisosporiasis should be included among the possible causative agents.

Routine Methods. Examination of a fecal specimen for the oocysts is recommended. However, wet preparation examination of fresh material either as the direct smear or as concentrated material is recommended rather than the permanent stained smear (Fig. 23.5; Table 23.3). The oocysts are very pale and transparent and can easily be overlooked. They can also be very difficult to see if the concentration sediment is from polyvinyl alcohol-preserved stool. The light level should be reduced, and additional contrast should be obtained with the microscope for optimal examination conditions (Fig. 23.16, 23.18, 23.19, and 23.20).

The oocysts are acid fast and can also be demonstrated by using auramine rhodamine stains. Organisms tentatively identified by using auramine rhodamine stains should be confirmed by wet smear examination or acid-fast stains, particularly if the stool contains other cells or excess artifact material (more normal stool consistency).

It is quite possible to have a positive biopsy specimen but not recover the oocysts in the stool because of the small numbers of organisms present. Stool microscopy cannot be used to rule out cystoisosporiasis, and even intestinal biopsies can provide false-negative results.

Histology. Based on multiple biopsies, the jejunal mucosa reveals a nodular appearance and villous atrophy with loss of villi. Histopathology reveals various *C. belli* life cycle stages, including trophozoites, schizonts, merozoites, and macro- and microgamonts (Fig. 23.21 and 23.22) (49). The mucosal tissues reveal villous atrophy, crypt hyperplasia, and diffuse infiltrations of eosinophils, lymphocytes, and plasma cells, which are consistent with cystoisosporiasis.

Molecular Testing. Although no test reagents are available commercially, a real-time quantitative PCR (qPCR) assay has been developed using melting curve analysis to detect, differentiate, and identify DNA from coccidian species of animal health, zoonotic, and food safety concern. The qPCR assay consistently detected DNA from as few as 10 *Toxoplasma gondii* oocysts, while demonstrating that *C. cayetanensis*, *C. parvum*, *Cryptosporidium muris*, *T. gondii*, *Eimeria bovis*, *Eimeria acervulina*, *Isospora suis*, and *Sarcocystis cruzi* could each be identified by unique melting curves and could be differentiated based on melting temperatures (50).

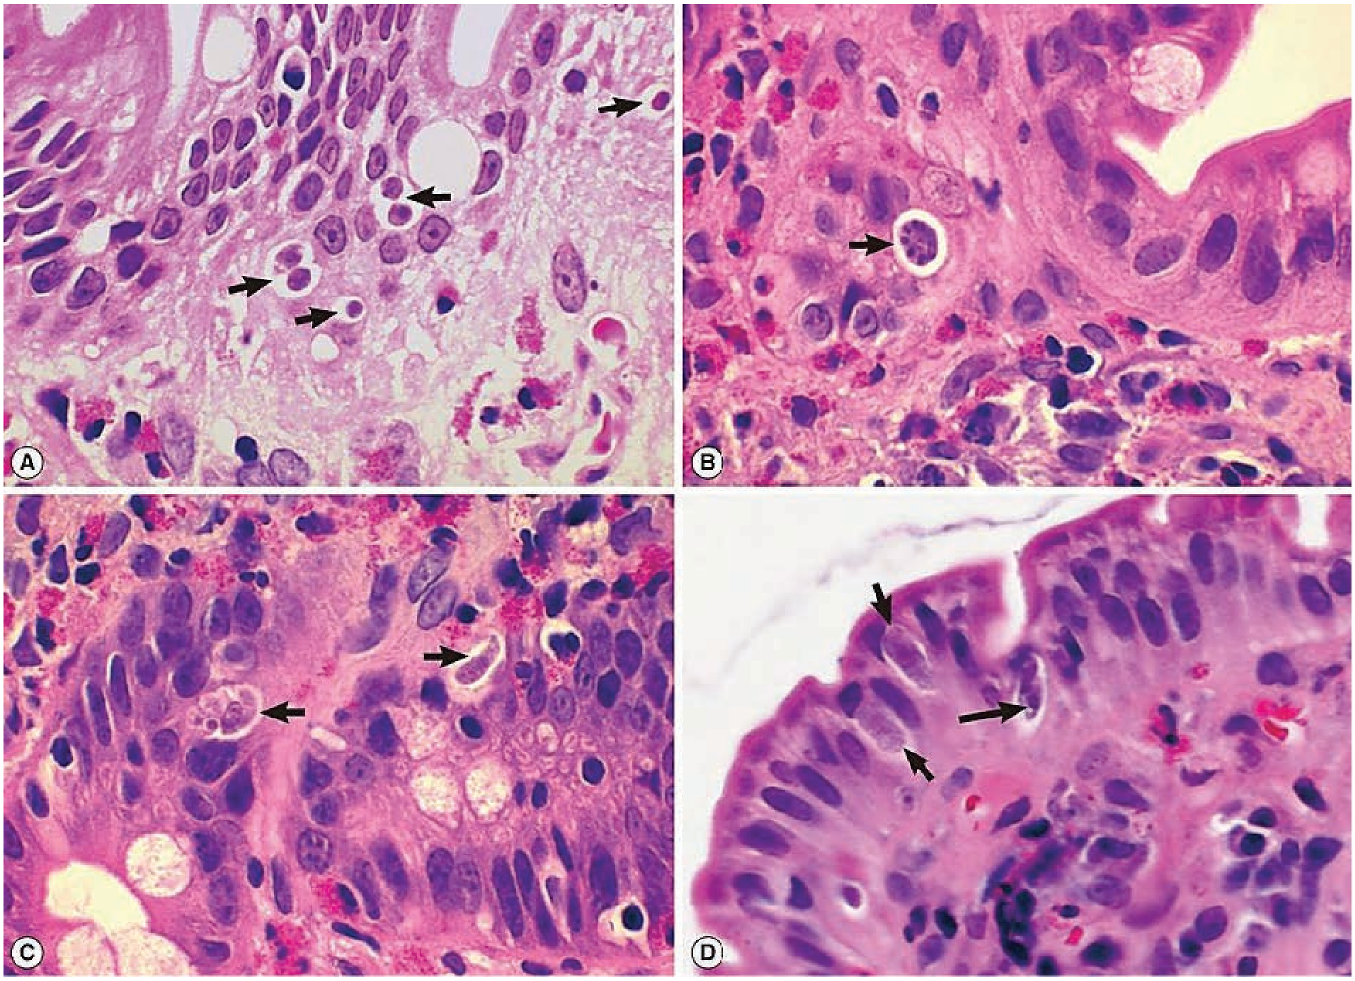


Figure 23.21 *Cystoisospora belli*. Sections of the upper jejunum showing various developmental (asexual and sexual) stages of *C. belli* (×1,000, hematoxylin and eosin stain). (A) Trophozoites (arrows), spherical in shape. (B) An immature schizont that has undergone nuclear division (arrow). Many eosinophils are infiltrated in the lamina propria. (C) A mature schizont with about six merozoites (left arrow) and a merozoite which has entered an enterocyte (right arrow). Eosinophil infiltrations are also seen in this figure. (D) Two merozoites in an enterocyte (long arrow), two macrogamonts (short arrows), and a developing trophozoite (lower left) are seen in the jejunal epithelial layer. KEY POINTS—LABORATORY DIAGNOSIS

Cystoisospora belli

1. The oocysts are more easily recovered and identified when wet preparations are examined (direct smear, concentration smear). In a permanent stained trichrome or iron-hematoxylin smear, the oocysts may appear as debris due to heavy staining.
2. Oocysts recovered in a concentrated sediment from polyvinyl alcohol-preserved stool may be very difficult to detect (the oocyst wall is very difficult to see). However, examination of the sediment from stool preserved in other fixatives is satisfactory (vials containing no polyvinyl alcohol, newer single-vial collection vials).
3. A biopsy can be positive while no organisms are seen in the stool. This is not necessarily due to poor-quality laboratory work but may reflect normal findings, particularly when oocyst numbers are low.
4. Although these organisms can be stained with auramine-rhodamine stains, they should be confirmed by wet smears or modified acid-fast stains.

Treatment

Effective eradication of the parasites has been achieved with cotrimoxazole, TMP-SMX, pyrimethamine-sulfadiazine, primaquine phosphate-nitrofurantoin, and primaquine phosphate-chloroquine phosphate (33). Other drugs proven to be ineffective include dithiazanine, tetracy-

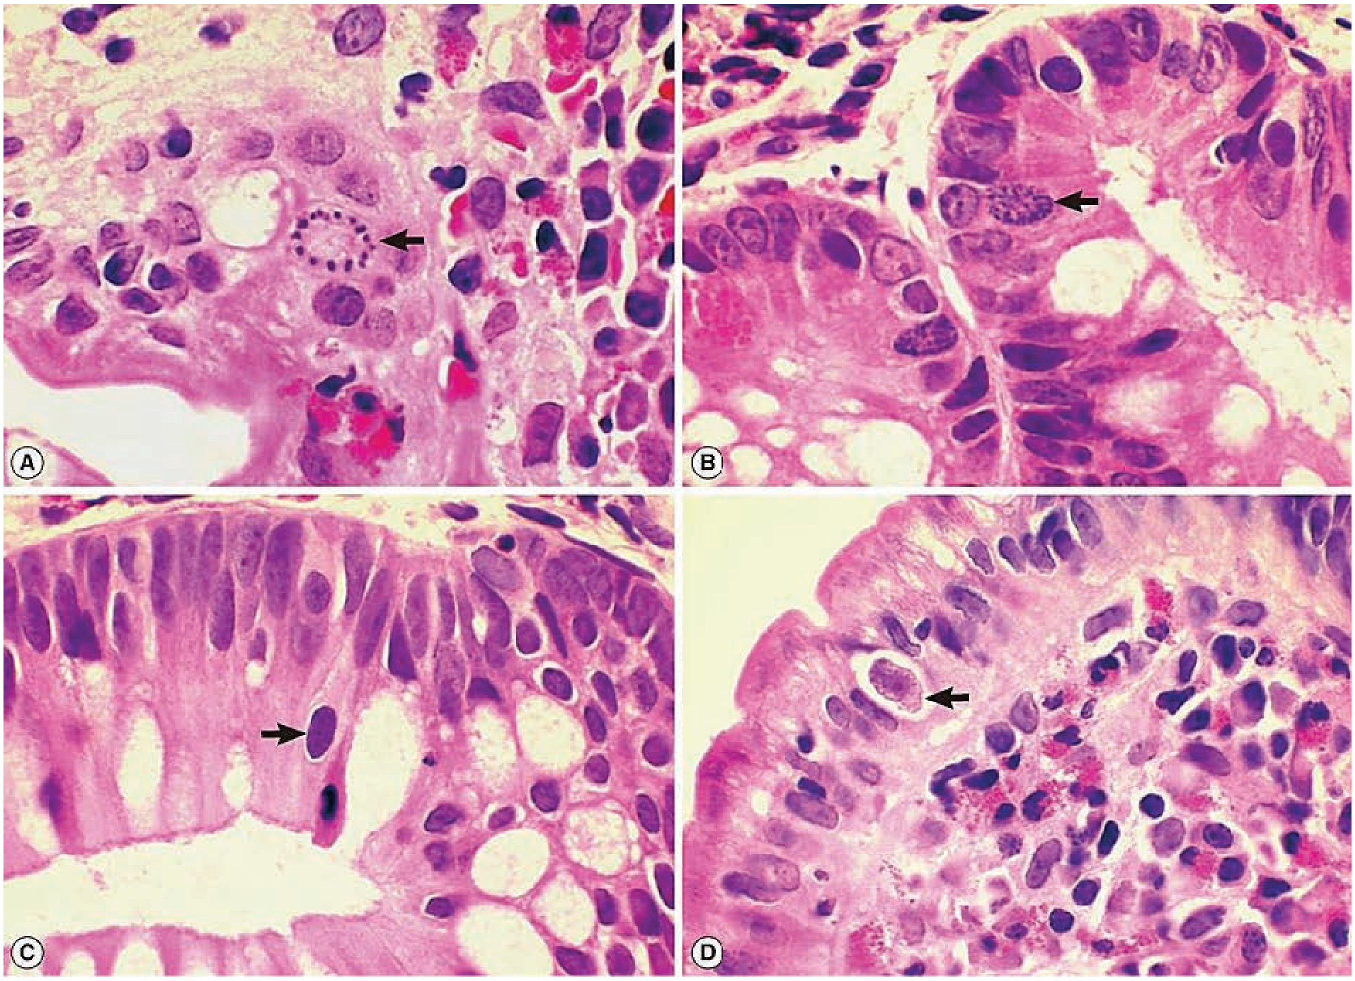

Figure 23.22 *Cystoisospora belli*. Sections of the upper jejunum showing various sexual stages of *Cystoisospora belli* (×1,000, hematoxylin and eosin stain). (A) A developing microgamont (arrow) with multiple nuclei that have migrated to the periphery. (B) A mature microgamont with multiple nuclei (arrow) in an enterocyte of the crypt layer. (C) A probable early macrogamont (arrow) in an enterocyte. (D) An old macrogamont or macrogamete (arrow) in a jejunal epithelial cell. cline, metronidazole, phanquone, and quinacrine hydrochloride. The drug of choice is TMP-SMX, which is classified as an investigational drug for treatment of this infection. TMP (160 mg) plus SMX (800 mg) is given every 6 h for 10 days and then twice a day for 3 weeks. Pyrimethamine alone (50 to 75 mg daily) has cured infections in patients allergic to sulfonamides. However, chronic relapsing *C. belli* infections have been reported in AIDS patients despite treatment with TMP-SMX and immune reconstitution; in immunosuppressed patients with recurrent or persistent infection, therapy must be continued indefinitely. See chapter 36.

Epidemiology and Prevention

C. belli is thought to be the only species of *Cystoisospora* that infects humans, and no other reservoir hosts are recognized for this infection. Transmission is through ingestion of water or food contaminated with mature, sporulated oocysts. Sexual transmission by direct oral contact with the anus or perineum has also been postulated, although this mode of transmission is probably much less common. The oocysts are very resistant to environmental conditions and may remain viable for months if kept cool and moist; oocysts usually mature within 48 h following stool evacuation and are then infectious. It has been speculated that diagnostic methods for laboratory examinations may tend to miss the organisms when they are present. Since transmission is via the infective oocysts, prevention centers on improved personal hygiene measures and sanitary conditions to eliminate possible fecal-oral transmission from contaminated food, water, and possibly environmental surfaces.

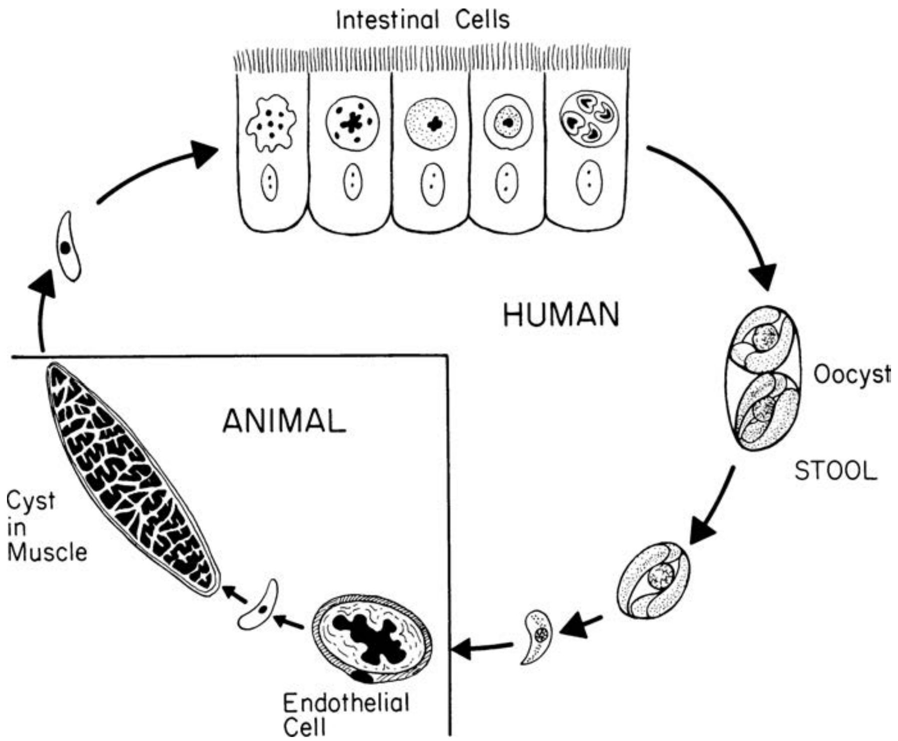

Figure 23.23 Life cycle of *Sarcocystis* spp. (Illustration by Gwen Gloege.)
doi:10.1128/9781555819002.ch23.f23

Sarcocystis spp.

The organism once known as *Isospora hominis* is now recognized as being a part of the life cycle of *Sarcocystis* spp. (Fig. 23.23). Two well-described species are *Sarcocystis hominis* (*bovihominis*) (cattle) and *S. suihominis* (pigs). When uncooked meat from these infected animals is ingested by humans, gamogony can occur within the intestinal cells, with the eventual production of the sporocysts in stool. In this case, humans who have ingested meat containing the mature sarcocysts serve as the definitive hosts (51, 52). There have been reports of fever, severe diarrhea, abdominal pain, and weight loss in immunocompromised hosts, although the number of patients with these symptoms has been quite small.

Life Cycle and Morphology

Species of *Sarcocystis* have an obligatory two-host life cycle. Intermediate hosts (including humans) such as herbivores and omnivores become infected through ingestion of sporocysts excreted in the feces of the definitive hosts such as carnivores and omnivores. The definitive hosts (including humans) become infected through ingestion of mature cysts found in muscles of the intermediate hosts. In some intermediate hosts, such as cattle and sheep, all adult animals may be infected (Table 23.18).

Sarcocystis hominis (bovihominis). Infection occurs when raw or poorly cooked infected meat is ingested by the human host. Known intermediate hosts include cattle (*Bos taurus*), American bison (*Bison bison*), water buffaloes (*Bubalus bubalis*), and wisents (European bison; *Bison bonasus*). These intermediate hosts harbor sarcocysts (muscle cysts) that are infective when ingested by humans. Infective bradyzoites (dormant merozoite-like stages) are present in the sarcocysts. The bradyzoites penetrate the human intestinal epithelium and develop as sexual stages (macrogametocytes and microgametocytes) in cells in the lamina propria of the intestine. Fertilization occurs, and the oocysts sporulate in the lamina propria.

The sporocysts that are recovered in the stool are broadly oval and slightly tapered at the ends, measure 9 to 16 μm, and contain four mature sporozoites and the residual body (Table 23.2). Normally, two sporocysts are contained within the oocyst (similar to that seen with *C. belli*); however, in *Sarcocystis* infections, the sporocysts are released from the oocyst and normally are seen singly (Fig. 23.23). They tend to be larger than *Cryptosporidium* oocysts, which contain four sporozoites, so there should be no confusion between the two. The oocysts are fully sporulated when passed in the stool.

In humans, the prepatent period is 8 to 39 days, and patent infections can last as long as 18 months. *S. hominis* occurs on all continents, anywhere cattle or buffaloes have access to human feces and humans ingest raw or undercooked beef.

TABLE 23.18 *Sarcocystis* development and disease symptoms in humans[a]

Topic	Muscle	Intestine
Infection source	Water or food contaminated with infected feces containing oocysts from unknown carnivore or omnivore	Raw or poorly cooked meat
Infective stage	Oocyst or free sporocysts	Sarcocyst containing bradyzoites
Developmental stages	Intravascular schizonts (not seen); intramuscular sarcocysts	Sexual stages found in lamina propria; oocysts excreted in feces
Incubation time from ingestion of infective stage to disease symptoms	Weeks to months, lasting months to years	3–6 h, lasting approximately 36 h
Disease symptoms	Musculoskeletal pain, fever, rash, cardiomyopathy, bronchospasm, subcutaneous swelling	Nausea, anorexia, vomiting, stomach ache, bloat, diarrhea, dyspnea, and tachycardia; may also include abdominal pain and eosinophilia; severe symptoms may include segmental necrotizing enteritis (rare and not well confirmed)
Diagnosis	Biopsy specimen(s) contains sarcocysts; antibodies to bradyzoites; routine histology on biopsy specimens; wall may be PAS positive, but stain variability is common	Oocysts or sporocysts in feces, beginning about 5–12 days after ingestion of raw or undercooked meat; *S. hominis* (beef) is excreted 14–18 days after meat ingestion, while *S. suihominis* (pork) is excreted 11–13 days after ingesting meat
Therapy	Cotrimoxazole, furazolidone, albendazole, anticoccidials, pyrimethamine, anti-inflammatories	None

[a]Adapted from reference 51.

Sarcocystis suihominis. The life cycle is similar to that described above for *S. hominis*, with pigs serving as the intermediate hosts. The prepatent period is 9 to 10 days, and patency is generally longer than 36 days. *S. suihominis* presumably occurs on all continents where swine have access to human feces and humans ingest raw or poorly cooked pork.

Muscular *Sarcocystis* Infections. Muscular *Sarcocystis* infections in humans are usually subclinical or associated with mild clinical signs. Many of the cases have been incidental findings or associated with eosinophilic myositis. Muscular sarcocystosis has been associated with malignancies, primarily involving the tongue and nasopharynx. In these cases, the life cycle is a dead end, as no oocysts are passed in the feces.

Clinical Disease

Intestinal Disease. When humans serve as definitive hosts, prevention involves adequate cooking of beef, pork, and other infected meats (51, 52). In cases of intestinal sarcocystosis, infections are often asymptomatic and clear spontaneously. Occasionally, mild fever, diarrhea, chills, vomiting and respiratory problems may occur (Fig. 23.24).

Muscular Disease. When humans are intermediate hosts, preventive measures involve careful disposal of animal feces that may contain the infective sporocysts. This may be impossible in the wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that in the past were grouped under the term *Sarcocystis* "*lindemanni.*" However, this name is no longer used. No specific therapy is known for the muscle stages of *Sarcocystis* spp. Various sizes of protozoan cysts, oocysts, and spores that occur in human stool specimens are given in Table 23.19.

When humans accidentally ingest oocysts from other animal stool sources, the sarcocysts that develop in human muscle apparently do little if any harm (schizogony) (51, 52). The prepatent period in humans is from 9 to 10 days. There is essentially no inflammatory response to these stages in the muscle and no conclusive evidence of pathogenicity of the mature sarcocyst. However, symptoms have been seen in some patients, probably associated with disin-

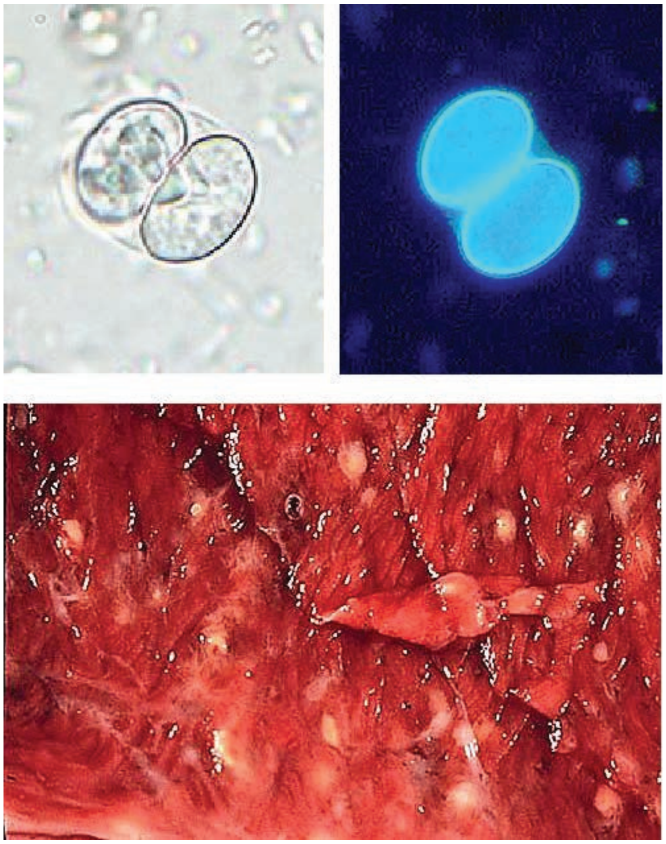

Figure 23.24 *Sarcocystis* spp. (Upper, left) Sporulated oocyst in unstained wet mount; (right) sporulated oocyst in wet mount viewed under UV microscopy, magnification ×400 (courtesy of the CDC Public Health Image Library). (Lower) Classic sarcocystosis in cut beef (courtesy of the University of Sydney, Centre for Veterinary Education, http://vetbook.org/wiki/cow/index.php/Sarcocystis_spp). doi:10.1128/9781555819002.ch23.f24

tegration of the sarcocysts (Table 23.18). Painful muscle swellings, measuring 1 to 3 cm in diameter, initially associated with erythema of the overlying skin in various parts of the body, occur periodically and last for 2 days to 2 weeks. Some patients also have fever, diffuse myalgia, muscle tenderness, weakness, eosinophilia, and bronchospasm. No apparent clinical manifestations have been found in patients in whom myocardial *Sarcocystis* infection was detected accidentally by autopsy. A number of different morphological types of skeletal and cardiac muscle sarcocysts have been recovered in humans. No specific therapy is known for this type of infection; however, corticosteroids should reduce the allergic inflammatory reactions occurring after cyst rupture.

Intact sarcocysts in skeletal or cardiac muscle of humans measure up to 100 by 325 µm and are usually not accompanied by an inflammatory reaction (Fig. 23.25). Each sarcocyst contains many bradyzoites, approximately 7 to 16 µm long. Inflammation follows disintegration of the cysts and death of the intracystic bradyzoites. Vasculitis is seen in the muscle and subcutaneous tissues. Histologic findings include myositis with vasculitis and sometimes myonecrosis.

Muscular Disease Outbreak. Prior to an outbreak from Tioman Island, Malaysia, in 2011–2012, <100 cases of intramuscular infection with *Sarcocystis* spp. had been reported in humans. Ninety-two persons attended a college retreat, which was held in a small hotel on the coast of Tioman Island, where all outdoor activities were conducted on the beach or in the ocean. In this outbreak, 89/92 patients were identified with onset of fever (94%), myalgia (91%), headache (87%), and cough (40%) ≤26 days upon return from the retreat. In persons who had a fever, the fever had a relapsing-remitting nature in 57% of patients. Some patients reported facial and calf muscle swelling and myalgias. Changes in mastication and masseter muscles were also seen. Typical sarcocysts (length ≈190 µm) were observed in cell cultures inoculated with the muscle tissue homogenates of one of the patients, and directly in the muscle tissue of another patient. DNA sequences obtained from 1,812-bp fragments were compared with fragments in GenBank by using BLAST (http://blast.ncbi.nlm.nih.gov/). Sequences matched 100% of those reported as *Sarcocystis nesbitti*, which has been reported in the skeletal muscles of *Macaca mulatta* monkeys. Although only two patients were confirmed to be acutely infected with *S. nesbitti*, it was likely that the remaining students and teachers in the group had the same infection. Almost everyone in the group had similar signs and symptoms, with onset of illness within days of each other (53).

Diagnosis

Intestinal Disease. Presumptive diagnosis is often based on the patient's symptoms, including a history of having ingested raw or poorly cooked meat. Confirmation of the diagnosis may depend on several stool examinations, some of which may reveal sporocysts. They are generally passed beginning 14 to 18 days after beef ingestion and about 11 to 13 days after pork ingestion. Some researchers think that the zinc sulfate fecal flotation method is preferred to the formalin-ethyl acetate sedimentation method for sporocyst and/or oocyst recovery (13). Sporocysts of *S. hominis* tend to be more elongated than those of *S. suihominis*, but the two may be difficult to differentiate.

Muscular Disease. Intramuscular infection would be suspected based on symptoms, including persistent myalgia, episodic weakness, subcutaneous nodules, dermatomyositis, eosinophilia, and elevated muscle creatinine kinase levels. Often these symptoms, coupled with a history of travel

TABLE 23.19 Protozoan cysts, oocysts, sporocysts, and spores seen in human feces[a]

Organism	Shape	Size (µm)	Features	Comments
Balantidium coli	Spherical to oval	50–70	Large macronucleus, thick wall	Although cilia are within the cyst wall, they are more difficult to see than the cilia surrounding the trophozoite form
Cystoisospora belli	Oval, more tapered ends	20–33 by 10–19	Generally immature oocysts passed, but some containing two sporocysts may be visible	Not infectious when passed; best diagnostic approach is wet mount of concentrated sediment; some recommend flotation rather than sedimentation concentration
Sarcocystis hominis				
Oocysts	Spherical	15–19 by 15–20	Contain 2 sporocysts, but oocyst wall appears to be missing	Generally infectious when passed
Sporocysts	Oval	15–19 by 8–10	Contain 4 sporozoites	Infectious
Sarcocystis suihominis				
Oocysts	Spherical	15–19 by 15–20	Contain 2 sporocysts, but oocyst wall appears to be missing	Generally infectious when passed
Sporocysts	Oval	15–19 by 8–10	Contain 4 sporozoites	Infectious
Entamoeba histolytica/ *E. dispar*	Spherical	12–15		Precyst contains single nucleus (generally), while mature cyst contains 4 nuclei and possible chromatoidal bars with rounded ends
Giardia lamblia	Spherical to oval	11–14	Contains 4 nuclei, curved median bodies, and linear axonemes	Some cysts appear to be found; important to focus up and down to see morphologic characteristics; infective when passed
Cyclospora cayetanensis	Spherical	8–10	May appear as "wrinkled cellophane"	Not infectious when passed
Cryptosporidium hominis and *C. parvum*	4–6	Nearly spherical	Sporozoites may be difficult to see; modified acid-fast stains recommended	Infectious when passed
Encephalitozoon spp. and *Enterocytozoon bieneusi*	1.5–3.5	Oval, mimic small yeast cells and/or bacteria	Horizontal or diagonal stripe (polar tubule) may be difficult to see in every spore	Infectious when passed

[a] Other pathogenic protozoa, *Dientamoeba fragilis* (very rare cyst forms) and *Blastocystis* spp., may overlap *Giardia* and *Entamoeba* spp. in size and may appear spherical to somewhat oval.

to or living in tropical locations, suggest the next step, which would be a muscle biopsy. Sarcocysts in biopsy specimens can be identified by microscopy of routine histologic sections stained with hematoxylin and eosin. Stain variability is common, and PAS positivity of the sarcocyst wall is not always seen.

Sarcocystis can be detected in meat by using routine histologic methods. Most sarcocysts in humans have been identified in skeletal and cardiac muscle; however, muscles in the larynx, pharynx, and upper esophagus have also been involved. Artificial digestion fluids can also be used on the meat source; after centrifugation, the sediment can be examined microscopically for the presence of bradyzoites.

Muscle sarcocystosis can be suspected in persons with signs and symptoms of myositis, with or without fever. Ill patients may have an elevated eosinophil count and may have an elevated creatine kinase (CK) with no other explanation for these findings. Eosinophil counts and CK levels may rise approximately 40 days after infection. A muscle biopsy may or may not demonstrate classic sarcocysts. Molecular testing is not widely available.

KEY POINTS—LABORATORY DIAGNOSIS

***Sarcocystis* spp.**

1. The oocysts are more easily recovered and identified in wet preparations (direct smear, concentration smear; flotation is recommended over sedimentation concentration methods).
2. The sporocysts are released from the oocyst and are seen singly (they are larger than *Cryptosporidium* oocysts).
3. Sarcocysts in muscle can be identified by routine histologic methods; however, there is a lot of staining variability (hematoxylin and eosin stains; PAS-positive sarcocyst walls may not be easily visible).

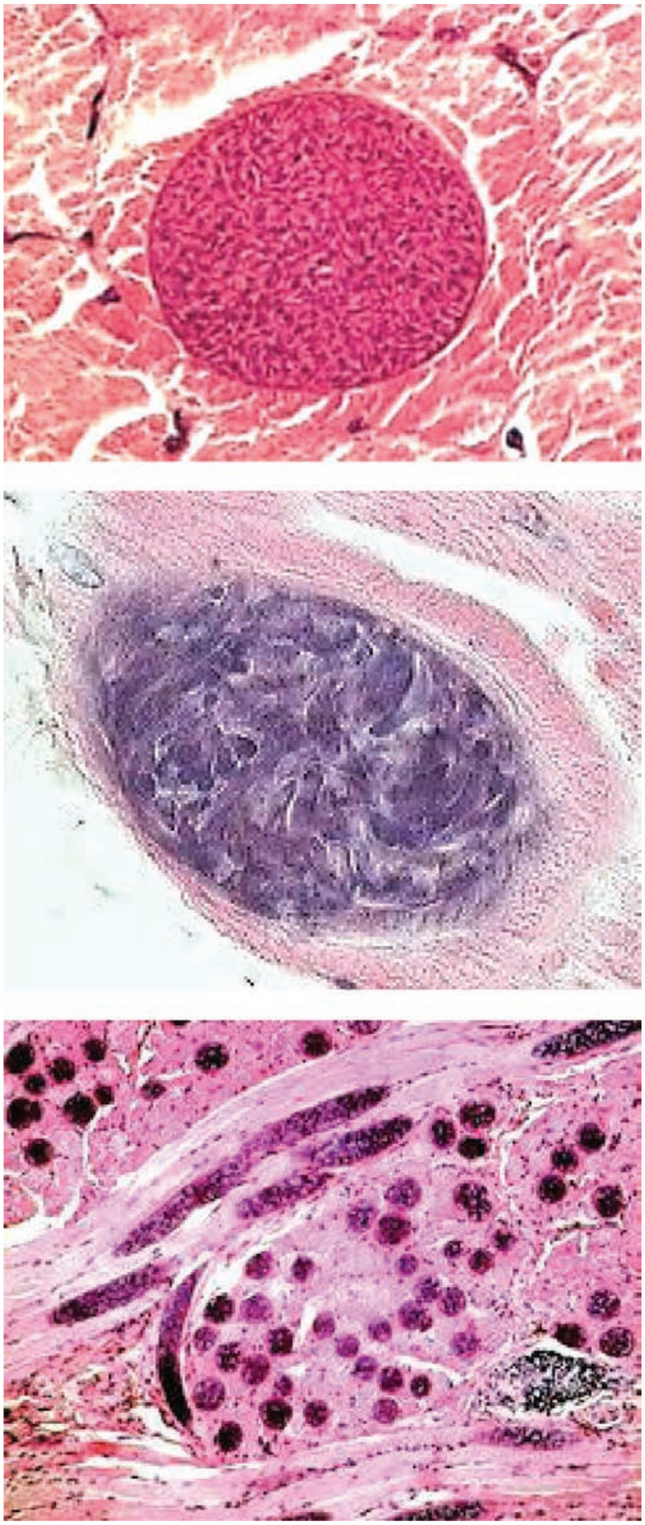

Figure 23.25 (Top) *Sarcocystis* spp. in human muscle. (Middle) Higher magnification showing individual elongate bradyzoites. (Bottom) Numerous sarcocysts in longitudinal and cross section in muscles of sheep tongue. Note the lack of direct inflammatory response to sarcocysts. (Bottom image courtesy of reference 51.) doi:10.1128/9781555819002.ch23.f25

Treatment

Intestinal sarcocystosis is self-limiting and often asymptomatic and lasts for a short time. Although cotrimoxazole and furazolidone have been used, their effectiveness is still questionable. Currently, no therapy has been approved for treatment for myositis, vasculitis, or related lesions in humans. The efficacy of albendazole has been reported but has not been demonstrated in controlled studies. Although drugs such as pyrimethamine and others used to treat toxoplasmosis have been considered, the efficacy of such drugs has not been documented. It is also unknown whether immunosuppressives might be effective in reducing the inflammatory reactions seen in vasculitis or myositis. Without more definitive data, no recommended course of therapy is currently available.

Epidemiology and Prevention

Apparently, multiple ruminant species serve as intermediate hosts of *Sarcocystis* spp. and as sources of infection for humans, and humans serve as intermediate hosts for several species of *Sarcocystis*, perhaps by ingesting sporocysts excreted by predators of nonhuman primates. Humans, baboons, and rhesus monkeys serve as definitive hosts for *S. hominis*, and humans, chimpanzees, and rhesus and cynomolgus monkeys serve as definitive hosts for *S. suihominis*. *S. hominis* occurs worldwide in areas where cattle or buffalo have access to human feces and humans ingest raw or undercooked beef. *S. suihominis* probably occurs worldwide in areas where swine have access to human feces and humans ingest raw or undercooked pork.

Thoroughly cooking or freezing meat to kill bradyzoites within the sarcocysts will prevent intestinal sarcocystosis. Freezing at –4 and –20°C for 48 and 24 h, respectively, is sufficient to kill bradyzoites. It has been documented that rare roast beef and hamburger purchased from a supermarket contained bradyzoites infectious for dogs whereas cooked products were not infectious for dogs.

Prevention of infection in food animals depends on eliminating the sporocyst stage from human feces in contaminated water, feed, and bedding. Also, to prevent humans from serving as intermediate hosts, ingestion of sporocysts must be prevented; the most likely source is contaminated water for drinking or washing foods. Boiling is the best method to guarantee disinfection. Thorough washing or cooking of foods is also recommended.

It has been reported that more than 27 outbreaks per year of food poisoning caused by consuming horse meat were reported in Kumamoto Prefecture (including Kumamoto City), Japan, from January 2009 to September 2011. It was found that the causative agent of the outbreaks was a protein that had originated from bradyzoites of *Sarcocystis fayeri* parasitizing the horse meat. After public health recommendations to freeze the meat at –20°C for

48 h or more, no subsequent cases were reported from the ingestion of raw horse meat containing *S. fayeri* (54).

Microsporidia

Although the microsporidia are true eukaryotes (i.e., they possess a typical eukaryotic nucleus, endomembrane system, and cytoskeleton), they also display molecular and cytological characteristics of prokaryotes, including features of the translational apparatus and genome size (range of bacteria), and lack recognizable mitochondria, peroxisomes, and typical Golgi membranes. These unusual features are thought to reflect their primitive eukaryotic nature. However, it is now well recognized that these unicellular organisms are best described as representing one of many offshoots of the fungal kingdom. Phylogenetic studies have confirmed that the microsporidia evolved from the fungi, being most closely related to the zygomycetes (55, 56). Other features that are shared with fungi include the presence of chitin and trehalose, similarities in cell cycles, and certain gene organizations. Microsporidia are now considered to be highly derived fungi that underwent genetic and functional losses, thus resulting in one of the smallest eukaryotic genomes known. However, at this point, clinical and diagnostic issues and responsibilities may remain with the parasitologists, and these organisms will be maintained as a part of this parasitology text. We may be in a transition stage, similar to that seen with *Pneumocystis jirovecii* as it was moved from the parasites to fungi in terms of classification status (Tables 23.20, 23.21, and 23.22).

During the early part of the 19th century, an epidemic disease was causing tremendous problems in the silkworm industry, particularly in Italy and France; the disease was called pébrine, which means "pepper disease." In 1863 Louis Pasteur was asked to study this problem, and by 1870 he had published his findings, in which he described a method for controlling and preventing the disease. This work represents the first scientific study of a disease caused by a protozoan, a microsporidian parasite, which resulted in practical control measures. Nägeli named the agent *Nosema bombycis*; however, he placed it in the Schizomycetes (at that time consisting of yeast and bacteria). A similar infection is seen in honeybee hives and is caused by *Nosema apis*. In 1882, Balbiani suggested the order Microsporida to handle *N. bombycis*, the only microsporidian known at the time. It was not until 1976 that the phylum Microspora was created, and it was updated in 1992 to propose that Microsporidia Balbiani 1882 should be the acknowledged phylum name, as well as the correct author and date (56). Currently, the phylum contains more than 170 genera and approximately 1,400 species, many of which are of medical, veterinary, and agricultural importance.

The microsporidia are obligate intracellular organisms that have been recognized in a variety of animals, particularly invertebrates. Typical sizes range from 1.5 to 5 μm wide and 2 to 7 μm long; unfortunately, the organisms found in humans tend to be quite small, ranging from 1.5 to 2 μm long. Until recently, awareness and understanding of human infections have been marginal; only with increased understanding of AIDS within the immunosuppressed population has attention been focused on these organisms. Limited availability of EM capability has also played a role in the inability to recognize and diagnose these infections. However, with the introduction of newer diagnostic methods, the ability to identify these parasites has definitely improved. The organisms are characterized by having spores containing a polar tubule, which is an extrusion mechanism for injecting the infective spore contents into host cells. To date, several genera have been recognized in humans: the more common, *Encephalitozoon* and *Enterocytozoon*, and the less common, *Brachiola*, *Pleistophora*, *Trachipleistophora*, *Vittaforma*, *Septata*, *Anncaliia*, *Tubulinosema*, and "Microsporidium," a catch-all genus for organisms that have not yet been classified (or may never be classified due to a lack of specimen). Classification criteria include spore size, configuration of the nuclei within the spores and developing forms, the number of polar tubule coils within the spore, and the relationship between the organism and host cell.

Microsporidiosis is an important emerging opportunistic infection in HIV-infected patients, and many patients with chronic diarrhea have been seen worldwide. Patients infected with *Cryptosporidium* spp. may also have concurrent infections with microsporidia, and this number may approach 30%. These findings emphasize the importance of considering both organisms as potential causative agents of diarrhea in compromised patients, particularly those with HIV. However, with the current use of antiretroviral combination therapy, the same decrease seen with cryptosporidiosis in this patient group has also been seen with microsporidiosis. Microsporidia also cause disease in organ transplant recipients, children, travelers, contact lens wearers, and the elderly. Microsporidiosis may involve any tissue of the body, including muscle, intestine, gallbladder, liver, kidneys, eyes, brain, lungs, skin, and nasal sinuses. Intestinal microsporidiosis is the most common, occurring in 30% to 50% of AIDS patients with chronic diarrhea.

Life Cycle and Morphology

The spore is the only life cycle stage able to survive outside of the host cell and is the infective stage. The spore normally reaches the new host through ingestion, although other routes of transmission have been identified. The life cycles of microsporidia infecting humans have three

TABLE 23.20 Microsporidia causing human infection[a]

Species	Nonhuman hosts	Sources of human infection	Sites of infection	Comments
Common				
Enterocytozoon bieneusi	Pigs, nonhuman primates, nonmammals (chickens, pigeons)	Fecal-oral; oral-oral, inhalation, ingestion, direct human-to-human; organ transplants	Small intestine, gallbladder, liver, disseminated (respiratory system)	Short-term culture only; 3 strains identified but not named; AIDS patients with chronic diarrhea, immunocompetent individuals; more than 90 genotypes described (17 infect humans); zoonotic and nonzoonotic genotypes; human isolates generally belong to group 1
Encephalitozoon cuniculi			Systemic, eye, respiratory system, urinary tract, liver, peritoneum, brain	
Strain I (rabbit)	Rabbits, rodents, carnivores, monkeys	Probably ingestion	Cerebrospinal fluid, intestine, respiratory, kidneys, nasal epithelium, eyes	Definitely zoonotic; spores highly resistant in environment (months under humid conditions); waterborne infections feasible
Strain II (mouse)	Mice, wild rats, blue foxes	Not relevant	Not relevant	Not identified in humans
Strain III (dog)	Dogs, tamarins (may have been imported from United States)	Probably ingestion	Kidneys, adrenal glands, ovaries, brain, heart, spleen, lungs, lymph nodes	Case occurred in Italy; AIDS (may be first report of infection involving ovaries); identified in humans in United States (not confirmed in dogs related to cases)
Encephalitozoon hellem	Psittacine birds	No epidemiologic studies; surface waters not confirmed; probably ingestion, aerosols, or oral or ocular direct inoculation; for drug addicts, contaminated syringes suggested but not proven	Disseminated; ocular in HIV-positive patients (patients with eye infections owned birds); respiratory tract, urinary tract, systemic	Asymptomatic respiratory infections reported; bronchoalveolar lavage in HIV-seronegative patients; stools from travelers (coinfected with *E. bieneusi*); *E. hellem* isolates from the United States and Europe are different populations
Encephalitozoon intestinalis	Dogs, donkeys, pigs, cows, goats, free-ranging gorillas	Probably ingestion, inhalation, direct inoculation; waterborne transmission suspected	Small intestine, disseminated; immunocompromised and immunocompetent, biliary tract, respiratory tract, bone, skin, systemic	Second most common species infecting humans; double infections with *E. bieneusi* occur
Uncommon				
Anncaliia (Brachiola, Nosema) algerae	Mosquitoes	Possible arthropod-borne	Eyes, muscle; possible dissemination; immunocompromised and immunocompetent	
Anncaliia (Brachiola, Nosema) connori	None identified	Unknown	Systemic	Formerly *Nosema connori*; immunocompromised child (SCID)
Anncaliia (Brachiola, Nosema) vesicularum	None identified	Unknown	Corneal stroma, skeletal muscle	Probably a *Nosema*-like species; non-HIV patient
Microsporidium (Nosema) africanum	None identified	Unknown	Corneal ulcer of African woman	Catch-all genus for organisms that could not be identified; HIV-seronegative individual at autopsy
Microsporidium (Nosema) ceylonensis	None identified	Unknown	Corneum	Boy gored by goat (injured eye), but may not be relevant

(continued)

TABLE 23.20 Microsporidia causing human infection[a] *(continued)*

Species	Nonhuman hosts	Sources of human infection	Sites of infection	Comments
Pleistophora ronneafiei	Fish, reptiles; possible animal reservoir not defined	Unknown	Muscle	Non-HIV and HIV positive; *Pleistophora* spp. (2 cases) may actually be *Trachipleistophora* spp.
Trachipleistophora anthropophthera	None identified, but may be insects	Unknown	Brain, heart, kidneys, eyes	AIDS patients
Trachipleistophora hominis	None identified, but may be insects	Unknown, but probably direct inoculation	Muscle, nasal epithelium, conjunctiva, keratitis	AIDS patient (severe sinusitis, myositis); immunocompetent patient
Vittaforma corneae (*Nosema corneum*)	Appear to be ubiquitous	Waterborne very likely; some intestinal infections may reflect intestinal passage of spores rather than infection	Eyes, corneal stroma; urinary tract	First human isolate established in an *in vitro* culture; non-HIV patient; formerly *Nosema corneum*
Tubulinosema acridophagus	Grasshoppers	Unknown	Systemic	From patient with chronic lymphocytic leukemia and acute renal failure

[a] Adapted from references 55, 56, 59, 60.

phases: infective, proliferative, and sporogonic (Fig. 23.26 and 23.27).

Infective Stage. As seen in Fig. 23.26, infection occurs with the introduction of infective sporoplasm through the polar tubule into the host cell. The sporoplasm passes through the tubule and is deposited into a new host cell in less than a second, thus initiating infection within a new host cell.

Proliferative Stage. The proliferative phase is initiated when a sporoplasm grows and divides extensively, producing many organisms within the new host-cell cytoplasm.The life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time.

Sporogonic Stage. During sporogony, a thick spore wall is formed, providing environmental protection for this infectious stage of the parasite. An example of infection potential is illustrated by *Enterocytozoon bieneusi*, an intestinal pathogen. The spores are released into the intestinal lumen and are passed in the stool. These spores are environmentally resistant and can then be ingested by other hosts. There is also evidence for inhalation of spores and evidence in animals that suggests that human microsporidiosis may also be transmitted via the rectal route (57).

While the spore structures themselves are characteristic of microsporidia, the number of spores produced in sporogony, the way they are produced, and the host-parasite interface will differ among the microsporidian genera. The host-parasite interface may involve (i) direct contact with host-cell cytoplasm, (ii) indirect contact with host-cell cytoplasm by production of a parasite-secreted envelope (sporophorous vesicle), (iii) indirect contact by production of a parasite-induced, host-produced envelope (parasitophorous vacuole), or (iv) indirect contact by a host-produced envelope (parasitophorous vacuole) and parasite-produced secretions. These characteristics, along with morphologic features of developmental stages, nucleation, site of infection, and serologic and molecular features, help to identify the genus and species (55) (Table 23.21).

Clinical Disease

Microsporidia were recognized as causing disease in animals as early as the 1920s but were not recognized as agents of human disease until the AIDS pandemic began in the mid-1980s. Several earlier human cases had been reported but were thought to be very unusual. Currently, with more than 1,300 species of microsporidia, one would expect confirmation of additional human parasites in the future (Table 23.20) (57, 58).

TABLE 23.21 Host-parasite interface among the microsporidia genera[a]

Type of interface	Description and examples
Type I. Direct contact	Direct contact with host-cell cytoplasm *Nosema*, *Brachiola*, *Anncaliia*, *Enterocytozoon*
Type II. Indirect contact; host-produced isolation	A. Parasitophorous vacuole: host forms single membrane surrounding the developing parasite cell cluster. This is present during the proliferative and the sporogonic phases; however, the parasite relationship to this membrane undergoes change. The developing parasite cells maintain a very close relationship with this envelope until they develop the thickened sporont plasmalemma, then they appear loose within the vacuole. *Encephalitozoon cuniculi*.
	B. Host ER[a]: double membrane surrounds parasite cells throughout development. In the proliferative phase, the host ER double membranes follow the plasmalemma of the dividing cells so that no obvious vacuole is formed. In sporogony, the host ER does not divide with the sporonts but forms a double-membrane parasitophorous vacuole surrounding the cluster of organisms formed in sporogony. *Vittaforma* sp.
Type III. Indirect contact; parasite-produced isolation	A. Parasite-secreted envelope surrounds parasite cells throughout development. It becomes a sporophorous vesicle in sporogony when the parasite plasmalemma pulls away from the secreted envelope and then the plasmalemma thickens. *Pleistophora* sp.
	B. The parasite develops in direct contact with the host cell cytoplasm during early development but then a parasite-formed membrane isolates the sporonts from host cytoplasmic contact. *Vairimorpha* sp.
Type IV. Indirect contact; host- and parasite-produced isolation	A. Host ER closely aligns itself against the parasite plasmalemma in merogony. Then the parasite produces “blisters” arising from the plasmalemma to form the interfacial envelope. Thus a sporophorous vesicle is formed in sporogony and may also contain tubules. *Loma* sp. and *Glugea* sp.
	B. The host and parasite contribute to the formation of a thick interfacial envelope that surrounds all stages of parasite cells. *Trachipleistophora* sp.
	C. Host-formed parasitophorous vacuole surrounds the parasite cluster, and parasite-secreted material surrounds each parasite cell inside the parasitophorous vacuole. *Encephalitozoon intestinalis*

[a] Adapted from reference 55.
[b] ER, endoplasmic reticulum.

***Enterocytozoon bieneusi*.** *Enterocytozoon* was the first genus of microsporidia created for a human infection. Primarily, the organism infects the apical portion of enterocytes of the small bowel and produces a slight flattening of the epithelium (Fig. 23.28). Villus atrophy occurs due to rapid desquamation of infected enterocytes.The parasite can disseminate to the epithelial lining of the common bile duct, gallbladder epithelium, and biliary and respiratory tracts. *E. bieneusi* has been documented most often in male AIDS patients, causing malabsorption resulting in chronic diarrhea, and has been associated with AIDS-related sclerosing cholangitis. This microsporidian has also been documented in HIV-negative individuals with and without diarrhea and has been found in tracheal, bronchial, and nasal epithelium. *E. bieneusi* can also be found in stool samples after staining with modified trichrome.

TABLE 23.22 Microsporidia: general information

Genus	Body site	Diagnosis	Comments
Anncaliia, *Brachiola*, *Encephalitozoon*, *Enterocytozoon*, *Microsporidium*, *Pleistophora*, *Septata*, *Trachipleistophora*, *Vittaforma*, *Tubulinosema* (*Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* are the most common pathogenic species recovered in humans)	All body organs, including eyes	Routine histology with hematoxylin and eosin (fair); tissue Gram, acid fast, PAS, silver recommended (spores); other specimens (stool, urine, etc.), modified trichrome stains, optical brightening agents, poly- or monoclonal antibody-based kits (FA, EIA); animal inoculation not recommended—laboratory animals may carry occult infections; EM may be required; some can be cultured, but results are not consistent among the various genera and species	These organisms have been found as insect or other animal parasites; route of infection may be ingestion, inhalation, or direct inoculation (eye); well documented as emerging opportunistic infection in AIDS and other immunocompromised patients; name changes and reclassifications continue to occur; also refer to Table 23.20

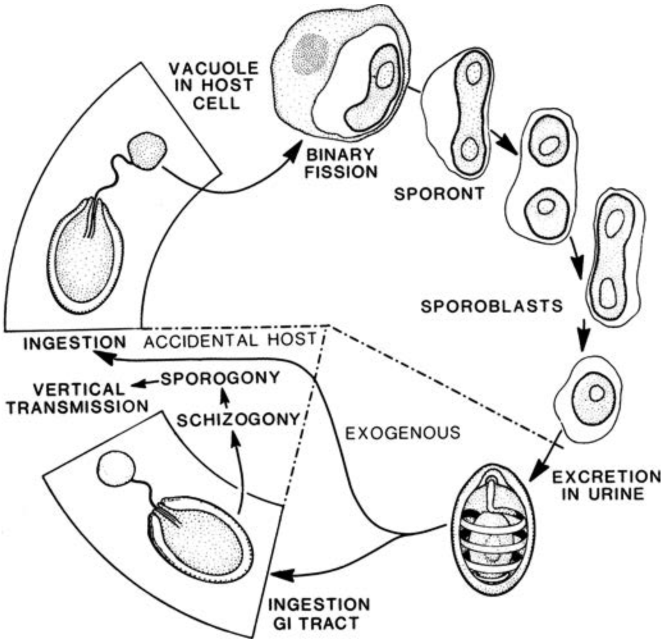

Figure 23.26 Life cycle of microsporidia. (From Gardiner CH et al, *An Atlas of Protozoan Parasites in Animal Tissues*, U.S. Department of Agriculture handbook no. 651, U.S. Department of Agriculture, Washington, DC, 1988.) doi:10.1128/9781555819002.ch23.f26

More than 90 *E. bieneusi* genotypes have been reported, with new genotypes continuing to be described. Nearly all of the genotypes that have been shown to infect humans so far belong to group 1. Currently, human infections by *E. bieneusi* isolates that cluster outside group 1 are exceptional and have been described in a single recent study performed in Central Africa.

Immunocompromised patients. Numerous cases of infection with *E. bieneusi* have been found in AIDS patients. Chronic intractable diarrhea, fever, malaise, and weight loss are symptoms of *E. bieneusi* infections and are similar to those seen in patients with cryptosporidiosis or isosporiasis. These patients have previously been diagnosed with AIDS, and they tend to have four to eight watery, nonbloody stools each day, which can be accompanied by nausea and anorexia. There may be dehydration with mild hypokalemia and hypomagnesia, as well as D-xylose and fat malabsorption. The patients tend to be severely immunodeficient, with a CD4 count usually below 200 and often below 100. Dual infections with *E. bieneusi* and *Encephalitozoon intestinalis* that infects the small intestine have also been reported. However, demonstration of *E. bieneusi* spores in extraepithelial tissues does not always appear to be associated with development of subsequent systemic infections.

E. bieneusi spores have been identified in sputum and bronchoalveolar lavage fluid, as well as stool samples. Although no pulmonary pathology can be established in all cases, it is well established that *E. bieneusi* is capable of colonizing the respiratory tract, and these clinical specimens may reveal the presence of spores. Using transmission EM, multiorgan microsporidiosis due to *E. bieneusi* has been diagnosed in some HIV-infected patients; organisms can be recovered in stools, duodenal biopsy specimens, nasal discharge, and sputum.

Recently, a new and highly divergent *E. bieneusi* genotype has been discovered in a human host (renal transplant patient); this genotype can be grouped with an equid species (59). Although the patient became sick 7 years post-transplantation, symptoms began soon after contact with water contaminated with horse stool. These findings should be taken into account for the management of immunocompromised patients such as HIV-infected patients and solid-organ transplant recipients. In these types of high-risk patients, they should be advised to avoid close contact with animals and follow prophylactic measures that may prevent infection.

Immunocompetent individuals. Infection with this organism has also been found in individuals with intact immune function; symptoms tend to be self-limited, and the diarrheal disease resolves within 2 weeks. These cases suggest that *E. bieneusi* may be more commonly associated with sporadic diarrheal disease than was previously suspected and that the immune system may play a role in the control of this organism within the intestine. It is also quite possible that *E. bieneusi* may persist as an asymptomatic infection in immunocompetent individuals.

Spore description. Finding several polar filaments within a multinucleate plasmodium by EM is diagnostic for *Enterocytozoon*. The development of multiple polar tubules within a multinucleate parasite cell is a unique feature of the developmental cycle of *Enterocytozoon*. The plasmodium divides by multiple fission, producing a dozen or more sporoblasts which mature into spores, all in direct contact with the host-cell cytoplasm. Spores measure 1.3 µm by 0.8 µm and contain a single nucleated sporoplasm surrounded by approximately six polar tubule coils, arranged in a double row (55).

***Encephalitozoon* spp.** Both *Encephalitozoon cuniculi* and *Encephalitozoon hellem* have been isolated from human infections, the first species from the central nervous system and the second from the eye. The first case occurred in a 9-year-old Japanese boy who presented with neurologic symptoms such as convulsions, vomiting, headaches, fever, and periods of unconsciousness. The spores were recovered in the cerebrospinal fluid and urine. This particular patient was treated with sulfisoxazole and recovered. Another case of *E. cuniculi* was in a 2-year-old child with a similar neurologic illness; the spores were recovered from the urine.

Immunocompromised patients. A case of keratoconjunctivitis and chronic sinusitis due to infection with *E. cuniculi* in an AIDS patient has been reported; diagnosis was confirmed by EM. This species has been found in the liver, as well as peritoneal, cerebral, and disseminated infections in AIDS patients. Several eye infections with *E. hellem* have been found in AIDS patients, including the first reported case of *E. hellem* infecting not only sinuses and conjunctivae but also the nasal epithelium. Overall, this species has been documented in disseminated infections and infection of the sinuses, nasal tissue, tongue, respiratory system, kidneys, and male genital tract. In the first case of disseminated *E. hellem* infection in an AIDS patient, a complete autopsy revealed organisms in the eyes, urinary tract, and respiratory tract. The presence of numerous organisms within the lining epithelium of almost the entire length of the tracheobronchial tree was very suggestive of respiratory acquisition. It is also interesting that although *E. cuniculi* and *E. hellem* differ biochemically and immunologically, their fine structure and development are indistinguishable. Some of the eye infections have also suggested a topical route rather than dissemination. Dual infection with *E. hellem* and *Vittaforma corneae* has also been found in an AIDS patient; this is the second isolation of *V. corneae* and the first description of urinary tract infection due to *V. corneae* in a patient with AIDS.

Spore description. The genus *Encephalitozoon* is characterized by a parasitophorous vacuole that surrounds the developing parasites and isolates them from the host-cell cytoplasm. Developing stages may contain one or more nuclei but the nuclei are not attached to each other. Multinucleate cells are long and narrow, not plasmodial. Proliferative cells usually break free of the vacuole membrane in sporogony. Sporonts form a thickened plasmalemma on individual cells. Within the parasitophorous vacuole, each

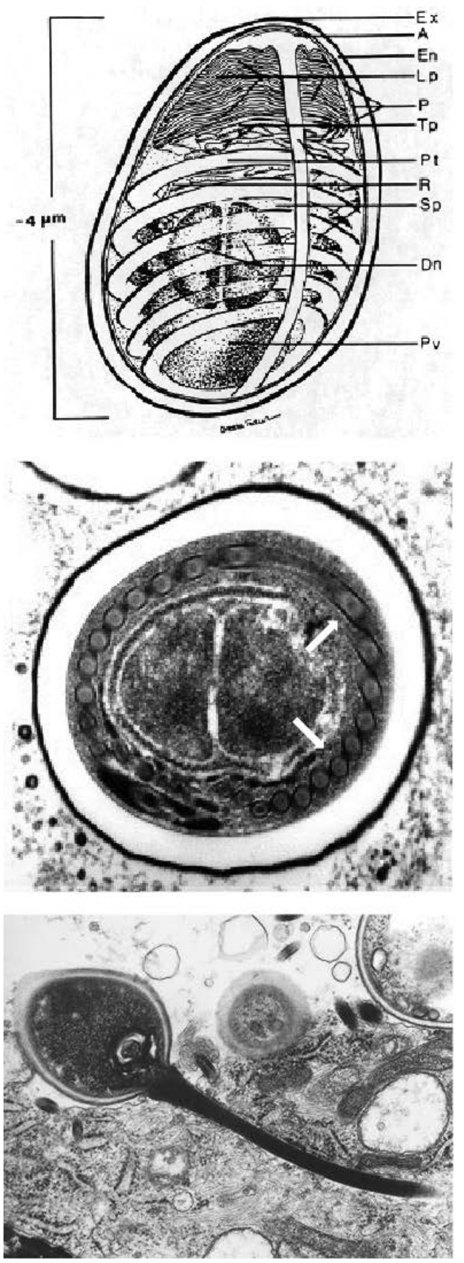

Figure 23.27 (Top) Diagram of the internal structure of a microsporidian spore. The spore coat has an outer electron-dense region called the exospore (Ex) and an inner, thicker, electron-lucent region, the endospore (En). A unit membrane (P) separates the spore coat from the spore contents. The extrusion apparatus—anchoring disk (A), polar tubule (Pt), lamellar polaroplast (Lp), spongiform polaroplast (Sp), and tubular polaroplast (Tp)—dominates the spore contents and is diagnostic for microsporidian identification. The posterior vacuole (Pv) is a membrane-bound vesicle, which sometimes contains a "membrane whirl," a "glomerular-like" structure, flocculent material, or some combination of these structures. The spore cytoplasm is dense and contains ribosomes (R) in a tightly coiled helical array. The nucleation may consist of a single nucleus or a pair of abutted nuclei, a diplokaryon (Dn). The size of the spore depends on the particular species and can vary from less than 1 µm to more than 10 µm. The number of polar tubule coils also varies from a few to 30 or more, again depending on the species observed. (Middle) EM of *Anncaliia* (*Brachiola*, *Nosema*) *connori* spore in adrenal gland showing the coiled polar filament (arrows) and two nuclei. Note the polar tubules are in a single row. Top and middle photographs taken with a 40× objective; bottom image taken with the 100× oil immersion objective. Note the dark-staining dot within the spores in the bottom photograph; this dot stains PAS positive. The tissue was stained with Giemsa stain. doi:10.1128/9781555819002.ch23.f28

sporont elongates, divides, and produces spores. Spores measure 1 to 1.5 μm by 0.5 μm and contain a sporoplasm with a single nucleus and approximately six polar tubule coils arranged in a single row. *E. hellem* is morphologically the same as *E. cuniculi*, although the parasitophorous vacuole is not always present (55).

Encephalitozoon (Septata) intestinalis. *Encephalitozoon* (*Septata*) *intestinalis* infects primarily small intestinal enterocytes, but infection does not remain confined to epithelial cells. *E. intestinalis* is also found in lamina propria macrophages, fibroblasts, and endothelial cells. Dissemination to the kidneys, lower airways, and biliary tract appears to occur via infected macrophages (57). Fortunately, these infections tend to respond to therapy with albendazole, unlike the infections with *E. bieneusi*. Infections have been reported in the liver, renal system, colon, gallbladder, lungs, sinuses, and conjunctiva. It has been misdiagnosed as *E. bieneusi* in the intestine and as *E. hellem* in the eye, sinuses, and urine.

Spore description. Encephalitozoon (*Septata*) *intestinalis* has parasite-secreted material surrounding the developing stages and spores inside the parasitophorous vacuole. Spores are 2 μm by 1.2 μm, with a single nucleus and four to seven (usually five) polar tubule coils arranged in a single row (55).

***Anncaliia (Brachiola, Nosema)* spp.** *Anncaliia* (*Brachiola*, *Nosema*) *connori* has been identified in human tissues, with the spores being oval, measuring approximately 2 by 4 μm, and having paired nuclei (Fig. 23.29). The polar tubule has about 11 coils arranged in one to three rows. The single human case occurred in a 4-month-old infant

Figure 23.29 Section of appendix showing *Anncaliia connori* spores in muscularis. The anterior end of the spore has a PAS-positive granule (arrows). (PAS, ×1,260; Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch23.f29

with combined immunodeficiency disease with a disseminated, fatal infection. Parasites were found in the myocardium, diaphragm, arterial walls, kidney tubules, adrenal cortex, liver, and lungs (Fig. 23.30). Concurrently, this patient also had *P. jirovecii* pneumonia.

Anncaliia (*Brachiola*, *Nosema*) *algerae* is apparently transmitted by mosquitoes. Infections have been found in the eye and muscle, possibly from a disseminated case. Both immunocompromised (HIV-negative, but receiving immunosuppressive therapy for rheumatoid arthritis) and immunocompetent patients have become infected. This organism has been known as an insect pathogen for some time. It appears that an initial infection of the eye allows the parasite to adapt to conditions within the mammalian host, thus spreading via macrophages to internal organs.

Brachiola vesicularum is probably a *Nosema*-like species found in non-HIV-infected patients. Corneal stroma and skeletal muscle were involved in a case in an AIDS patient. Although it was thought that *A. algerae* and *B. vesicularum* might be identical, there are ultrastructural differences between the two organisms. Thus, the designation of two species is currently accepted.

Tubulinosema sp. (closely related to *T. acridophagus*) myositis was documented in a patient with chronic lymphocytic leukemia and renal failure. This organism is similar to several species included in the genus *Nosema*, and *Anncaliia* has been classified within the same family. Since some of these organisms are well-known parasites of insects, the source of this particular infection was thought to probably be some type of insect (60).

***Microsporidium* spp.** *Microsporidium africanum* was identified in the histiocytes of a corneal ulcer. Although it was first thought to be a *Nosema* sp., EM confirmed the differences and it was designated *M. africanum*. No information on other hosts is available.

M. ceylonensis was found in an eye infection in a child who had been gored by a goat and suffered an eye injury. *Nosema helminthorum* was considered a possibility, since the organism is a parasite of goat tapeworms; however, since a generic classification could not be completed, it was assigned to the genus *Microsporidium*. Since no additional infections have been seen and there is no tissue left for further study, this genus name, *Microsporidium*, will probably remain. Since it is now accepted, you will see it written as *Microsporidium* rather than "*Microsporidium*."

Eye infections. Since 1990, hundreds of microsporidian keratoconjuctivitis cases have been reported, in both HIV negative and positive patients; however, only a few reports have identified the organisms to the specific genus level other than *Microsporidium*. Common features include follicular papillary conjunctivitis and coarse punctuate epithelial lesions evolving into keratitis before resolution. Additional clinical features include diffuse endotheliitis (inflamed corneal endothelium) with corneal edema and atopic keratoconjunctivitis (rare, affects young men with atopic dermatitis). Almost all of these cases resolved with the use of topical fluoroquinolone monotherapy (Fig. 23.31).

***Pleistophora* spp.** Microsporidia of the genus *Pleistophora* have rarely been identified in humans; however, three cases in immunocompetent patients have been reported. In these cases, atrophic and degenerating muscle fibers were full of spores, which were seen in clusters of about 12 organisms, each cluster enclosed by an enveloping membrane, the pansporoblastic membrane. The spores were oval, measuring approximately 2.8 by 3.4 μm. In one patient, the disease was characterized by a 7-month history of progressive gen-

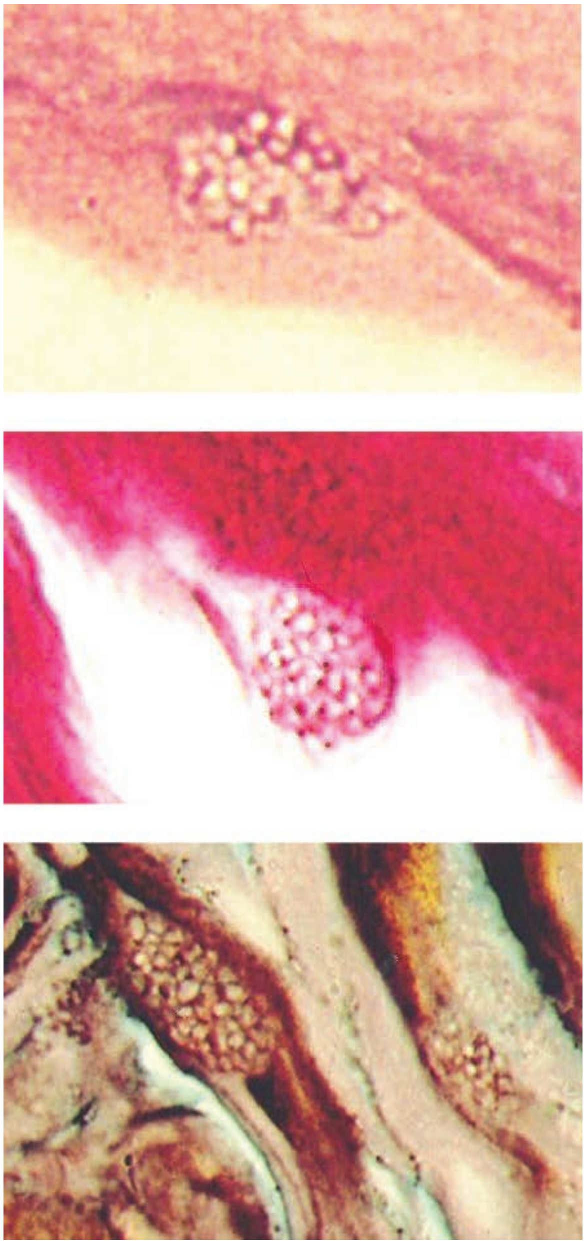

Figure 23.31 Microsporidian spores seen in an eye infection. (Top) Hematoxylin and eosin stain. (Middle) PAS stain; note the dark staining dot at the end of each spore. (Bottom) Silver stain; note spores are outlined. doi:10.1128/9781555819002.ch23.f31

eralized muscle weakness and contractions in addition to fever, generalized lymphadenopathy, and an 18-kg weight loss. Although the patient was diagnosed as having AIDS, the presence of HIV was never demonstrated. Early biopsies demonstrated atrophic and degenerating muscle fibers; later biopsies showed fibrosis and scarring. *Pleistophora* microsporidia have been identified in a confirmed HIV-positive patient. Ultrastructural studies of specimens from one of the cases led to the classification of *P. ronneafiei*; no information is available about possible animal reservoirs.

***Trachipleistophora* spp.** *Trachipleistophora hominis* causes severe myositis and sinusitis and was first detected in an AIDS patient. To date, no natural hosts other than humans have been identified, although when inoculated intraperitoneally into athymic mice, the organisms infect the skeletal muscle, as seen in human infections. *T. anthropophthera* is the second species in this genus to be described in humans and has been found in brain tissue of two AIDS patients at autopsy; the organisms were also found in the brain, heart, kidney, pancreas, thyroid, parathyroid, liver, bone marrow, lymph nodes, and spleen.

Vittaforma corneae. This organism has been documented in both immunocompromised (urinary tract) and immunocompetent (ocular) patients. These organisms are found everywhere, but no specific natural common hosts have been identified. PCR and sequencing data from surface water studies suggest that these organisms may be present in surface water and that they can also be present in human feces; it has been suggested that this might represent intestinal passage of microsporidial spores, although these patients were symptomatic with diarrhea (57).

Summary: Infections in Immunocompetent Hosts. In studies of rabbits and mice, the majority of immunologically competent hosts that become infected with microsporidia develop chronic and persistent infections with few clinical signs or symptoms. Spore shedding has been described as sporadic, and parasite replication seems to be regulated by the host immune system. However, if these animals are intentionally immunosuppressed, more severe symptoms are seen. On the basis of serologic studies, it is very likely that immunocompetent humans have persistent or chronic infections with microsporidia. This is also supported by the fact that patients with microsporidiosis who are HIV seronegative show clinical resolution of their infections after a few weeks. As improved diagnostic methods, such as PCR, are developed and used, verification of human subclinical microsporidial infections should become possible. Data strongly suggest that the true distribution of microsporidiosis in healthy humans is probably underestimated. Many eye infections with various species of microsporidia have been seen in immunocompetent patients; this possibility should always be considered when routine eye cultures show nothing clinically significant or in cases of corneal transplantation. Keratoconjunctivitis tends to be a self-limiting disease, while stromal keratitis is an ill-defined disease. Stromal keratitis is characterized by a slowly progressive course. The corneal picture resembles herpes simplex virus stromal keratitis or fungal keratitis cases, and is characterized by deep stromal infiltrates with overlying and surrounding stromal edema and keratic precipitates.

Summary: Infections in Immunocompromised Hosts. In the immunocompromised host, microsporidial infection may lead to overwhelming disease and death. The first cases of human microsporidiosis were identified in children with impaired immune systems, and infections have been widely recognized and studied in individuals with AIDS, primarily those with fewer than 100 $CD4^+$ T lymphocytes. Infection has also been recognized in organ transplant recipients who are intentionally immunosuppressed before and after transplantation; cases involve pediatric and adult kidney and liver transplant recipients, as well as those receiving bone marrow, lung, or heart-lung transplants. Microsporidiosis should always be considered in the differential diagnosis for a wide range of clinical syndromes in immunocompetent as well as immunocompromised individuals.

Diagnosis

Routine Histology. A number of techniques are available for recovery and identification of microsporidia in clinical specimens (Tables 23.22 and 23.23). Although the organisms have been identified in routine histologic preparations, they do not tend to stain predictably if at all. Occasionally, the spores take on a refractile gold appearance in formalin-fixed, paraffin-embedded, routine hematoxylin-and-eosin-stained sections. Some of the difficulty may be attributed to the use of formalin; alternative fixatives are optional. Spores are occasionally seen very well by using PAS stain, silver stains, Giemsa stain, or acid-fast stains. Modified Gram stains have also been found to be sensitive although not always standardized. The spore has a small, PAS-positive posterior body, the spore coat stains with silver, and the spores are acid-fast variable (Fig. 23.29 to 23.31). There is also evidence to indicate that specimens from plastic-embedded tissues are seen more easily, regardless of the fixative used. Tissue examination by EM techniques is still considered the best approach for identification to the genus/species levels (Fig. 23.32). However, this option is not available to all laboratories, and the sensitivity of EM may not be equal to that of other methods when examining stool or urine. Also, the amount of specimen sampled using EM is quite small and may result in a false negative if the appropriate infected tissue is not examined.

Techniques that do not require tissue embedding are now becoming more popular. Touch preparations of fresh biopsy material that are air dried, methanol fixed, and Giemsa stained have been used; however, screening must be performed at ×1,000 magnification. Another study, using cytocentrifugation followed by Giemsa staining, found that 27% of 55 AIDS patients with chronic diarrhea were positive for *E. bieneusi*; all results were confirmed by EM.

For histologic examination of tissue sections, glutaraldehyde fixation and plastic embedding are highly recommended, even if EM is unavailable. Parasites may be obscured by the host tissue in 6-μm paraffin-embedded preparations. Using light microscopy, 1-μm-thick plastic sections, heat-fixed to a glass slide and stained with toluidine blue, provide better visualization of microsporidia because of the thinness of the section. Plastic embedding provides a permanent tissue specimen that can be reevaluated by EM at a later time. Additionally, paraffin-embedded tissue can be deparaffinized and reprocessed for plastic embedding (55).

Routine Clinical Specimens. *Modified trichrome stains*. Other, more recent options recommend using modified trichrome stains in which the chromotrope 2R component added to the stain is 10 times the concentration normally used in the routine trichrome stain for stool (17, 57, 58) (Fig. 23.33). It is important to remember that the stool preparations must be very thin, the staining time must be 90 min, and the slide must be examined at ×1,000 (or higher) magnification. Unfortunately, there are many objects within stool material that are oval, stain pinkish with trichrome, and measure approximately 1.5 to 3 μm. If this stain is used for the identification of microsporidia in stool, positive control material should be available for comparison. Additional modifications of this method include the use of heat and a shorter staining time (17). There is also some evidence to indicate that pretreatment of fecal specimens (1:1) with 10% KOH may provide a better quality smear to examine when using the modified trichrome stains. Unfortunately, there are always situations in which artifact material can be confused with actual spores (Fig. 23.33).

Optical brightening agents. Another approach involves the use of chemofluorescent agents (optical brightening agents) such as calcofluor, Fungi-Fluor, or Uvitex 2B (Fig. 23.33). These reagents are sensitive but nonspecific; objects other than microsporidial spores will also fluoresce. This is a particular problem when examining stool specimens; both false-positive and false-negative results have been seen. When these reagents are used with other body fluids, particularly urine (generally cleaner specimen with less debris), the interpretation of results is much easier than when they are used with stool. There is now general agreement that this method is recommended as a simple, sensitive screening method for the detection of microsporidial spores in stool specimens.

Antigen detection. The newest approach for the identification of spores in clinical specimens uses antisera in an indirect FA procedure (Fig. 23.34). Fluorescing microspor-

TABLE 23.23 Microsporidia: recommended diagnostic techniques[a]

Technique	Use[b]	Comments
Light microscopy		
Stool specimens (more artifacts)		
Modified trichrome	++	Reliable, available; light infections difficult to identify
Giemsa	–	Not recommended for routine use; hard to read
Optical brightening agents	+	Calcofluor, Fungi-Fluor, Uvitex 2B; sensitive but nonspecific
IF technique	++	Commercial availability limits use; products in development
Other body fluids (fewer artifacts)		
Modified trichrome	++	Reliable, available; light infections difficult to identify
Giemsa	+	Urine, conjunctival swab, BAL, CSF, duodenal aspirate
Optical brightening agents	++	Calcofluor, Fungi-Fluor, Uvitex 2B; sensitive but nonspecific
IF technique	++	Commercial availability limits use; products in development
Routine histology		
Hematoxylin and eosin	+	Sensitivity uncertain with small parasite numbers
PAS	+	Controversy over effectiveness
Modified Gram stains (Brown Brenn, Brown-Hopps)	++	Sensitive, generally recommended
Giemsa	+	Sensitivity uncertain with small parasite numbers
Warthin-Starry	+	Not standardized, may not be necessary
Modified trichrome	++	Reliable, sensitive
IF technique	++	Commercial availability limits use; products in development
Electron microscopy		
Body fluids	+	Specific, sensitivity unknown; used for identification to species level
Tissue sections	++	"Gold standard" for confirmation, but sensitivity lower than for detection of spores in stool or urine; used for identification to species level
Serologic antibody detection	–	Reagents not commercially available, preliminary results controversial
Cultures	–	Generally used in the research setting; continued advances in culture options and organism survival/growth
PCR	–	Availability limited to research laboratories; studies ongoing

[a] IF, immunofluorescence detection procedure; BAL, bronchoalveolar lavage; CSF, cerebrospinal fluid.
[b] –, not available or recommended for routine use; +, reported; ++, techniques in general use (probably most widely used).

idial spores were distinguished by a darker cell wall and by internal visualization of the polar tubule as diagonal lines or cross lines within the cell. In another study with the same antiserum, 9 (30%) of 27 patients who had already been diagnosed as having cryptosporidiosis (8 AIDS patients and 1 non-AIDS but immunodeficient patient) were found to have *Encephalitozoon* spp. in the stool. Although there is some cross-reactivity with bacteria, this technique offers a more sensitive approach than routine staining methods currently available for the examination of stool specimens. Very specific reagents are in various stages of development and clinical testing and should provide some additional, more sensitive methods than are currently available at this time. Some of these reagents are also being used in conjunction with flow cytometry. As clinicians begin to suspect these infections and laboratorians become more familiar with the diagnostic methods, the number of positive patients, particularly those who are immunocompromised, may increase dramatically. Current recommendations also suggest that multiple diagnostic methods may be necessary to diagnose microsporidiosis, particularly when examining fecal specimens (17).

Molecular Methods. Molecular studies of the microsporidia have been limited to date (61–63). Few genes have been located, and DNA sequence studies have been reported for just a few of the identified human pathogens. Microsporidia have extremely small genomes, very similar to those seen in bacteria. This may be due to the early divergence of microsporidia or may be related to the highly adapted parasitic lifestyle of these organisms. Although PCR methods have been tried in the research setting, commercial products are not yet available. For HIV-infected patients suspected of having microsporidiosis but with negative stool and biopsy results, PCR testing of intestinal biopsy specimens may be helpful in diagnosing the infection. Application of molecular techniques to diagnosis, identification of isolates to the species level, and classification will

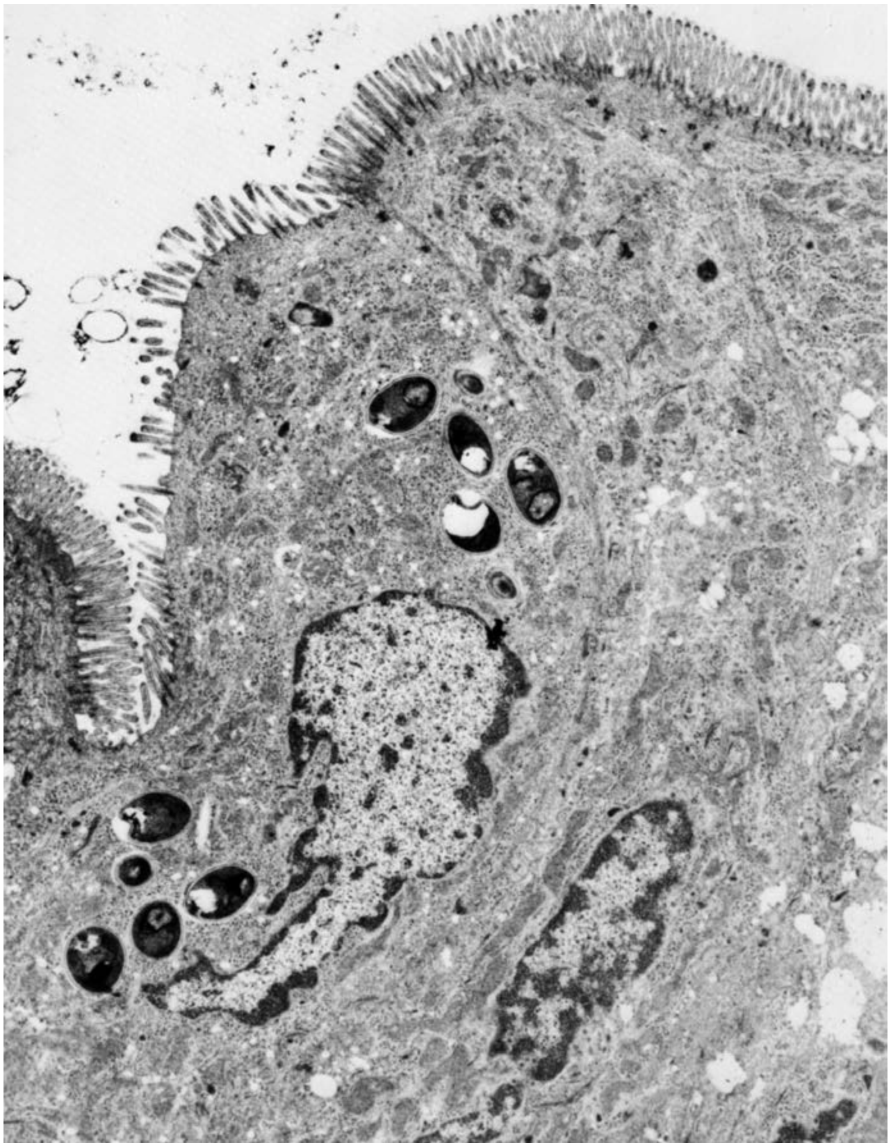

Figure 23.32 Spores in cytoplasm of intact jejunal enterocyte of a man with intractable diarrhea and malabsorption; transmission electron micrograph of a jejunal suction biopsy specimen. Note the dark oval developing spores; at higher magnification, some of the elements of the polar tubules would be visible. doi:10.1128/9781555819002.ch23.f32

certainly continue to expand during the next few years. These advances should include newer diagnostic reagent kits that will simplify molecular testing in the routine clinical laboratory setting, particularly tests applicable to the stool specimen.

Several PCR-based methods to amplify different regions of small- and large-subunit rRNA genes are available for diagnosis of *E. bieneusi* and *E. intestinalis* infections; however, PCR inhibitors may interfere with the test. *In situ* hybridization can be performed for *E. bieneusi* in humans. Multiplex nested PCR for microsporidia is also available. The predominant species tend to be *E. bieneusi* or *E. intestinalis*.

Other diagnostic molecular methods include random amplified polymorphic DNA obtained by PCR, PCR-RFLP, and SDS-PAGE. A 75-kDa band on one-dimensional Western blot of *E. cuniculi* and *E. intestinalis* spore protein can be obtained using purified C1 Hsp70 protein. PCR amplification and species determination of microsporidia in formalin-fixed feces can also be performed after immunomagnetic separation (63).

Cell Culture. The use of *in vitro* culture methods continues to provide confirmatory as well as diagnostic information. This approach has been instrumental in the development of immunologic reagents for diagnosis and species differentiation. *In vitro* culture has also been used to assess the efficacy of antimicrobial agents on several microsporidian species including *Encephalitozoon cuniculi*, *E. hellem*, and *E. intestinalis* (57). However, the use of cell culture in routine clinical diagnosis is not practical and is generally

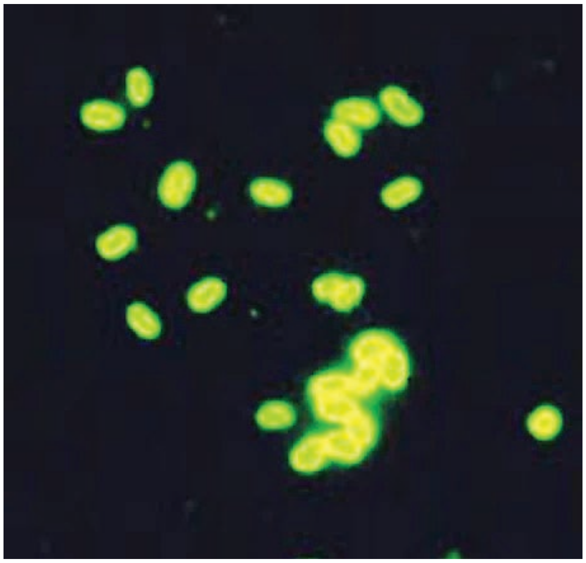

Figure 23.34 Microsporidian spores. This image shows a positive FA test using *Encephalitozoon*-specific reagent. Note the fluorescing spores, indicating the organisms are within the genus *Encephalitozoon*. doi:10.1128/9781555819002.ch23.f34

reserved for research facilities. A number of cell lines have been used, including monkey and rabbit kidney cells (Vero and RK13), human fetal lung fibroblasts (MRC-5), MDCK cells, and various fish and insect cells.. Although a number of the microsporidia have been cultured using these techniques, one of the most common human microsporidial pathogens, *E. bieneusi*, has been propagated only in short-term cultures (6 months); however, the use of salmonid leukocytes appears to support the development of this species. Difficulties encountered in growing this organism in continuous culture may reflect additional nutritional requirements that have not yet been identified.

Serologic Testing. A variety of serologic tests (carbon immunoassay, indirect immunofluorescent-antibody test, enzyme-linked immunosorbent assay, counterimmunoelectrophoresis, and Western blotting) have been used to detect

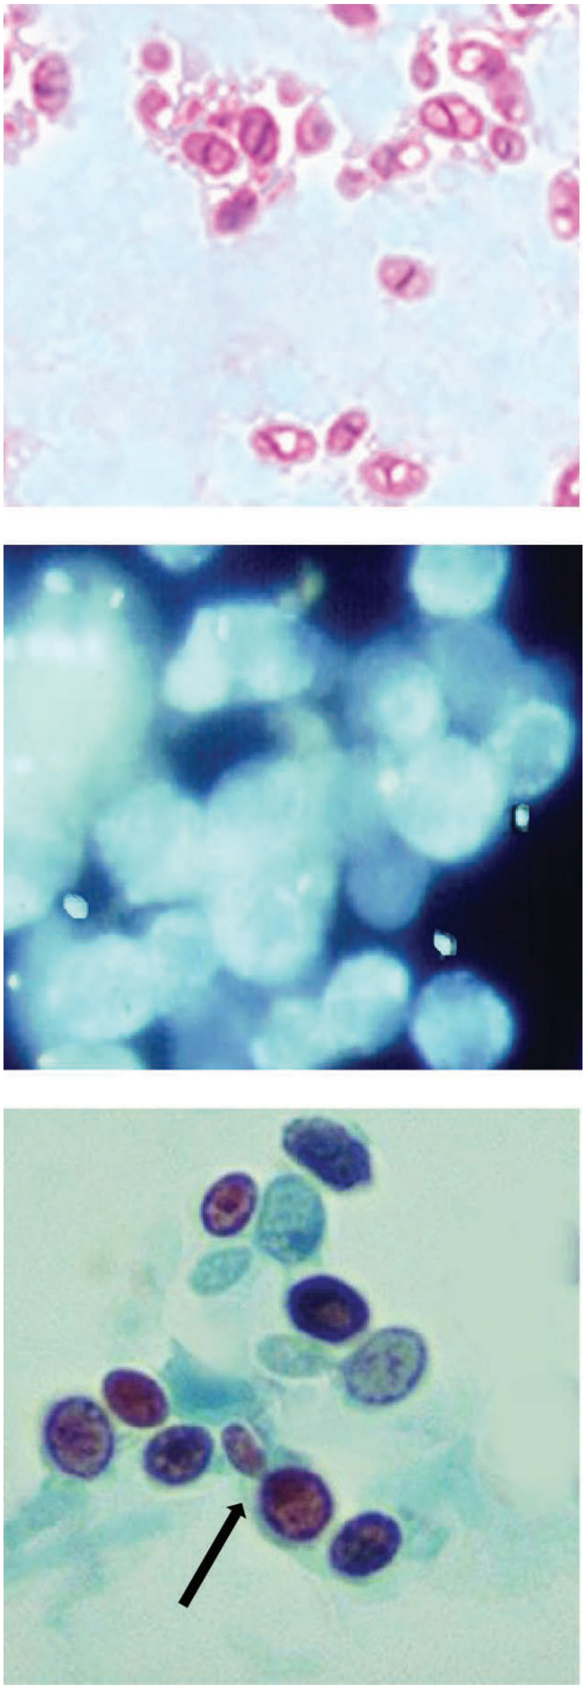

Figure 23.33 Microsporidian spores. (Top) Spores stained with modified trichrome stain (Ryan blue); note the diagonal or horizontal "stripes" that are evidence of the polar tubule. (Middle) Calcofluor white staining of urine sediment; note the small oval intracellular and extracellular spores. This is a nonspecific stain but is more likely to represent a true positive than when seen in a stool specimen containing many fluorescing artifacts. (Bottom) Yeast artifacts; note the large size, lack of the polar tubule, and evidence of budding (arrow).
doi:10.1128/9781555819002.ch23.f33

IgG and IgM antibodies to microsporidia, particularly to *E. cuniculi*. The indirect immunofluorescent-antibody test and the enzyme-linked immunosorbent assay have been the most useful because of the simplicity of the test methods; however, the actual sensitivity and specificity of all the available tests have not yet been defined. Antibodies to *E. cuniculi* and *E. intestinalis* have been found in humans both with and without HIV infection; whether this represents true infection, cross-reactivity with other species, or nonspecific reactions is not clear. Serologic surveys for antibodies to *E. cuniculi* appear to show a link between exposure to a tropical environment and microsporidiosis. Unfortunately, there are no serologic assays available for *E. bieneusi* due to the lack of success in long-term culture and development of available antigens. Whether antibodies to this organism will cross-react with those to *E. cuniculi* is not known. At present, the available serologic data are interesting but the tests are not useful as diagnostic tools for the diagnosis of microsporidiosis.

Although *E. bieneusi* appears to be the most common human microsporidian, serologic evidence is based primarily on results for *E. cuniculi* as the parasite antigen. Whether these surveys reveal actual infections with this organism or whether there is cross-reactivity with other microsporidia is unknown. However, the data are highly suggestive that latent infections with microsporidia occur in a number of groups, ranging from patients with other infections such as tuberculosis, typhoid fever, leprosy, malaria, schistosomiasis, toxoplasmosis, Chagas' disease, and toxocariasis to normal individuals and a group of homosexual men. Microsporidian infections in immunocompetent patients may result in a self-cure following mild symptoms over a short time frame, a situation similar to that seen with both cryptosporidiosis and isosporiasis. As awareness of this infection increases and more sensitive diagnostic techniques are developed, we may find that these infections are not uncommon in immunocompetent hosts.

KEY POINTS—LABORATORY DIAGNOSIS

Microsporidia

1. Approximately 30% of AIDS patients and those with cryptosporidiosis may also have infections with microsporidia. Microsporidian infections must be considered for this group of patients with chronic diarrhea. Identification to genus and species is not possible from light microscopy of stained specimens, including tissues.
2. The modified trichrome staining procedure for stool may be difficult to interpret without positive controls to review. Make sure that the material on the slides is very thin, the smear is stained for the recommended time, and the smear is examined under oil immersion (total magnification of at least ×1,000). When using various stains, optical brightening agents, or experimental immunoassay reagents where diagnosis is based on seeing the actual spores, it is recommended that the fecal specimen be concentrated and centrifuged at 500 × *g* for 10 min. Personal experience in our laboratory has demonstrated a larger number of spores in the concentrated sediment than in the unconcentrated specimen *or in specimens that have been centrifuged at a lower speed or for a shorter time*.
3. The optical brightening agents (calcofluor, Fungi-Fluor, Uvitex 2B) provide a sensitive screening method, but the results are nonspecific. False-positive results have been reported because of fluorescent artifact material.
4. As immunoassay reagents become commercially available, we may see diagnostic procedures with greater specificity and sensitivity. Reagents are currently being used in a few institutions; these preparations are generally easier to read than are the routine stains.
5. Touch preparations can be methanol fixed and stained with Giemsa.
6. Plastic-embedded tissues stained with PAS, silver, acid-fast, and routine hematoxylin-eosin stains generally stain better than paraffin-embedded tissues. This finding may be related to the use of formalin as a tissue fixative. Tissue Gram stains (Brown Brenn, Brown-Hopps) are also highly recommended.
7. Be sure to gain some experience in examining these preparations before sending out patient specimen results. This work almost mandates the use of positive control material, regardless of which technique(s) is used. Once a laboratory has gained experience with these methods, it is appropriate to begin accepting clinical specimens.
8. EM is the "gold standard" (very specific) for confirming infection and for attempting to classify the organisms seen in tissues. However, EM procedures may not be as sensitive as some of the other available methods, due to the very small specimens obtained and examined.
9. It is recommended that more than one procedure be used when working with stool specimens (modified trichrome, optical brightening agent); this is primarily because of the large number of artifacts present in stool. Urine and other body fluid specimens are much easier to examine for the presence of microsporidial spores, since less artifact material is seen in these specimens than in stool.

Treatment

Although a number of drugs have been tried, results have been variable (33). Agents such as metronidazole, itraconazole, octreotide, primaquine, Lomotil, sulfasalazine, loperamide, and albendazole have been used in various patients. In some cases, the diarrhea subsided; however, biopsy specimens showed the continued presence of organisms, which were probably *E. bieneusi*. Over the past few years, confirmatory evidence indicates that a complete parasitological cure is possible with albendazole. However, these patients had disseminated infections with *Encephalitozoon* (*Septata*) *intestinalis*; albendazole, a benzimidazole that binds to β-tubulin, appears to be very effective in treating this particular organism (33). Currently, the recommended dose for ocular (*E. cuniculi*, *V. corneae*), intestinal (*E. bieneusi*, *Encephalitozoon* [*Septata*] *intestinalis*), and disseminated (*E. hellem*, *E. cuniculi*, *E. intestinalis*, *Pleistophora* spp., *Trachipleistophora* spp.) infections with albendazole is 400 mg orally twice a day plus fumagillin. *In vitro*, albendazole has activity at concentrations of 0.1 μg/ml against all of the *Encephalitozoonidae*. Although apparently static rather than cidal effects are seen with *E. bieneusi* infections, treatment with albendazole results in reduction of symptoms in as many as 50% of patients infected with this organism. Albendazole as a systemic agent is recommended when the organisms have been confirmed in urine or nasal smears.

Fumagillin (soluble salt Fumidil B) has activity against microsporidia, and solutions applied topically have been used in corneal infections. The effects of this drug are static rather than cidal, and relapses of infection occur when the treatment has been discontinued. In one study, the efficacy of fumagillin was measured by clearance of *E. bieneusi* from stools and intestinal biopsy specimens; four patients who received fumagillin remained free of *E. bieneusi* after a mean follow-up of 10 months. The dosage is 20 mg once a day orally for 14 days. Also see chapter 36.

Itraconazole can also be recommended to treat ocular, nasal, and paranasal sinus infection caused by *E. cuniculi* parasites when albendazole treatment fails. In a patient with sinusitis and keratoconjunctivitis, the symptoms completely resolved with itraconazole treatment (200 mg/day for 8 weeks) after albendazole therapy (400 mg/day for 6 weeks) was unsuccessful.

Epidemiology and Prevention

The sources of human infections are not yet totally defined. From what we currently know, possibilities include human-to-human and animal-to-human transmission (57). Although there is some speculation that insect microsporidia can infect humans, this is still unknown. Many questions relating to reservoir hosts and possible congenital infections are still unanswered. Primary infection can occur by inhalation or ingestion of spores from environmental sources or by zoonotic transmission. There is serologic evidence to indicate widespread occurrence of antibodies to *E. cuniculi* in humans. Recent data indicate that the presence of *Encephalitozoon intestinalis* was confirmed in tertiary sewage effluent, surface water, and groundwater; *Enterocytozoon bieneusi* was confirmed in surface water; and *V. corneae* was confirmed in tertiary effluent. This study represents the first confirmation, to the species level, of human-pathogenic microsporidia in water, indicating that these parasites may be waterborne pathogens.

The presence of infective spores in human clinical specimens suggests that precautions when handling body fluids and personal hygiene measures such as hand washing may be important in preventing primary infections in the health care setting. However, comprehensive guidelines for disease prevention will require more definitive information regarding sources of infection and modes of transmission.

Algae (*Prototheca*)

Although algae are not parasites, it is important to know what they are and the relationship of opportunistic infections with these organisms to the compromised patient. The genus *Prototheca* contains several species, the most prevalent of which is *Prototheca wickerhamii*. These organisms are achlorophyllic algae found in the slime flux of trees and freshwater environments. Cutaneous infections were reported more than 30 years ago, and subsequent reports describe other manifestations including systemic disease. Disseminated *Prototheca* infections tend to occur in immunocompromised patients (solid organ transplants, hematological malignancies) with high mortality. The other species implicated in human infections is *Prototheca zopfii* (15, 64, 65). Susceptibility to infection is not well defined but may involve the inability of neutrophils to effectively kill phagocytosed organisms. Approximately 100 cases have been reported throughout the temperate and tropical areas of all continents. Protothecosis is being reported with increasing frequency; within the United States the majority of cases have been reported from the southeastern states (9).

Life Cycle and Morphology

Prototheca spp. are unicellular organisms that reproduce asexually by internal septation and cleavage; they then rupture, releasing endospores. The sporangium contains 2 to 16 sporangiospores, which develop into mature endosporulating cells. No sexual reproductive stages have been identified. These organisms are thought to be achlorophyllous mutants of green algae in the genus *Chlorella*.

They are ubiquitous in nature and colonize the human skin, fingernails, respiratory tract, and digestive system.

Clinical Disease

The main underlying conditions are solid organ transplantation, hematological malignancies with or without stem cell transplants, alcoholism, diabetes mellitus, chronic glucocorticoid use, peritoneal dialysis, HIV/AIDS, and cancers. The overall incubation time is not known but is generally considered to be about 2 weeks from the time of trauma and possible implantation of infectious organisms. The majority of infections involve the skin and underlying structures, such as the olecranon bursa (15, 64, 65); however, disseminated infection may also occur. Cutaneous or bursal infection may result from accidental inoculation or from trauma, including surgical. One patient developed nasopharyngeal ulceration due to *P. wickerhamii* after prolonged endotracheal intubation. Bursal infection presents with indolent swelling and tenderness. Cutaneous lesions have been described as painless papules, papulonodules, diffuse erythema, plaques (may be verrucous), and eczematoid or ulcerated areas. Immunocompromised patients may have more severe lesions. In addition to disseminated infection, peritonitis has been found in patients undergoing chronic ambulatory peritoneal dialysis and in the blood of patients with central venous access infections. Infections have also been seen in the gallbladder, peritoneum, and liver in a patient presenting with symptoms consistent with sclerosing cholangitis.

One 80-year-old woman receiving 2 mg of dexamethasone daily presented with tenderness in an area of diffuse erythema of the right arm, forearm, and dorsum of the hand together with several 4- to 6-mm flesh-colored papules. Biopsy revealed granulomatous inflammation with many organisms present in the dermis (15, 64, 65). These organisms stained with both PAS and Gomori's methenamine-silver (GMS) stain and were approximately 5 to 15 µm in diameter. They contained multiple internal septa. Another patient presented with recalcitrant ulcerated papules and plaques on both legs.

This infection has also been found in an HIV-positive patient (65). The patient presented with a nodule in the extensor face of the thumb. A routine excision was performed, and histology revealed numerous granulomas, some with central fibrinoid necrosis. Large numbers of prototheca were found in PAS and GMS stains, showing endosporulation with diagnostic morula- or daisy-like sporangia. On the basis of the relative number of polymorphonuclear leukocytes, lymphocytes, and plasma cells present, the cellular response was considered minimal. The organisms were found extracellularly or within macrophages and giant cells. Protothecal meningitis has also been found in an AIDS patient. In general, these cases are seen in patients who are immunocompromised, either from other underlying diseases or from immunosuppressive therapy (64).

Diagnosis

These algae are easily recovered on routine culture media; however, they are inhibited by cycloheximide, which is present in many selective fungal media. Diagnosis of protothecosis is dependent on histological findings or microbiological isolation of the organism from affected sites or blood. Colony characteristics of *Prototheca* spp. resemble other yeast-like organisms such as *Candida* or *Cryptococcus*. The optimal temperature for growth is 30°C, and these algae grow as white to creamy yeast-like colonies on Sabouraud's medium. Microscopic examination of culture material reveals the same structures as seen in tissue, including spherical sporangia containing multiple sporangiospores (endospores) (Fig. 23.35 to 23.37). The organisms have been described as looking like a spoked wheel. Macroscopically, the cells are variable in size and shape and do not bud or form hyphae. Asexual reproduction occurs through release of sporangiospores from sporangia. Sporangia of *P. zopfii* range from 14 to 16 µm in diameter, and those of *P. wickerhamii* are 7 to 13 µm. Cells of *P. wickerhamii* tend to be round, while those of *P. zopfii* are oval or cylindrical. Both species assimilate glucose and galactose; *P. wickerhamii* also assimilates trehalose. These organisms are nonfermentative.

In cutaneous histologic preparations, the typical tissue response includes a granulomatous inflammation with giant cells, histiocytes, lymphocytes and plasma cells accompanied by the presence of *Prototheca* organisms. The organisms may be numerous or few and can be seen as single cells or clusters. The GMS stain is recommended. In tissue the sporangia are usually larger (30 µm) than those seen in culture (*P. wickerhamii*, 7 to 13 µm; *P. zopfii*, 14 to 16 µm).

Laboratories and clinicians who care for immunocompromised patients should thoroughly investigate "fungemia"

and organism identification, especially in cases of persistent infection that fails to respond to appropriate therapy (9, 38).

Treatment

Most of the protothecal infections are indolent and very slow to heal. Although surgical debridement or excision may be necessary and effective, most infections are treated with antifungal agents. Combined therapy with tetracycline and amphotericin B appears to be effective. Infections that are multifocal or visceral or occur in an immunocompromised host require amphotericin B or combined therapy. Recent reports indicate that itraconazole is effective; however, healing may be gradual. Infections caused by *Prototheca* spp. tend to be resistant to 5-fluorocytosine.

Epidemiology and Prevention

Prototheca spp. have been isolated from a number of different environmental sites, including slime flux of trees, freshwater and seawater, soil, and sewage. Organisms have also been isolated from dogs, cats, cattle, sheep, deer, and some wild animals. *Prototheca* spp. have been recovered from human feces, sputum, skin scrapings, and fingernails, even in cases with no true infectious process. Although infections caused by *Prototheca* spp. are relatively uncommon, the true incidence worldwide may be underestimated. These infections should always be suspected in cases where the skin and subcutaneous tissues are involved and/or olecranon bursitis is present with indolent swelling and tenderness. An awareness of the possibility of infection with these organisms is critical to accurate diagnosis and prompt treatment.

Free-Living Amebae

Naegleria fowleri
Acanthamoeba spp.
Balamuthia mandrillaris
Sappinia (*diploidea*) *pedata*

Infections caused by small, free-living amebae belonging to the genera *Naegleria*, *Acanthamoeba*, *Balamuthia*, and *Sappinia* are less well known or recognized clinically than the intestinal amebae. Also, methods for laboratory diagnosis are unfamiliar and not routinely offered by most laboratories. However, infections caused by these organisms include primary amebic meningoencephalitis (PAM) caused by *Naegleria fowleri;* granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris*; and amebic keratitis, cutaneous lesions, and sinusitis caused by *Acanthamoeba* spp. (Table 24.1) (1–10). Another organism recently identified, *Sappinia* (*diploidea*) *pedata*, has been linked to encephalitis and has been confirmed as a human pathogen. Effective therapy remains a problem with these infections. When free-living, these organisms feed on bacteria and nutrients in moist soil and in freshwater and marine water. The development of diagnostic molecular methods represents a specific and potentially rapid method for the identification of some of these organisms soon after their primary isolation from the environment (1–3).

Although it is well known that both free-living and pathogenic protozoa harbor a variety of endosymbiotic bacteria, it is unclear what role these organisms play in terms of host survival, infectivity, and invasiveness. The study of parasites and symbionts of free-living amebae is relatively new; many of the terms used to describe these relationships are listed in Table 24.2 (6, 11). Serologic evidence that some of the endosymbionts within the free-living amebae might be human pathogens has led to additional studies of these relationships. The ameba-resistant bacteria are varied; some are natural hosts and coexist with free-living amebae, some have been recovered by amebic coculture, and some are resistant to a particular amebic host *in vitro*. Some bacteria are obligate intracellular organisms, others are facultative intracellular bacteria, and some are extracellular. While some of these bacteria are established human pathogens, some are emerging potential pathogens which were formerly considered environmental species. The presence of intracellular bacteria has been detected in axenically grown *Acanthamoeba* isolates. *Legionella pneumophila* can infect, multiply within, and kill both *Naegleria* and *Acanthamoeba* amebae. These amebae may be natural hosts for *Legionella* organisms as well as for other bacteria such as *Campylobacter jejuni*, *Listeria monocytogenes*, *Vibrio cholerae*, *Mycobacterium*

doi:10.1128/9781555819002.ch24

TABLE 24.1 Free-living amebae causing disease in humans[a]

	Disease parameter					
	Acanthamoeba					
Characteristic	**GAE**	***Acanthamoeba* keratitis**	**Cutaneous lesions, sinusitis**	***Balamuthia* GAE (BAE)**	***Naegleria* PAM**	***Sappinia* Meningitis, encephalitis**
General disease description	Chronic, protracted, slowly progressive CNS infection (may involve lungs); generally occurs in individuals with underlying diseases	Painful, progressive, sight-threatening corneal disease; patients generally immunocompetent	Most common in patients with AIDS, with or without CNS involvement, and in those receiving immunosuppressive therapy for organ transplantation	Chronic, protracted, slowly progressive CNS infection (may involve lungs); generally occurs in individuals with underlying diseases (HIV/AIDS, organ transplantation, steroid therapy), but has been seen in immunocompetent patients	Rare but nearly always fatal infection; migration of amebae to brain through olfactory nerve; symptoms can mimic bacterial meningitis; death usually occurs 3–7 days after onset of symptoms; clinical suspicion based on history is critical	Single case reported in Texas; loss of consciousness, vomiting, photophobia, headache, and blurring of vision; solitary 2-cm mass in the posterior left temporal lobe revealed necrotizing hemorrhagic inflammation containing the trophozoites of free-living amebae
Entry into the body	Olfactory epithelium, respiratory tract, skin, sinuses	Corneal abrasion	Skin, sinuses, respiratory tract	Olfactory epithelium, skin, respiratory tract	Olfactory epithelium	Unknown; environmental organism
Incubation	Weeks to months	Days	Weeks to months	Weeks to months	Days	Unknown
Clinical symptoms	Confusion, headache, stiff neck, irritability	Blurred vision, photophobia, inflammation, corneal ring, pain	Skin lesions, nodules, sinus lesions, sinusitis	Slurred speech, muscle weakness, headache, nausea, seizures	Headache, nausea, vomiting, confusion, fever, stiff neck, seizures, coma	Loss of consciousness, vomiting, photophobia, headache, and blurring of vision
Disease pathology	Focal necrosis, granulomas	Corneal ulceration	Granulomatous reaction in skin, inflammation	Multiple necrotic foci, inflammation, cerebral edema	Hemorrhagic necrosis	Tumor in brain
Diagnostic methods[b]	Brain biopsy, CSF smear/wet prep, culture, indirect immunofluorescence of tissue, PCR	Corneal scrapings or biopsy, stain with calcofluor white, culture, confocal microscopy	Skin lesion biopsy, culture, indirect immunofluorescence of tissue	Brain biopsy, culture on mammalian cells, indirect immunofluorescence of tissue	Brain biopsy, CSF wet prep, culture, indirect immunofluorescence of tissue, PCR	Brain biopsy

[a] Table information adapted from references 4–10.

[b] Indirect immunofluorescence on tissue and PCR methods available from CDC.

TABLE 24.2 Definitions pertaining to the relationships among free-living amebae and other organisms[a]

Description	Definition
Adaptation	Selection pressure = change in an organism
Ameba-resistant microorganisms	Microorganisms that evolved to resist destruction by amebae, neither internalized nor killed while within the ameba
Ameba-resistant bacteria	Bacteria that evolved to resist killing by amebae
Character	Phenotypic characteristics of an organism
Crib	"Baby bed"—free-living amebae that serve as a reservoir and incubator of new antibiotic-resistant bacteria = adaptation to human macrophages
Commensalism	Symbiosis—one organism benefits and the other neither is harmed nor benefits
Endosymbiont	Symbiont that lives within another organism
Endosymbiotic	During portion of life cycle or throughout; no lysis activity
Lytic	Lyses the host cell
Mutualism	Symbiosis in which both organisms benefit
Parasite	Benefits from an association but is harmful to the host
Symbiont	Lives in close contact with another organism during most of life cycle
Symbiosis	Two organisms living in close contact for most of their life spans
Symbiosis island	Gene cluster that confers symbiotic traits, which may be transferred horizontally
Trojan horse	Protozoan "horse" that may bring ameba-resistant organisms into the human host
Virulence	Pathogenicity

[a]Adapted from references 6 and 11.

leprae, *Burkholderia cepacia*, *Burkholderia pickettii*, and *Pseudomonas aeruginosa* (6, 11, 12). Because of their well-known resistance to chlorine, the amebic cysts are considered to be vectors for these intracellular bacteria. This can have tremendous significance for any hospital where the water source is contaminated with free-living amebae. There is also evidence to suggest that the presence of amebae in domestic water supplies may provide growth conditions that enhance the pathogenicity of the organisms for the human host (13). These amebae are also acceptable hosts for *Chlamydia pneumoniae*, echoviruses, and polioviruses (11).

Naegleria fowleri

Culbertson and his colleagues in 1958 were the first to develop the concept that free-living soil and water amebae could cause disease in humans. A number of fatal cases of acute meningoencephalitis have been reported since that time (8, 9). Almost all patients whose cases were documented in the years immediately following this awareness of amebic infections had a history of swimming in freshwater lakes or ponds a few days prior to the onset of symptoms.

Infections of the central nervous system (CNS) caused by free-living amebae have been recognized only since the mid-1960s, and our understanding of this disease process is still incomplete. One type of meningoencephalitis (PAM) is a fulminant and rapidly fatal disease that affects mainly children and young adults. The disease closely resembles bacterial meningitis but is caused by *Naegleria fowleri*, an organism found in moist soil and freshwater habitats. Close to 200 cases of PAM have occurred worldwide, and approximately 90 of those cases have been reported from the United States. Until recently, it was thought that this infection was limited to humans; however, infections have also been reported in other animals.

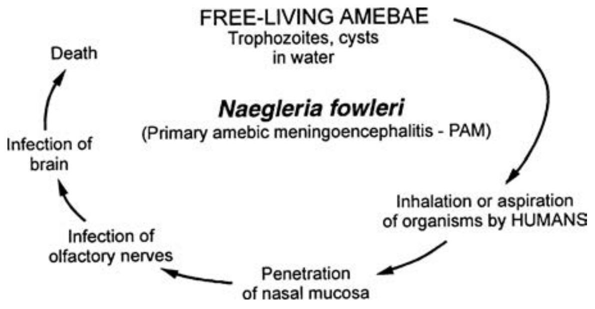
Life Cycle and Morphology

N. fowleri has a three-stage life cycle: trophozoite, flagellate, and cyst, with the stage primarily depending on environmental conditions (Fig. 24.1). Trophozoites can be found in water or moist soil and can be maintained in tissue culture or other artificial media.

Morphology of Trophozoites. The trophozoites can occur in two forms, ameboid and flagellate (Fig. 24.2 through 24.4). Motility can be observed in hanging-drop preparations from cultures of cerebrospinal fluid (CSF); the ameboid form (the only form recognized in humans) is elongate with a broad anterior end and tapered posterior end (Table 24.3). The size ranges from 7 to 35 µm. The diameter of the rounded forms is usually 10 to 18 µm. There is a large, central karyosome and no peripheral nuclear chromatin. The cytoplasm is somewhat granular and contains vacuoles (Fig. 24.2).

Morphology of Flagellates. The ameboid-form organisms change to the transient, pear-shaped flagellate form when they are transferred from culture or teased from tissue into

Figure 24.1 Life cycle of *Naegleria fowleri*. doi:10.1128/9781555819002.ch24.f1



FREE-LIVING AMEBAE
Trophozoites, cysts in water
Naegleria fowleri
(Primary amebic meningoencephalitis - PAM)
Inhalation or aspiration of organisms by HUMANS
Penetration of nasal mucosa
Infection of olfactory nerves
Infection of brain
Death

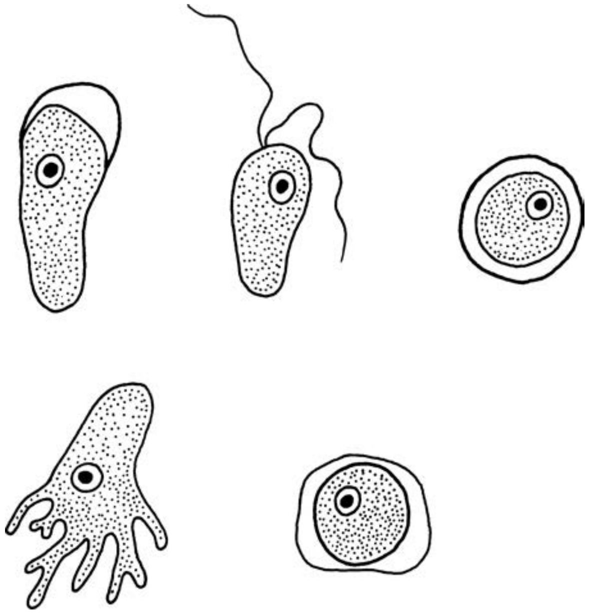


Figure 24.2 Diagram of trophozoite. (Upper row) Flagellate and cyst forms of *Naegleria fowleri*; (lower row) trophozoite and cyst of *Acanthamoeba* spp. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch24.f2

water and maintained at a temperature of 27 to 37°C. The change may occur very quickly (within a few hours) or may take as long as 20 h. The flagellate form has two flagella at the broad end. Motility is typical, with either spinning or jerky movements. These flagellate forms do not divide, but when the flagella are lost, the ameboid forms resume reproduction.

Morphology of Cysts. Cysts from nature and from agar cultures look the same and have a single nucleus almost identical to that seen in the trophozoite. They are generally round, measuring from 7 to 15 μm, and there is a thick double wall (Fig. 24.2; Table 24.3). They are not seen in tissues.

Clinical Disease

PAM caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges (Fig. 24.5). With extremely rare exceptions, the disease is rapidly fatal in humans. The period between contact with the organism and onset of clinical symptoms such as fever, headache, and rhinitis may vary from 2 to 3 days to as long as 7 to 15 days.

The amebae may enter the nasal cavity by inhalation or aspiration of water, dust, or aerosols containing the trophozoites or cysts. The organisms then penetrate the nasal mucosa, probably through phagocytosis of the olfactory epithelium cells, and migrate via the olfactory nerves to the brain (4, 8). Data suggest that *N. fowleri* directly ingests brain tissue by producing food cups or amebostomes, in addition to producing a contact-dependent cytolysis which is mediated by a heat-stable hemolytic protein, heat-labile cytolysis, and/or phospholipase enzymes (8). Cysts of *N. fowleri* are generally not seen in brain tissue.

Early symptoms include vague upper respiratory distress, severe bifrontal or bitemporal headache, lethargy, photophobia, fever, and occasionally olfactory problems. The acute phase includes sore throat, stuffy blocked or discharging nose, and severe headache. Progressive symptoms include spiking fever of 40°C, vomiting, and stiffness of the neck. Mental confusion and coma usually occur approximately 3 to 5 days prior to death. The cause of death is usually cardiorespiratory arrest and pulmonary edema. PAM usually occurs in children and young adults who have recently swum in lakes, heated swimming pools with inadequate chlorination, or other bodies of freshwater that contain amebae.

There are no defined differences between PAM and acute bacterial meningoencephalitis. The peripheral white blood count is usually elevated, with a predominance of neutrophils. CSF may be clear or appear grayish to yellowish-white and may be tinged with red. CSF pressure is usually elevated, ranging from 300 to 600 mm H_2O. CSF pleocytosis is usually seen, with a predominance of neutrophils, a condition which may be mistaken for bacterial infection. Early in the infection the CSF white cell count may be low, but during disease progression it may increase to 26,000 cells/mm^3. The CSF glucose level is usually low to normal and CSF protein is high, ranging from 100 to 1,000 mg/dl. Thus, PAM and acute purulent bacterial meningitis may be difficult to differentiate, particularly in the early stages. Unfortunately, if the CSF Gram stain is interpreted incorrectly (identification of bacteria as a false positive), the resulting antibacterial therapy has no impact on the amebae and the patient will usually die within several days.

Extensive tissue damage occurs along the path of amebic invasion; the nasopharyngeal mucosa shows ulceration, and the olfactory nerves are inflamed and necrotic. Hemorrhagic necrosis is concentrated in the region of the olfactory bulbs and the base of the brain with pockets of amebic trophozoites within edematous and hemorrhagic CNS tissue. Organisms can be found in the meninges, perivascular spaces, and sanguinopurulent exudates.

The first case of organ transplantation from a donor who had died of undiagnosed *N. fowleri* infection was reported in 1997 (8). While no subsequent amebic infections occurred in the three organ recipients, this report emphasizes the need for adequate evaluation of the benefits and risks of transplanting tissues from persons whose illness might have been caused by an infectious agent. Apparently, the Centers for Disease Control and Prevention (CDC) is also aware of another instance in which kidneys

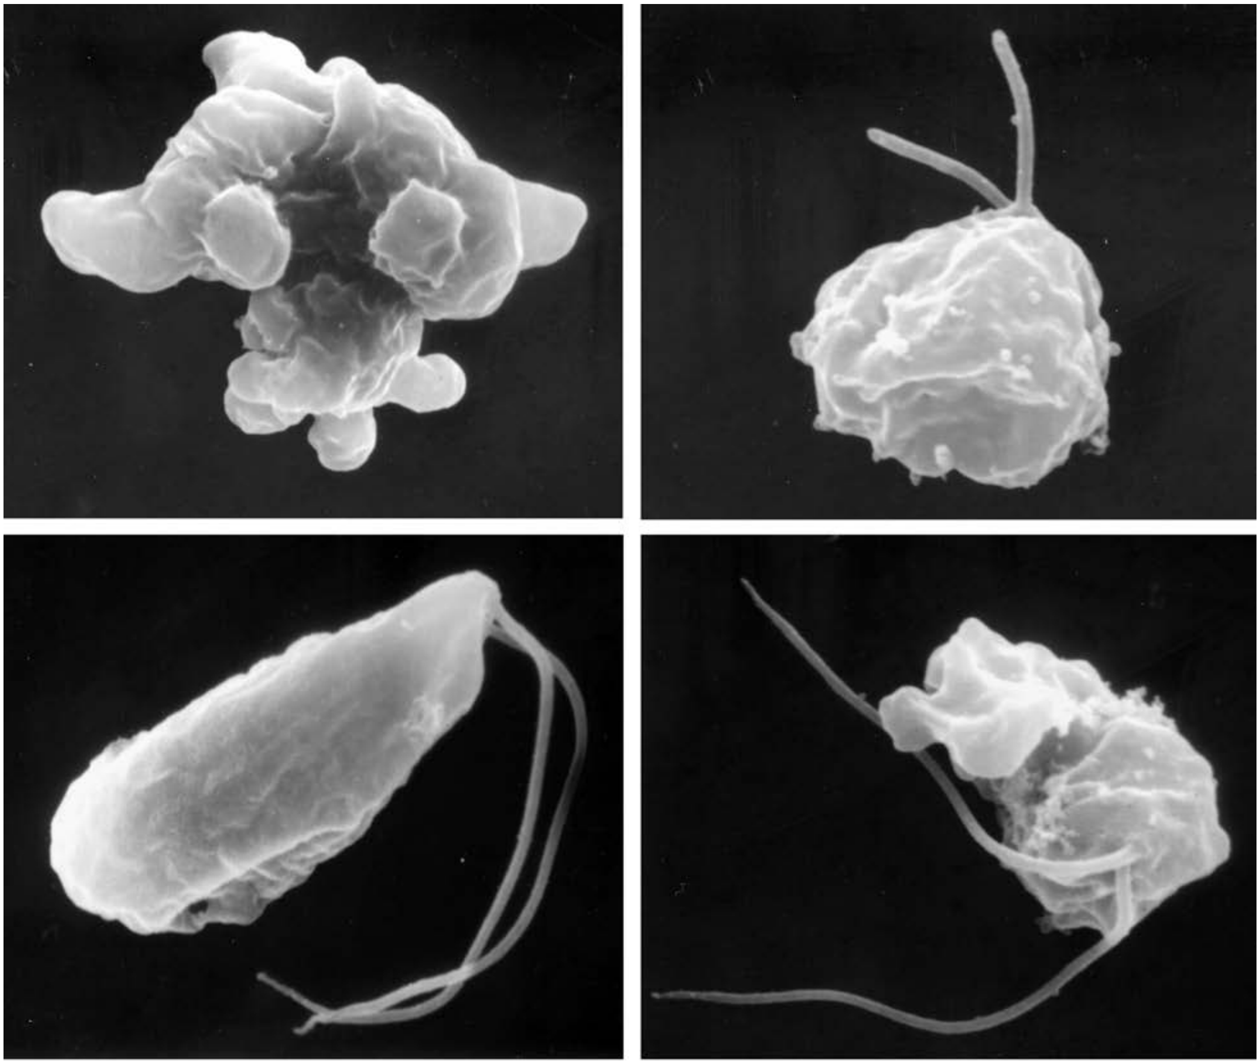

Figure 24.3 (Upper, left) Scanning electronic micrograph (SEM) of *N. fowleri* (Lovell strain) ameboid cell with numerous blunt pseudopods; (right) SEM of *N. fowleri* (Lovell strain) preflagellate, rounded and producing two short, blunt flagella. (Lower, left) SEM of *N. fowleri* (Lovell strain) flagellate with two long, pointed flagella emerging from the anterior rostrum; (right) SEM of *N. fowleri* (Lovell strain) reverting flagellate with two long, pointed flagella. (Courtesy of D. T. John, reprinted from Cable BL, John DT, *J Protozool* **33:**467–472, 1986, with permission.) doi:10.1128/9781555819002.ch24.f3

were transplanted prior to determination that the donor was infected with *N. fowleri* (8). At present, the risk of transmission of *N. fowleri* by donor organs has not been clarified, and no practical test is available to ensure that donor organs are organism free. Also, no prophylactic drug regimen to treat transplant recipients has been established.

Although most PAM infections are associated with recreational freshwater exposure, recent reports indicate that ablution, including nasal rinsing, has been associated with *N. fowleri* cases globally (14). In the United States, during 2003–2012, 3 of 31 persons infected with *N. fowleri* became infected after performing nasal rinsing with contaminated tap water. Two of the three patients performed nasal rinsing using a neti pot or similar device (14, 15) (Fig. 24.6). Detection of *N. fowleri* in the shower and hot water heater suggests that the organism had colonized the home's plumbing system and points to the home as the likely site of exposure. It is imperative that patients understand the need for using safe water to reduce the risk of becoming infected with *Naegleria* during ritual nasal rinsing and ablution (Fig. 24.7) (Table 24.4).

Diagnosis

Clinical and laboratory data usually cannot be used to differentiate pyogenic meningitis from PAM, and so the diagnosis may have to be reached by a process of elimina-

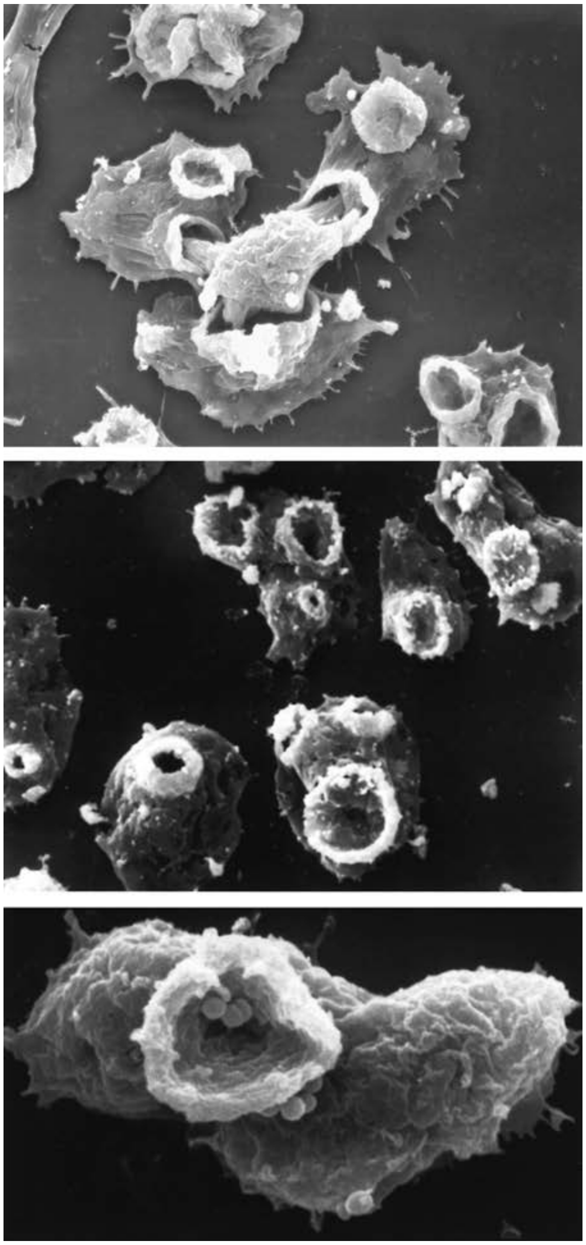

Figure 24.4 (Top) Three amebae of the pathogenic free-living ameba *N. fowleri* attacking and engulfing a fourth, presumably dead, ameba. The amebae are using sucker-like structures (amebostomes) in this novel form of phagocytosis. (Courtesy of D. T. John, from John DT, Cole TB Jr, Carciano-Cabral FM, *Appl Environ Microbiol* **47**:12–14, 1984). (Middle) *N. fowleri* trophozoites. (Bottom) *N. fowleri* trophozoite ingesting starch granules. TABLE 24.3 Comparison of *Naegleria fowleri* and *Acanthamoeba* spp.

Characteristic	*Naegleria fowleri*	*Acanthamoeba* spp.
Trophozoite	Biphasic (amebic) and flagellate forms; 8–15 (7–35) µm; lobate pseudopodia (amebic form)	Large (15–25 µm): no flagella; filiform pseudopodia
Cysts	Not present in tissue; small, smooth, rounded; 7–15 µm	Present in tissue; large with wrinkled double wall
Growth on media	Require living cells (bacteria or cell culture); do not grow with >0.4% NaCl	May grow without bacteria; not affected by 0.85% NaCl
Appearance in tissue[a]	Smaller than *Acanthamoeba* spp.; dense endoplasm; less distinct nuclear staining	Large; rounded; less endoplasm; nucleus more distinct

[a] *Entamoeba histolytica* has a delicate nuclear membrane and a small, pale-staining nucleolus. Freshwater amebae have a distinct nuclear membrane and a large, deep-staining nucleolus.

tion. A high index of suspicion is often mandatory for early diagnosis (8). Although most cases are associated with exposure to contaminated water through swimming or bathing, this is not always the case. The rapidly fatal course of 3 to 6 days after the beginning of symptoms (with an incubation period of 1 day to 2 weeks) requires early diagnosis and immediate chemotherapy if the patient is to survive.

Analysis of the CSF shows decreased glucose and increased protein concentrations. Leukocytes may range from several hundred to >20,000 cells/mm^3. Gram stains and bacterial cultures of CSF are negative; however, the Gram stain background debris can incorrectly be identified as bacteria, thus leading to incorrect therapy for the patient.

A definite diagnosis could be made by demonstration of the amebae in the CSF or in biopsy specimens. Either CSF or sedimented CSF (500 × *g* for 10 min) should be placed on a slide, under a coverslip, and observed for motile trophozoites; smears can also be stained with Wright's or Giemsa stain. Some have recommended a lower centrifugation speed (250 × *g*); however, routine centrifugation does not appear to be problematic. CSF, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Although phase-contrast is recommended, bright-field illumination with reduced light is acceptable. Care must be taken not to mistake leukocytes for actual organisms or vice versa. It is very easy to confuse leukocytes and amebae, particularly when one is examining CSF by using a counting chamber, hence the recommendation to use just a regular slide and coverslip. Motility may vary, and so the main differential characteristic is the spherical nucleus with a large karyosome.

After all but 0.5 ml of the supernatant has been aspirated, the sediment should be inoculated onto the center of an agar plate that has been seeded with bacteria; the plate should then be incubated at 37°C. Biopsy or autopsy material should be triturated in a small amount of ameba saline (0.5 ml), placed in the center of a nonnutrient agar plate seeded with *Escherichia coli* bacteria as a food source, and incubated in the same way (16, 17) (Fig. 24.8). Under a microscope, *N. fowleri* amebae appear as small, motile blotches. After 2 to 3 days of incubation, the amebae begin to encyst. After 4 to 5 days of incubation, trophozoites and cysts should be visible.

Specimens should never be refrigerated prior to examination. Use of smears stained with Giemsa or Wright's stain or a Giemsa-Wright's stain combination can also be helpful. If *N. fowleri* is the causative agent, trophozoites only are normally seen. If the infecting organism is *Acanthamoeba*, cysts may also be seen in specimens from patients with CNS infection. Unfortunately, most cases are diagnosed at autopsy; confirmation of these tissue findings must include culture and/or special staining with monoclonal reagents in indirect fluorescent-antibody procedures (Fig. 24.9).

In cases of presumptive pyogenic meningitis in which no bacteria are identified in the CSF, the computed tomography appearance of basal arachnoiditis (obliteration of basal cisterns in the precontrast scan with marked enhancement after the administration of intravenous contrast medium) should alert the staff to the possibility of acute PAM.

The amebae can be identified in histologic preparations by indirect immunofluorescence and immunoperoxidase techniques. The organism in tissue sections looks very much like an *Iodamoeba bütschlii* trophozoite, with a very large karyosome and no peripheral nuclear chromatin; the organisms can also be seen with routine histologic stains (Fig. 24.5).

In infections possibly caused by *Acanthamoeba* spp., periodic acid-Schiff (PAS) stains the cyst wall red and methenamine silver stains the cyst black; these stains may be helpful. Normally, *Naegleria* and *Acanthamoeba* isolates are identified to the species level by a reference laboratory, such as the CDC, using indirect fluorescent-antibody procedures with a monoclonal or polyclonal antibody. The formalin stability of at least one of the epitopes may be useful in detecting *N. fowleri* in fixed biopsy specimens and in investigating the pathologic process (8).

A multiplex real-time PCR is available at CDC that identifies all three amebae (*Acanthamoeba* sp., *B. mandrillaris*, and *N. fowleri*). The real-time multiplex PCR is a rapid, sensitive, and specific assay, which can be performed and results reported within 4 to 5 hours.

In general, serologic tests have not been helpful in the diagnosis of this infection. The disease progresses so rapidly that the patient is unable to mount an immune response.

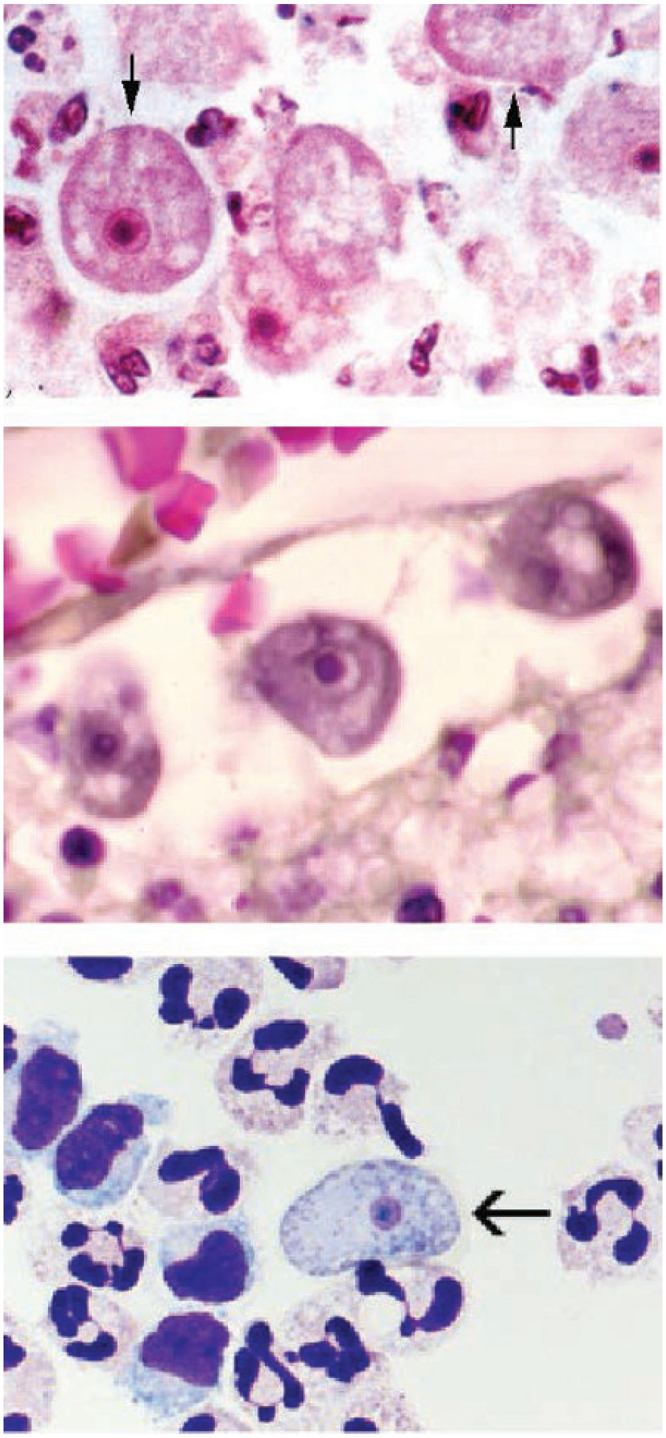

Figure 24.5 *Naegleria fowleri.* (Top, middle) Organisms in brain tissue from a human with PAM. (Bottom) A cytospin of fixed CSF showing a *Naegleria fowleri* trophozoite stained with Giemsa-Wright stain (courtesy of the CDC Public Health Image Library).
doi:10.1128/9781555819002.ch24.f5

KEY POINTS—LABORATORY DIAGNOSIS

Naegleria fowleri

1. Never refrigerate the specimen(s) prior to examination or culture.
2. Beware of the false-positive Gram stain, especially since PAM usually mimics bacterial meningitis and debris may be confused with bacteria (CSF contains increased numbers of leukocytes, increased protein concentrations, and decreased sugar concentrations).
3. The *Naegleria* trophozoites mimic leukocytes in a counting chamber. Motility is more likely to be seen if a drop of CSF is placed directly on a slide and a coverslip is added. Phase-contrast optics are recommended; however, if regular bright-field microscopy is used, the light level should be low. The slide can also be warmed to 35°C to stimulate trophozoite motility.
4. Organisms can be cultured on nonnutrient agar plated with *Escherichia coli*.
5. Low-speed centrifugation is recommended for CSF (150 × *g* for 5 min); however, routine centrifugation speed and time (500 × g for 10 min) also appear to be successful.
6. Incubate the plate in room air at 35 to 37°C for tissues from the CNS and at 30°C for tissues from other sites. *If* a single agar plate is used with no particular causative agent suspected, 30°C is acceptable and will also allow recovery of *Naegleria*. If *Naegleria* is strongly suspected (acute CNS infection), culture at 35 to 37°C for maximum growth.
7. Using the low-power objective (10×), observe the plates daily for 7 days.
8. Remember that *B. mandrillaris* does not grow on agar plates seeded with bacteria.
9. Standard precautions should be used when handling these specimens and cultures. Procedures should be performed in a biological safety cabinet.

Treatment

Many antimicrobial and antiparasitic drugs have been screened for *in vitro* and *in vivo* activity against *N. fowleri*. Although *N. fowleri* is very sensitive to amphotericin B *in vitro*, only a few patients have recovered after receiving intrathecal and intravenous injections of this drug alone or in combination with miconazole (8, 18). One case within California in which the patient was successfully treated with intrathecal and intravenous amphotericin B, miconazole, and oral rifampin has been documented (19). There

TABLE 24.4 Safe water for ritual nasal rinsing and ablution (prevention of *Naegleria* infection)[a]

Method or type of water	Comments
Boil	Use water that has been previously boiled for 1 minute and left to cool. At elevations above 6,500 feet, boil for 3 minutes.
Filter	Use a filter designed to remove some water-loving microbes. The label may read "NSF 53" or "NSF 58." Filter labels that read "absolute pore size of 1 micron [1 µm] or smaller" are also effective.
Buy	Use water with a label specifying that it contains distilled or sterile water.
Disinfect: clear water[b]	Add 1/8 teaspoon (or 8 drops; about 0.625 ml) of unscented liquid household chlorine (5–6%) bleach for each gallon of clear water (or 2 drops of bleach for each liter or each quart of water), Stir the mixture well. Let it stand for 30 minutes or longer before you use it. Store the disinfected water in clean, sanitized containers with tight covers.
Disinfect: cloudy water[b]	Filter it through a clean cloth, paper towel, or coffee filter OR allow any sediment to settle. Draw off the clear water. Add 1/8 teaspoon (or 8 drops; about 0.625 ml) of unscented liquid household chlorine (5–6%) bleach for each gallon of clear water (or 2 drops of bleach for each liter or each quart of water), Stir the mixture well. Let it stand for 30 minutes or longer before you use it. Store the disinfected water in clean, sanitized containers with tight covers.

[b] *Naegleria fowleri* does not survive in sea water and has not been detected in sea water.

was a synergistic effect with miconazole and amphotericin B *in vitro*; however, rifampin was ineffective. Dexamethasone and phenytoin were also given to this patient to decrease intracranial pressure and seizure, respectively. *Naegleria* infections have also been treated successfully with amphotericin B, rifampin, and chloramphenicol; amphotericin B, oral rifampin, and oral ketoconazole; and amphotericin B alone (8, 9, 18). Delay in diagnosis and the fulminant nature of PAM result in few survivors; this is unfortunate since *N. fowleri* is quite sensitive to the antifungal agent amphotericin B.

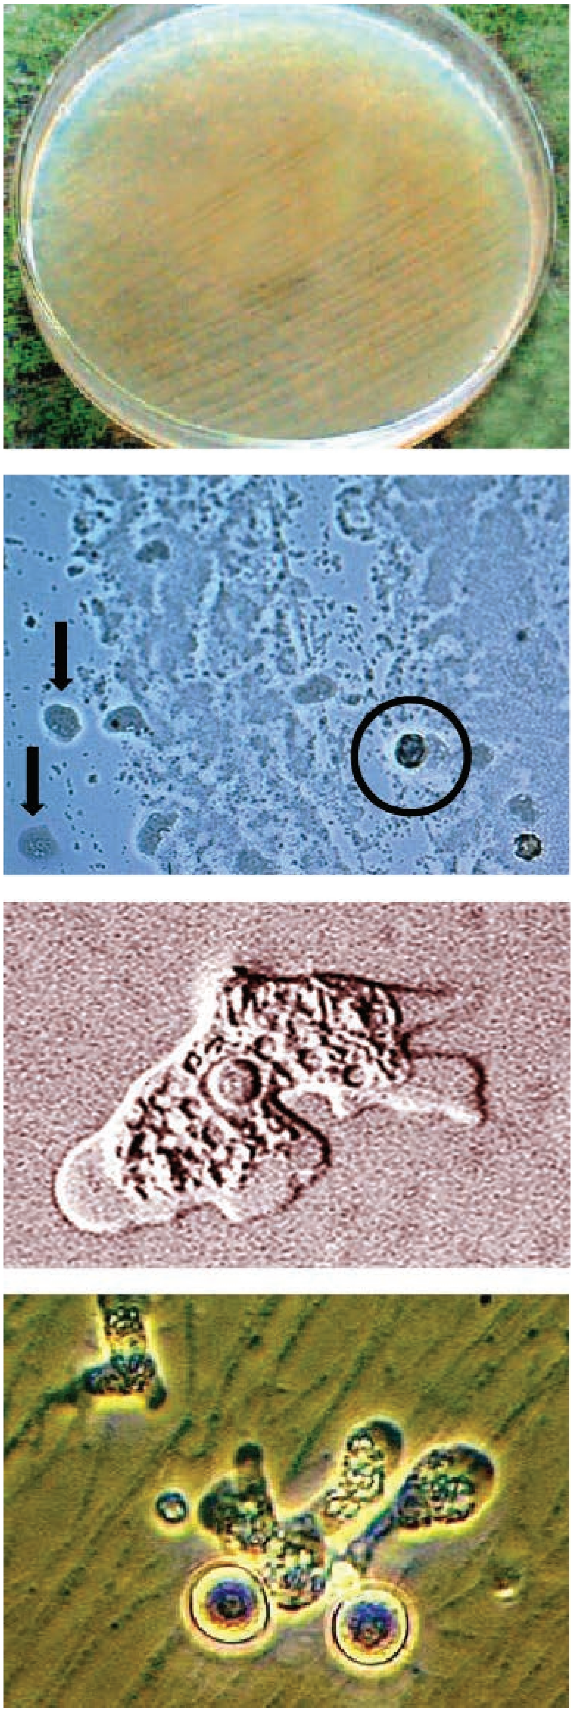
Epidemiology and Prevention

Nearly 200 presumptive or proven cases of PAM have been reported in the literature, including cases from the United States, Ireland, England, Belgium, Czechoslovakia, Australia, New Zealand, Brazil, and Zambia. Clinical patient histories indicate exposure to the organism via freshwater lakes or swimming pools shortly before onset; patients had been previously healthy with no specific underlying problems (8). Pathogenic *Naegleria* organisms have also been isolated from nasal passages of individuals with no history of water exposure, suggesting the possibility of airborne exposure.

The first isolations of the environmental strains of pathogenic *N. fowleri* were reported from water and soil in Australia and from sewage sludge samples in India. Detection of *N. fowleri* in heated discharge water has been reported in Belgium and Poland. Since then, there have been additional reports describing isolations of virulent or avirulent strains of *N. fowleri* from the environment. Studies in Belgium have clearly indicated that *N. fowleri* strains are present in artificially heated waters (power plant warm discharge), and studies in the United States have indicated that virulent strains are also found in lakes in geographic latitudes with water temperatures of 14 to 35°C that are totally isolated from any source of thermal discharge (8). These data suggest that the presence of pathogenic or potentially pathogenic amebic strains may depend on both climate and modification of the natural environment. The ability of the cysts to survive under various environmental conditions has been investigated by several workers. These findings suggest that *N. fowleri* cysts produced in the warm summer months may survive the winter and are capable of growth during the following summer.

General preventive measures include public awareness of potential hazards of contaminated water. It has been recommended that warm discharge water not be used for sports and recreational purposes (8), particularly since DNA restriction fragment profiles of environmental strains and human isolates were homogeneous.

In one study, 30 strains of *N. fowleri* were investigated by the randomly amplified polymorphic DNA (RAPD)



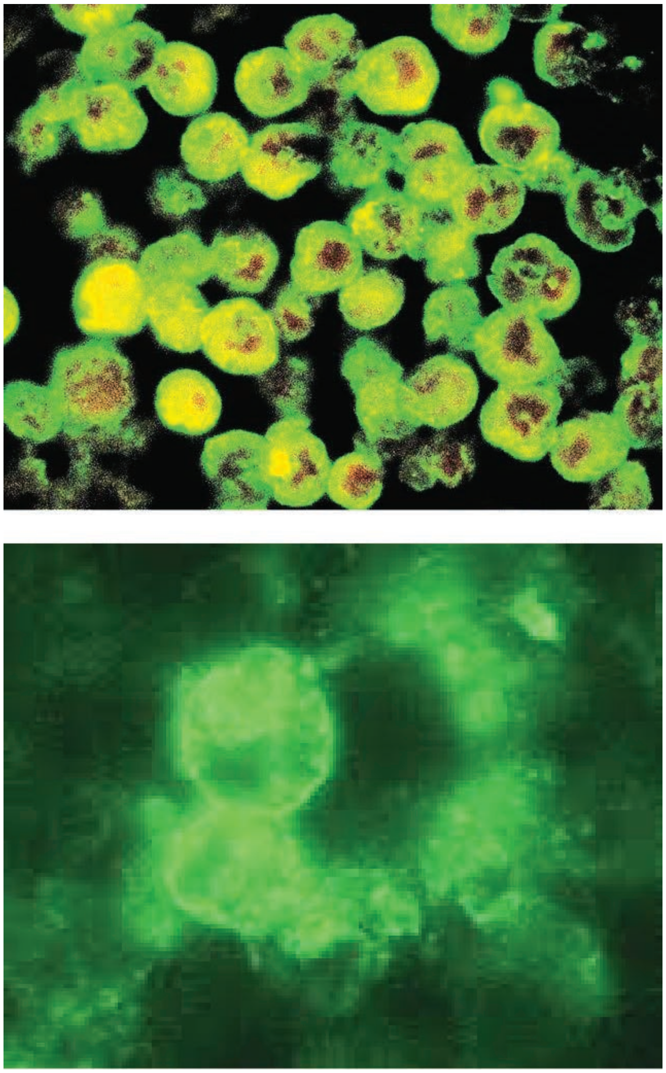


Figure 24.9 *Naegleria fowleri*. (Upper) Direct fluorescent antibody stain; (lower) indirect immunofluorescence (IIF) assay for *Naegleria fowleri*, 1,000× oil magnification (courtesy of the CDC Public Health Image Library).

method. The data confirmed earlier work indicating that RAPD variation is not correlated with geographic origin. In particular, Mexican strains belong to the variant previously detected in Asia, Europe, and the United States. In France, strains gave RAPD patterns identical to those of the Japanese strains. All of these strains, in addition to another strain from France, exhibited similarities to South Pacific strains. The results confirmed the presence of many variants in Europe, while only two variants were detected in the United States; these two variants were different from the South Pacific variants (8).

Acanthamoeba spp.

Formerly, the genus *Acanthamoeba* was included in the genus *Hartmanella*. In 1975, Sawyer and Griffin proposed a new family, *Acanthamoebidae*, for the spiny amebae, with *Acanthamoeba* as the type genus and *Acanthamoeba castellanii* as the type species (4). The most characteristic feature of this genus is the presence of spine-like pseudopods called acanthapodia. Several species of *Acanthamoeba* (*A. culbertsoni*, *A. castellanii*, *A. polyphaga*, *A. astronyxis*, *A. healyi*, and *A. divionensis*) cause GAE, primarily in immunosuppressed, chronically ill, or otherwise debilitated persons. These patients tend to have no relevant history involving exposure to recreational freshwater. *Acanthamoeba* spp. also cause amebic keratitis, and it is estimated that to date approximately 1,000 cases of *Acanthamoeba* keratitis have been seen in the United States. Species of *Acanthamoeba* linked to keratitis include *A. castellanii*, *A. polyphaga*, *A. hatchetti*, *A. culbertsoni*, *A. rhysodes*, *A. griffini*, *A. quina*, and *A. lugdunensis* (6). The number of cases worldwide has also been increasing; apparently, the incidence of *Acanthamoeba* keratitis in the United Kingdom is 15 times that in the United States and 7 times that in Holland (20).

The pathogenesis of *Acanthamoeba* infection involves the ability of the organism to invade tissues. This capability depends on adherence to mucosal surfaces, migration through tissues, and the release of oxygen radicals and proteases that can destroy connective tissue. Studies have found that alkaline cysteine proteinases were more active in pathogenic strains whereas serine proteases were found in both pathogenic and nonpathogenic strains (6).

Humoral immunity and complement activation appear to be the primary defense mechanisms against *Acanthamoeba* infections; serum antibodies are mainly the IgM and IgG classes. Both antibody and complement promote recognition of the organisms by phagocytic cells. The amebae are destroyed by neutrophils, which are activated by lymphokines to accelerate the respiratory burst and to release lysosomal enzymes. Macrophages and neutrophils are the major inflammatory cell types found in tissues surrounding amebae. Although the cornea is infiltrated by neutrophils and there is a measurable humoral response, the disease will progress to corneal opacity or perforation without therapy in the immunocompetent patient. It has been suggested that the organisms mask their antigens from cellular immune responses, thus suppressing macrophage functions and/or preventing neutrophil activity. Total serum immunoglobulins do not differ significantly between healthy subjects and patients with *Acanthamoeba* keratitis, but levels of ameba-specific tear IgA were significantly lower in patients with keratitis (6). Although *Acanthamoeba* infections stimulate a granulomatous response, the response in AIDS patients is minimal or absent, findings which are consistent with the poor immune response in these patients.

Another type of meningoencephalitis, GAE, caused by freshwater amebae is less well defined and may occur as a subacute or chronic disease with focal granulomatous lesions in the brain (Table 24.5). The route of CNS invasion is thought to be hematogenous, with the primary site being the skin or lungs. In this infection, both trophozoites and cysts can be found in the CNS lesions. An acute-onset case of fever, headache, and pain in the neck preceded by 2 days of lethargy has also been documented (6). The causative organisms are probably *Acanthamoeba* spp. in most cases,

TABLE 24.5 *Acanthamoeba* infection: clinical manifestations of patients with AIDS[a]

General	Neurologic	Nasal	Cutaneous	Musculoskeletal

but it is possible that other genera are involved (6, 8). In the acute-onset case mentioned above, *A. culbertsoni* was repeatedly found in and cultured from the CSF. The patient responded dramatically to a combination therapy of penicillin and chloramphenicol. Cases of GAE have been reported in chronically ill or immunologically impaired hosts; however, some patients apparently have no definite predisposing factor or immunodeficiency. Conditions associated with GAE include malignancies, systemic lupus erythematosus, HIV infection, Hodgkin's disease, skin ulcers, liver disease, pneumonitis, diabetes mellitus, renal failure, rhinitis, pharyngitis, and tuberculosis. Predisposing factors include alcoholism, drug abuse, steroid treatment, pregnancy, systemic lupus erythematosus, hematologic disorders, AIDS, cancer chemotherapy, radiation therapy, and organ transplantation. This infection has become more widely recognized in AIDS patients, particularly those with a low CD4$^+$ cell count.

The *Acanthamoeba* group also causes keratitis and corneal ulceration. There are a number of published cases that emphasize the need for clinicians to consider acanthamoebic infection in the differential diagnosis of eye infections that fail to respond to bacterial, fungal, or viral therapy. These infections are often due to direct exposure of the eyes to contaminated materials or solutions. It is now recognized that the wearing of contact lenses is the leading risk factor for keratitis. Conditions which are linked with disease include the use of homemade saline solutions, poor contact lens hygiene, and corneal abrasions.

Life Cycle and Morphology

Unlike *N. fowleri*, *Acanthamoeba* spp. do not have a flagellate stage in the life cycle, only the trophozoite and cyst (Fig. 24.10 and 24.11) (Table 24.3).

Morphology of Trophozoites. Motile organisms have spine-like pseudopods; however, progressive movement is usually not very evident (Fig. 24.2, 24.12, and 24.13). There is a wide range (25 to 40 µm), with the average diameter of the trophozoites being 30 µm. The nucleus has a typical large karyosome, like that seen in *N. fowleri*. This morphology can be seen on a wet preparation. In the environment, these organisms feed on bacteria, algae, and yeast; however, they can also exist on liquid nutrients taken

up through pinocytosis (6). Organelles typically found in higher eukaryotic cells have been identified and include a Golgi complex, smooth and rough endoplasmic reticula, free ribosomes, digestive vacuoles, mitochondria, and microtubules.

Morphology of Cysts. The cysts are usually round with a single nucleus, also having the large karyosome seen in the trophozoite nucleus. The double wall is usually visible, with the slightly wrinkled outer cyst wall and what has been described as a polyhedral inner cyst wall (6) (Fig. 24.2, 24.12, and 24.13). Cysts are uninucleate and have a proteinaceous ectocyst and an endocyst made of cellulose, thus making the cyst visible using calcofluor white. This cyst morphology can be seen in organisms cultured on agar plates. Cyst formation occurs under adverse environmental conditions; cysts are resistant to biocides, chlorination, and antibiotics and can also survive low temperatures (0 to 2°C).

Clinical Diseases

Granulomatous amebic encephalitis. *Acanthamoeba* sp. GAE tends to affect immunosuppressed, chronically ill, or otherwise debilitated persons, generally with no particular history of exposure to freshwater sources. There have been a few reported infections in immunocompetent individuals with no known immunodeficiency or risk factors. *Balamuthia mandrillaris* GAE tends to affect the very young or very old and patients with HIV/AIDS. Whether caused by *Acanthamoeba* sp. or *B. mandrillaris*, GAE is a slowly progressive disease of the CNS.

Meningoencephalitis caused by *Acanthamoeba* spp. may present as an acute suppurative inflammation of the brain and meninges like that seen with *N. fowleri* infection. However, *Acanthamoeba* spp. are generally reported to cause a more chronic, protracted, slowly progressive form of meningoencephalitis. Due to the confusion in the earlier literature regarding the nomenclature of *Acanthamoeba* and *Hartmanella* spp., these organisms have been referred to in the past as belonging to the *Hartmanella-Acanthamoeba* group. However, since no true *Hartmanella* species has been found to be pathogenic to humans, references to *Hartmanella* in human tissues should be revised to read *Acanthamoeba* or *Balamuthia* spp. (6, 21).

The incubation period of GAE is unknown; several weeks or months are probably necessary to establish the disease. The clinical course tends to be subacute or chronic and is usually associated with trauma or underlying disease, not swimming. GAE is characterized by confusion, dizziness, drowsiness, nausea, vomiting, headache, lethargy, stiff neck, seizures, and sometimes hemiparesis. Within the CNS, the cerebral hemispheres are the most likely tissue to be involved. There may be edema and hemorrhagic necrosis within the temporal, parietal, and occipital lobes. A chronic inflammatory exudate can be seen over the cortex, mainly of polymorphonuclear leukocytes and mononuclear cells. Unlike in PAM caused by *N. fowleri*, both trophozoites and cysts are found throughout the tissue. Granulomatous inflammation necrosis and thrombosed vessels are seen in the brain (Fig. 24.14). Multinucleated giant cells forming granulomas can be seen in immunocompetent patients, while granuloma formation is generally poor or lacking in immunocompromised individuals. It is unknown whether brain necrosis is due to direct tissue destruction caused by the organisms, to inflammatory cytokines such as interleukin-1 or tumor necrosis factor, or both. Also, dissemination to other tissues such as the liver, kidneys, trachea, and adrenals can occur in immunocompromised individuals; more unusual sites also include the ears and necrotic bone from a bone graft of the mandible (6).

In the differential diagnosis, other space-occupying lesions of the CNS (tumor, abscess, fungal infection, etc.) must also be considered. Some of the predisposing factors have included Hodgkin's disease, diabetes, alcoholism, pregnancy, and steroid therapy. Organisms have also been found in the adrenal gland, brain, eyes, kidneys, liver, pancreas, skin, spleen, thyroid gland, and uterus.

Amebic meningoencephalitis can also be an unusual complication of bone marrow transplantation. A case has been reported in a patient with non-Hodgkin's lymphoma after autologous stem cell transplantation. Leg weakness, fever, and urinary retention developed 69 days after transplantation. The patient then developed fever, seizures, rapid deterioration of mental functions, and hypercapneic respiratory failure. Magnetic resonance imaging demonstrated a ring-enhancing lesion at the level of thoracic spines 11 and 12. Pleocytosis was seen in the CSF. On autopsy, a subacute meningoencephalitis secondary to *A. culbertsoni* infection was seen (6).

AIDS Patients. The first case of an *Acanthamoeba* infection in a patient with AIDS was in 1986, and many additional cases have been reported since that time. *Acanthamoeba* spp. are now well accepted as opportunistic pathogens in immunocompromised patients with AIDS. Unfortunately, most of the cases have resulted in death and have been confirmed postmortem. These individuals usually have advanced HIV disease with a very low $CD4^+$ T-cell count, generally less than 200/mm^3. Often the patients expire within a month after the onset of CNS symptoms. Unfortunately, the diagnosis of this infection requires a high index of suspicion, since both clinical and histologic findings may mimic those of disseminated fungal or algal disease (Tables 24.5 and 24.6). The primary site of infection is thought to be the sinuses and lungs. The skin is also thought to be a possible portal of entry. Clinical manifestations of patients with AIDS and *Acanthamoeba* infection can be reviewed in Table 24.5. They may include general complaints such as fever and chills, nasal congestion or lesions, neurologic symptoms, and musculoskeletal and cutaneous lesions. Some patients, especially those with AIDS, can develop erythematous nodules, chronic ulcerative skin lesions, or abscesses. Although CSF lymphocytosis is seen in non-AIDS patients, the CSF may reveal no cells in HIV-positive patients. These patients also tend to exhibit chronic sinusitis, otitis, and cutaneous lesions. Patients with CNS symptoms and AIDS may be misdiagnosed with toxoplasmosis, although serologic tests for *Toxoplasma* may be negative. Other patients have been misdiagnosed with CNS vasculitis, squamous cell carcinoma, or bacterial meningitis.

TABLE 24.6 *Acanthamoeba* infection: examples of clinical features in specific patients with AIDS[a]

Other illnesses[b]	Initial diagnosis	Clinical syndrome
Chronic sinusitis, PCP, disseminated MAC, CMV retinitis	Disseminated fungal infection	Suspected GAE, disseminated cutaneous infection
PCP, esophageal candidiasis, recurrent sinusitis	Cat scratch disease or vasculitis	Disseminated cutaneous infection
Toxoplasma encephalitis, CMV retinitis, giardiasis	Kaposi's sarcoma	Nasal, disseminated cutaneous infection, possible GAE
Cryptococcal meningitis, oral candidiasis, disseminated herpes zoster	*Toxoplasma* encephalitis or lymphoma	GAE
PCP, MAC infection, Kaposi's sarcoma	*Acanthamoeba* infection	Nasal ulcer (single nodule), intramuscular abscess
Inflammatory demyelinating polyneuropathy, esophageal candidiasis, varicella zoster, dendritic keratitis	*Acanthamoeba* infection	Disseminated cutaneous infection, possible GAE

[a] Adapted from Sison JP et al, *Clin Infect Dis* **20**:1207–1216, 1995.
[b] CMV, cytomegalovirus; MAC, *Mycobacterium avium* complex; PCP, *Pneumocystis* pneumonia.

Both PAM and GAE carry a grave prognosis and, although considered rare, should be considered in the differential diagnosis of patients who present with appropriate histories and imaging findings, including nonspecific brain edema on computed tomography in PAM and focal punctate enhancing lesions in the posterior cranial fossa on T1-weighted magnetic resonance imaging in GAE. The initial symptoms are commonly fever and headache. It is important to remember that in patients thought to have toxoplasmosis, review of the cranial computed tomogram could not distinguish between the two etiologic agents *Toxoplasma* and *Acanthamoeba*.

In patients with disseminated disease, the duration of infection from onset to death can range from 7 days to 5 months. Once neurologic symptoms become obvious, the survival time is generally about a month. Since early therapy can alter the clinical outcome, recognition of this disease as a potential cause of the patient's presentation is critical. It is important to initiate appropriate diagnostic testing for confirmation of the causative agent as soon as possible.

Keratitis. Keratitis, uveitis, and corneal ulceration have been associated with *Acanthamoeba* spp. Infections have been seen in both hard- and soft-lens wearers, and particular attention has been paid to soft-lens disinfection systems, including homemade saline solutions. Heat disinfection overall appears to be more effective than cold disinfection methods in killing *Acanthamoeba* trophozoites and cysts. Recent studies indicate that not all commercial contact lens disinfectant solutions are equal in their ability to kill *A. castellanii* (22). Solutions containing hydrogen peroxide or chlorhexidine-thimerosal were active against both trophozoites and cysts. A benzalkonium chloride-based solution was effective only against trophozoites, and solutions containing polyaminopropyl biguanide or polyquaternium 1 were completely ineffective. Unfortunately, a lack of standard methods for testing disinfection solutions may also complicate the issue, although the use of a more reproducible approach may be helpful (22). Obviously, the cyst form of the parasite is much more resistant, and the need to test any solution for both trophozoites and cysts is critical. In addition to the active ingredient(s), it is important to consider adequate exposure times. In general, products containing hydrogen peroxide were the most active, demonstrating the best minimum trophozoite amebicidal concentration for both trophozoites (3 min) and cysts (9 h). It is always important to remember that different products containing hydrogen peroxide at the same concentration may have different killing properties; one report indicated that when hydrogen peroxide was used according to the manufacturer's directions (30 min of contact time), it was not effective against *A. castellanii* trophozoites and cysts. An excellent discussion of the manufacturer's minimum recommended disinfection time for contact lens solutions can be found in reference 4. In order for a disinfectant to be cysticidal, it must be able to gain access to the trophozoite contained within the cyst wall. The most likely route would be the pores in the double cell wall; however, it is thought that these pores (ostioles) are plugged with mucopolysaccharide. Thus, the disinfectant would need to be able to disrupt these "plugs" in order to reach the trophozoite.

The onset of corneal infection with *Acanthamoeba* spp. can vary tremendously; however, two factors often appear to be involved: trauma and contaminated water. When corneal abrasions occur, the disease process is usually more rapid, with ulceration, corneal infiltration, iritis, scleritis, severe pain, hypopyon (pus in the anterior chamber), and loss of vision. When this process occurs in an individual who wears contact lenses, the onset is more gradual but the results are often the same. A contact lens can act as a mechanical vector for transport of amebae present in the storage case onto the cornea. Subsequent multiplication and invasion of the tissue may occur. Another consideration involves the potential infection of the nasal cavity via lacrimal drainage, a condition that probably causes no problems in a healthy individual. However, it remains unknown whether the presence of these organisms in the nasopharynx of an immunocompromised individual increases the risk of GAE.

Decreased corneal sensation has contributed to the misdiagnosis of *Acanthamoeba* keratitis as herpes simplex keratitis; this mistake can also be attributed to the presence of irregular epithelial lesions, stromal infiltrative keratitis, and edema, which are commonly seen in herpes simplex keratitis (Fig. 24.15). *Acanthamoeba* keratitis may be present as a secondary or opportunistic infection in patients with herpes simplex keratitis. Unfortunately, as a result, treatment can be delayed for 2 weeks to 3 months. The presence of nonhealing corneal ulcers and the presence of ring infiltrates are also clinical signs that alert the ophthalmologist to the possibility of amebic infection.

It is important to consider *Acanthamoeba* infection in the differential diagnosis of uveitis in patients with AIDS. It is also important to remember that incisional keratotomy may predispose the cornea to delayed-onset infectious keratitis; *Acanthamoeba* should always be considered as a possible cause of infection, and clinical specimens should be cultured in refractory cases.

One of the mechanisms of *Acanthamoeba* adhesion to the corneal surface may involve interactions between the mannose-binding protein of *Acanthamoeba* and mannose-containing glycoproteins on the surface of the corneal epithelium (6, 8). It appears that enhanced growth is seen in surface-attached amebae and that cocontamination of lens systems with bacteria may be a prime factor in the development of amebic keratitis. Data also suggest that obligate bacterial endosymbionts are able to enhance the amebic pathogenic potential *in vitro*, although the exact mechanisms have not yet been identified (11). There are also data to show that monoclonal anti-*Acanthamoeba* IgA antibodies can protect against *Acanthamoeba* keratitis, suggesting that this occurs by inhibiting adhesion of the amebae to the corneal epithelium (6).

Acanthamoeba spp. produce a variety of proteases, which may facilitate cytolysis of the corneal epithelium, invasion of the extracellular matrix, and dissolution of the corneal stromal matrix (8). *Acanthamoeba* spp. are also resistant to complement lysis. The ability of *Acanthamoeba* spp. to activate the alternative complement pathway but to resist complement-mediated cellular lysis can be attributed to both the release of a transport-dependent extracellular matrix and the presence of complement-inhibitory surface proteins.

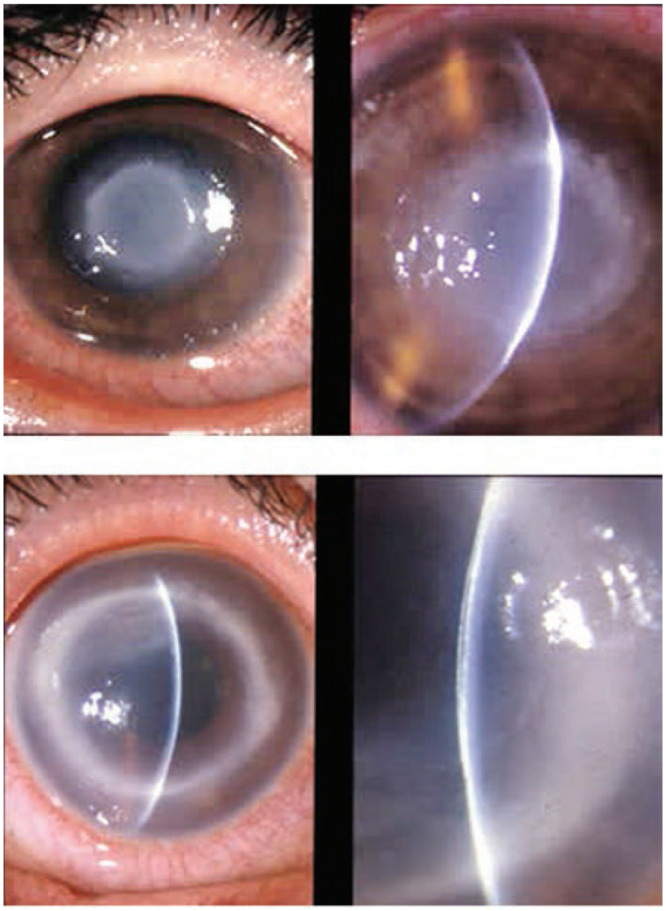

Figure 24.15 *Acanthamoeba* keratitis. (Upper) Left, broad illumination; right, slit beam illumination. Early, central stromal inflammation (keratitis); resembles the immunogenic form of herpes simplex stromal keratitis. (Lower) Left, broad illumination with slit beam; right, high magnified slit beam. Typical advanced ring infiltrate. (Courtesy of the CDC Public Health Image Library, photographs by Dan B. Jones.)
doi:10.1128/9781555819002.ch24.f15

Although previous studies have shown that early diagnosis and therapy are definitely related to outcome, differences among patients with and without contact lenses should also be considered. The mean time to diagnosis could be significantly longer in patients who are not contact lens users than in those who are, primarily due to the differences in the index of suspicion regarding the link between contact lens use and *Acanthamoeba* keratitis. These differences could be directly related to poor outcome, with patients who did not wear contact lenses having a very poor visual acuity or penetrating keratoplasty compared with patients who wore contact lenses. It is important to remember that all patients with unresponsive microbial keratitis, even those who do not wear contact lenses, should be evaluated for possible *Acanthamoeba* infection.

Cutaneous Lesions. Although cutaneous infections are more common in patients with AIDS, regardless of the presence or absence of CNS involvement, they have also been seen in immunocompetent patients. The disease includes the presence of hard erythematous nodules or skin ulcers (Fig. 24.16 and 24.17). The early lesions appear as firm papulonodules that drain purulent material; these lesions then develop into nonhealing indurated ulcers. Although disseminated skin lesions may be the first sign of *Acanthamoeba* infection, it is unclear whether the skin lesions represent a primary focus or may result from hematogenous spread from other body sites. Although the mortality rate for these individuals without CNS involvement is around 75%, it increases to 100% if cutaneous infection is accompanied by CNS disease (6).

Histology reveals necrosis surrounded by inflammatory cells, vasculitis, and the presence of trophozoites and cysts of the amebae (Fig. 24.18). However, these findings can also mimic skin lesions caused by fungi, viruses, mycobacteria, or foreign-body reactions. The amebae can also resemble yeast forms of *Blastomyces dermatitidis*, sporangia of *Rhinosporidium seeberi*, *Cryptococcus neoformans*, or *Prototheca wickerhamii*. Because cutaneous acanthamoebiasis has been misdiagnosed as a number of different conditions, it is important to repeat the examination of biopsy material with a different specimen if the first results are negative and no amebae are seen.

Diagnosis

Nonnutrient Agar Plate Culture. Laboratory examinations similar to those for *N. fowleri* can be used to recover and identify these organisms; the one exception is recovery by culture, which has not proven to be as effective with GAE patients infected with *B. mandrillaris*. The most effective approach uses nonnutrient agar plates with Page's saline and an overlay growth of *Escherichia coli* on which the amebae feed (6, 8) (Fig. 24.19). There is also evidence that phosphate-buffered saline can be used. Specimens transported in ameba-saline (5.0 ml) and filtered through 13-mm, 0.22-µm-pore-size cellulose acetate and nitrate filters (Millipore Corp., Bedford, MA) have also been acceptable for organism recovery. The filter is then placed in the center of the nonnutrient agar plate seeded with *E. coli*. Tissue stains are also effective, and cysts can be stained with Gomori's silver methenamine, PAS, and calcofluor white (6, 8).

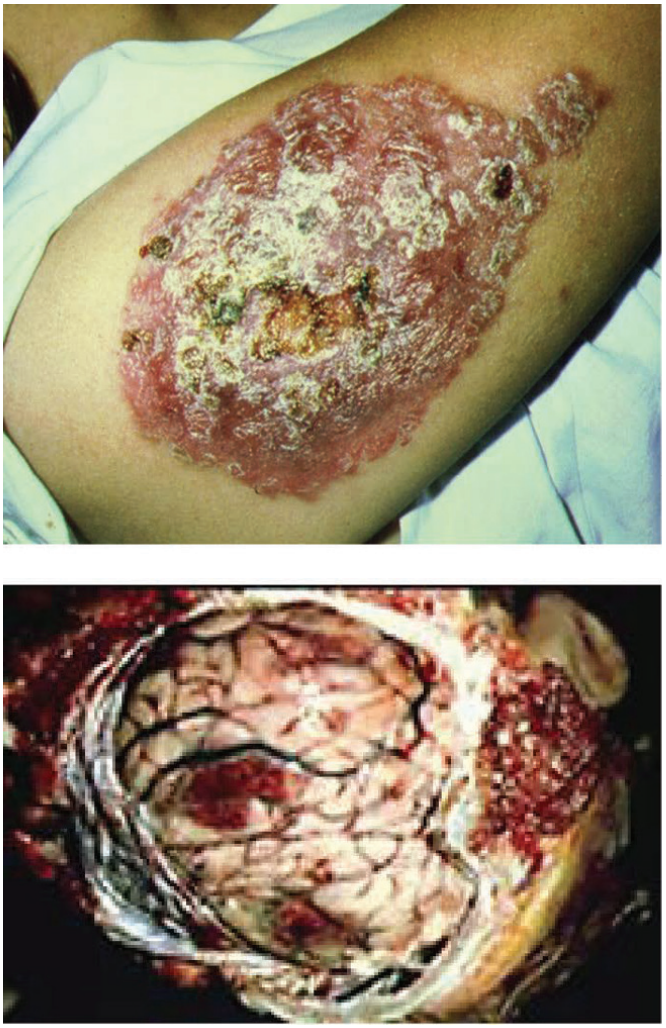

Figure 24.16 *Acanthamoeba* infection in a 28-year-old woman whose arm was bitten by her child. (Upper) Cutaneous lesion after approximately 6 months; (lower) brain lesions in same patient, disseminated disease. doi:10.1128/9781555819002.ch24.f16

Other Media Approaches. Various improved medium formulations have been developed and provide some additional options. *Acanthamoeba* isolates have been recovered from clinical specimens inoculated onto buffered charcoal-yeast extract agar (BCYE), nonnutrient agar with live or dead *E. coli*, and tryptic soy agar (TSA) with 5% horse or sheep blood. Good recovery of trophozoites has been obtained on BCYE, TSA with rabbit blood, TSA with horse blood, and Remel TSA with sheep blood. BBL TSA with horse blood or rabbit blood provided good recovery of

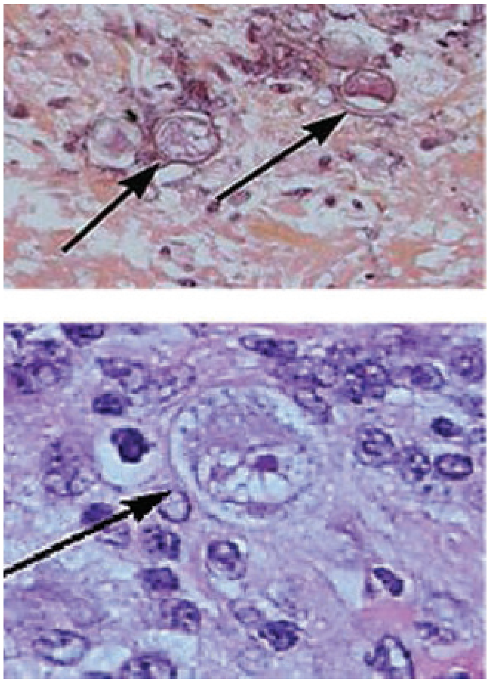

Figure 24.18 Microscopic view of *Acanthamoeba* amebae in skin. (Upper) Surgical skin biopsy specimen showing amebic cysts (arrows) in the dermal-hypodermal junction (hematoxylin and eosin stain). (Lower) Surgical skin biopsy specimen showing intravascular amebic trophozoite (arrow) characterized by acanthapodia, cytoplasmic vacuoles, and a prominent nucleolus (hematoxylin and eosin stain). (From Barete S et al, *Emerg Infect Dis* **13**[5], 2007, http://wwwnc.cdc.gov/eid/article/13/5/06-1347_article.htm.) doi:10.1128/9781555819002.ch24.f18

cysts. All species of live or dead bacteria (*Enterobacter aerogenes*, *Escherichia coli*, *Klebsiella pneumoniae*, *P. aeruginosa*, *Serratia marcescens*, *Staphylococcus aureus*, and *Stenotrophomonas maltophilia*) yielded good recovery of trophozoites; however, only nonnutrient agar with live *P. aeruginosa*, live *E. aerogenes*, or live *S. maltophilia* gave good recovery of cysts. TSA with rabbit blood or horse blood, BCYE, and nonnutrient agar prepared with live *P. aeruginosa*, *E. aerogenes*, or *S. maltophilia* offered optimal recovery of *Acanthamoeba*. Filtration of specimens through cellulose membranes and cultivation on nonnutrient agar plates covered with *E. coli* was compared with culture of centrifuged specimens (9). Significantly higher parasite detection could be obtained with samples processed by filtration (100% of specimens containing 10 parasites and 65% of specimens containing 2 parasites compared with 8 and 0%, respectively, with centrifugation).

Cryopreservation studies have also found that the highest viability of trophozoites of *A. culbertsoni* occurs when dimethyl sulfoxide is used at a final concentration of 10% and an equilibrium temperature of 4°C. Gross cultural or morphological changes were not noted in trophozoites thawed from frozen suspension; the organisms were grown in serum-casein-glucose-yeast extract medium (23).

Histology. Identification of acanthamoebae in ocular and other tissues can be difficult, even for trained microscopists; in histologic preparations the organisms look much like keratoplasts, as well as neutrophils and monocytes. It has been estimated that up to 70% of clinical *Acanthamoeba* keratitis cases are misdiagnosed as viral keratitis. Also, the mean time to diagnosis of keratitis due to *Acanthamoeba* infection can average 2.5 weeks longer for noncontact lens wearers than for contact lens users. Certainly the availability of rapid, accurate, and relatively simple diagnostic tests would increase the timely application of appropriate chemotherapy. Genetic markers have also been developed and used to identify pathogenic *Acanthamoeba* strains associated with nonkeratitis infections (24).

Cutaneous lesion material can be inoculated onto various growth media, including nonnutrient agar plates with a bacterial overlay. Inoculation of mammalian cell culture monolayers is also possible, as for GAE. Histologic stains such as hematoxylin and eosin, PAS, or calcofluor white

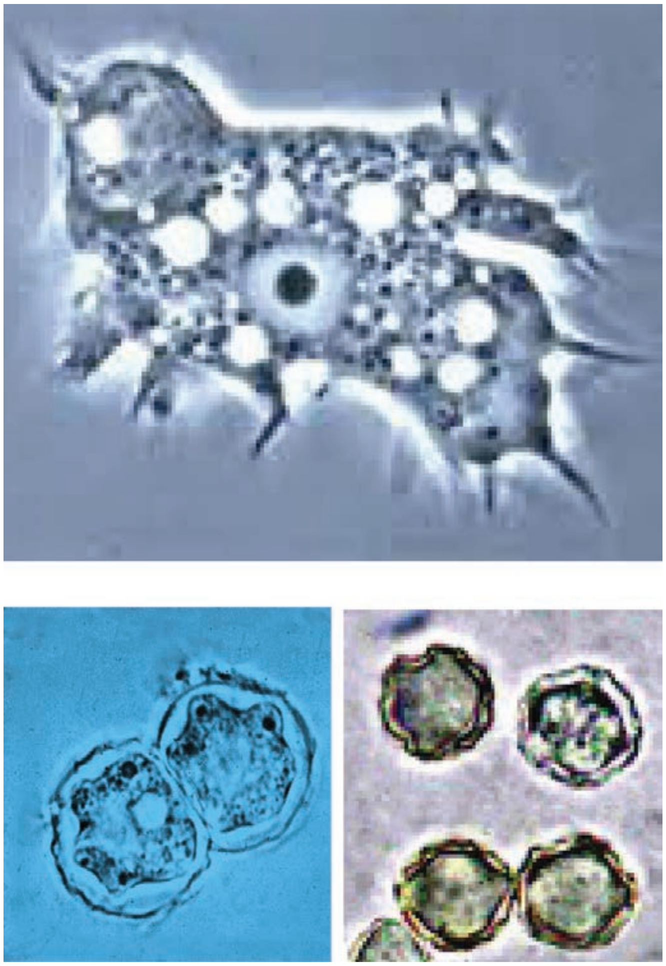

Figure 24.19 (Upper) *Acanthamoeba* trophozoite in wet preparation (note the "spiky" pseudopods, called acanthapodia). (Lower) *Acanthamoeba* cysts in wet preparation (note the double-wall appearance). (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch24.f19

can be used. Also, DNA-based molecular methods such as restriction fragment length polymorphism and randomly amplified DNA analysis can be used (25, 26).

Cytospin. CSF or bronchoalveolar lavage fluid cytospin preparations can be used to look for amebae in patients with GAE or respiratory symptoms. The characteristic morphology of the *Acanthamoeba* trophozoites, such as the prominent nucleolus, contractile vacuole, and cytoplasmic vacuoles, can be seen more easily using trichrome or hematoxylin and eosin stains on fixed preparations after cytocentrifugation.

Antibody Detection. Although detection of antibodies to *Acanthamoeba* spp. has been confirmed, the usefulness of serologic tests for the diagnosis of these infections has not been proven. Also, these procedures are not generally available. Further work related to the issue of false-positive and false-negative results and interpretive guidelines regarding past exposure or present infection must be performed before these diagnostic procedures can be routinely used.

Molecular Testing. Analysis of the 18S rRNA gene PCR product has been used to identify *Acanthamoeba* isolates from reservoirs in Taiwan (27). Molecular testing was also valuable in the investigation of an outbreak of *Acanthamoeba* keratitis, a rare, potentially blinding, corneal infection, which was detected in the United States in 2007; cases had been increasing since 2004. Although the Advanced Medical Optics Complete Moisture Plus (AMOCMP) solution was not found to be contaminated prior to opening, its anti-*Acanthamoeba* efficacy was insufficient (28).

KEY POINTS—LABORATORY DIAGNOSIS

Acanthamoeba spp.

1. As with *N. fowleri*, beware of a false-positive Gram stain (debris being misinterpreted as bacteria) (the leukocyte count in CSF may be elevated).
2. Examine clinical material on a slide with a coverslip; do not use a counting chamber (organisms in CSF within a counting chamber resemble leukocytes).
3. Nonnutrient agar with Page's saline and an *E. coli* overlay can be used for culture recovery.
4. Various other media containing different agar bases, some of which contain horse, sheep, or rabbit blood, are also available.
5. Tissue stains are also effective, and the use of calcofluor white to visualize the double-walled cyst is recommended.
6. Refer to chapter 8 for specific methods and recommendations.

Treatment

Disseminated Infections. Trophozoites and cysts of *Acanthamoeba* isolates vary in their sensitivity to antimicrobial agents. They are sensitive *in vitro* to ketoconazole, pentamidine, hydroxystilbamidine, paromomycin, 5-fluorocytosine, polymyxin, sulfadiazine, trimethoprim-sulfamethoxazole, azithromycin, and extracts of medicinal plants and, especially, to combinations of these drugs (1, 9). Increased awareness of these infections and early therapy play a large role in patient outcomes. Although steroids have been used in the past to treat cerebral edema and inflammation in CNS infections, this approach should not be used since the steroids tend to exacerbate the *Acanthamoeba* infection. Encephalitis has been treated, somewhat successfully, with antimicrobial combinations including sterol-targeting azoles (clotrimazole, miconazole, ketoconazole, fluconazole, and itraconazole), pentamidine isethionate, 5-fluorocytosine, and sulfadiazine. The use of drug combinations helps address resistance that may exist or occur during treatment. *In vitro* testing confirms strain and species differences in sensitivity, so that no single drug is effective against all amebae (29).

Amebic Keratitis. Because the infection may be misdiagnosed and/or therapy may be delayed, total blindness may result in the infected eye(s). However, if the infection is correctly diagnosed early and the epithelium alone is involved, debridement may be sufficient for cure. This approach not only removes organisms but also enhances the delivery of topical medications. However, if treatment is delayed and the organisms invade the cornea or tissues below the cornea, therapy may need to be continued for many months to a year or longer. These patients must be monitored continually because the cysts tend to be quite resistant to therapy; treatment failures tend to be fairly common. *In vitro* susceptibility testing may be very helpful in these cases (18, 29).

A topical biguanide, 0.02% chlorhexidine or polyhexamethylene biguanide (PHMB, 0.02%), either alone or combined with a diamidine, propamidine isethionate (Brolene) or hexamidine (Desomodine), has been used successfully. They are administered hourly (or alternating every half hour) day and night for the first 48 hours and then continued on a reduced schedule for days to months (30). None of these drugs is commercially available or approved for use in the United States, but they can be obtained from compounding pharmacies. Leiter's Park Avenue Pharmacy (San Jose, CA; 800-292-6773; www.leiterrx.com) is a compounding pharmacy that specializes in ophthalmic drugs. Expert Compounding Pharmacy (6744 Balboa Blvd., Lake Balboa, CA 91406; 800-247-9767) and Medical Center Pharmacy (New Haven, CT; 203-688-7064) are also compounding pharmacies. Other compounding pharmacies may be found through the National Association of Compounding Pharmacies (800-687-7850) or the Professional Compounding Centers of America (800-331-2498, www.pccarx.com). Propamidine is available over the counter in the United Kingdom and Australia. Hexamidine is available in France. Debridement is most useful during the stage of corneal epithelial infection; keratoplasty in medically unresponsive keratitis was successful in 31 eyes in 30 patients (18).

Cutaneous Disease. Cutaneous infections with subsequent dissemination to other body sites have been found in patients who are immunocompromised due to HIV infection or preparation for organ transplantation. As with other disease manifestations, a number of drug combinations have been tried, some of which were successful. However, not all combinations are effective; toxicity with certain drugs also becomes a consideration (Table 24.7).

In a case of skin ulcers due to *Acanthamoeba* in an immunodeficient individual who had undergone kidney transplantation, the patient was successfully treated after extended therapy over a period of 8 months. He received topical as well as systemic administration of combination therapy. The skin ulcers were cleaned twice daily with chlorhexidine gluconate solution, and 2% ketoconazole cream was applied topically. He also received pentamidine isethionate intravenously for 1 month and was then given oral itraconazole therapy for 8 months. This resulted in complete healing of the ulcers (6).

Successful treatment of *Acanthamoeba* infections has been limited; specific examples of patients, disease manifestations, treatment, and outcomes are seen in Table 24.7.

Epidemiology and Prevention

General Preventive Measures. General preventive measures are similar to those for *N. fowleri*. Several disinfectants have been tested against both *Naegleria* and *Acanthamoeba* spp. The conclusion is that *Naegleria* spp. are generally susceptible to swimming-pool levels of chlorine but *Acanthamoeba* spp. are more resistant (6). The recovery of *Acanthamoeba* spp. in nasal isolates and pharyngeal swabs may indicate human introduction of the organisms into swimming pools. With the increasing reports of infection in wearers of soft contact lenses, it will be important to carefully consider the effectiveness of various contact lens disinfection systems. A number of factors probably play a role in the increased incidence of infection: a large number of HIV-infected individuals and more patients undergoing cancer chemotherapy or immunosuppressive therapy for organ transplantation.

Mitochondrial DNA fingerprinting of *Acanthamoeba* spp. from the American Type Culture Collection and environmental sources has confirmed that approximately half of the 35 isolates displayed fingerprints similar to those of clinical isolates. Comparisons with other published mitochondrial DNA fingerprints indicated that two groups have counterparts in Europe and Japan and in Europe and Australia. These data provide strong evidence that the most common clinical isolates do have counterparts that are geographically widespread and can be isolated from the environment.

Acanthamoeba cysts can remain viable in water at 4°C for 24 years and have survived desiccation for 20 years (31). In animal studies, it has been shown that some of the isolates completely lost their virulence only after 8 years of *in vitro* cultivation. On the basis of these results, one can assume that cyst viability may be as long as 25 years and that these cysts can maintain their invasive properties (6, 8).

Contact Lens Care. In one recent study of marketed contact lens disinfection solutions against keratitis-causing *Acanthamoeba castellanii*, none of the contact lens disinfection solutions exhibited cysticidal effects using qualitative assays; i.e., cysts treated with these solutions reemerged as viable amebae upon inoculation in the growth medium.

TABLE 24.7 *Acanthamoeba* infections, treatment, and positive patient outcomes[a]

Immunocompetent or underlying disease	Amebic disease involvement	Treatment[b]	Outcome
Immunocompetent	CNS (2 patients)	TMP/SMZ + KC + rifampin	Survived
AIDS	Cutaneous/sinusitis	Ketoconazole + i.v. FC	Resolution of lesions; no CNS involvement
AIDS	Cutaneous/sinusitis	Debridement of sinuses + pentam + topical chlorhexidine + 2% KC; pentam toxicity, maintenance on FC	Survived
AIDS	CNS lesion	Sulfadiazine + pyrimethamine, flucon + sulfadiazine; one localized brain lesion excised	Survived
AIDS	Rhinosinusitis	Removal of all diseased nasal mucosa; pentam, levofloxacin, FC, AmpB	Survived
HIV positive	Sinusitis	Debridement of sinuses, IT + gentamicin nasal wash	Resolution of lesions
HIV positive	Sinusitis/cutaneous, lobular panniculitis	Surgical debridement + IT, azithromycin, 5FC, rifampin	Survived
Renal transplant	Cutaneous lesions, IgA deficiency	Pentamidine + chlorhexidine + 2% KC cream; maintenance on oral IT	Resolution of lesions; no CNS involvement
Lung transplant	Cutaneous	AmpB + i.v. pentam + IT + chlorhex/KC cream + azithro + FC + pentam, maintenance FX + clarithromycin	Survived, but died 6 months after *Acanthamoeba* diagnosis

[a] Based on references 6–9, 18, 29, 30.

[b] FC, fluorocytosine; IT, itraconazole; azithro, azithromycin; AmpB, amphotericin B; KC, ketoconazole; TMP/SMZ, trimethoprim-sulfamethoxazole; pentam, pentamidine; flucon, fluconazole; chlorhex, chlorhexidine; i.v., intravenous.

These data indicate possible serious sequelae for contact lens users (32).

Both failure to disinfect daily-wear soft contact lenses and the use of chlorine-release lens disinfection systems, which have little effect against the organism, are major risk factors for *Acanthamoeba* keratitis. These risks have been very common in disposable-lens use. Some investigators think that over 80% of cases of *Acanthamoeba* keratitis could be avoided by the use of lens disinfection systems that are effective against the organism.

Current recommendations for contact lens wearers include (i) regular scrubbing of contact lens case interiors to disrupt biofilms, (ii) exposure of the contact lens case to very hot water (at least 70°C) to kill *Acanthamoeba* contaminants, (iii) allowing the contact lens case to air dry between uses, (iv) use of a two-step system if hydrogen peroxide disinfection is preferred, and (v) regular replacement of the contact lens case. It has also been documented that some bottled waters contain large numbers of potential ocular pathogens and that, as a general recommendation, bottled water is not safe for routine use with contact lenses.

Pathogenic Bacteria Carriage within Free-Living Amebae. There have been a number of studies reviewing the potential for carriage of pathogenic bacteria within free-living amebae. In one study in Germany, *Legionella*-contaminated hot water systems and moist sanitary areas in six hospitals were sampled for amebae. Amebae were detected in 29 of 56 hot-water samples and 23 of 49 swabs; six *Acanthamoeba* species isolated from the moist areas were considered potential pathogens (11). It has also been shown that *Acanthamoeba* species can produce vesicles containing live *Legionella pneumophila* cells. Such vesicles may be agents for the transmission of legionellosis associated with cooling towers, and the risk may be underestimated by plate count methods since each vesicle could contain several hundred bacteria. Data also demonstrate that obligate anaerobic bacteria can survive and multiply in *Acanthamoeba* spp. under aerobic conditions, thus suggesting a previously undescribed mechanism for the spread, replication, and persistence of obligate anaerobes in the environment (11). *E. coli* O157 also survives and replicates within *A. polyphaga*. These amebae may serve as an important environmental reservoir for transmission of *E. coli* O157 and other pathogens (11).

The incidence of lung and other diseases due to nontuberculous mycobacteria (NTM) is increasing. NTM sources include potable water, especially in households where NTM populate pipes, taps, and showerheads. NTM share habitats with free-living amebae and can grow in these amebae as parasites or as endosymbionts. Free-living amebae containing NTM may form cysts that protect mycobacteria from disinfectants and antibiotics (33).

Balamuthia mandrillaris

The free-living ameba *Balamuthia mandrillaris* is relatively uncommon and was originally thought to be another harmless soil organism, unlikely or unable to infect mammals. However, since *B. mandrillaris* was first discovered in 1986 in a pregnant mandrill at the San Diego Wild Animal Park that died of meningoencephalitis, a number of primates including gorillas, gibbons, baboons, orangutans, and monkeys, as well as a sheep and a horse, have died of CNS infection caused by this organism. Over 200 cases of human amebic encephalitis worldwide have been identified, with >30 being seen within the United States (3, 34). Death can occur from 1 week to several months after the onset of stroke-like symptoms, which can mimic other conditions including brain stem glioma. Patients eventually die of a massive CNS infection. One individual who survived the infection was left with severe neurologic deficits.

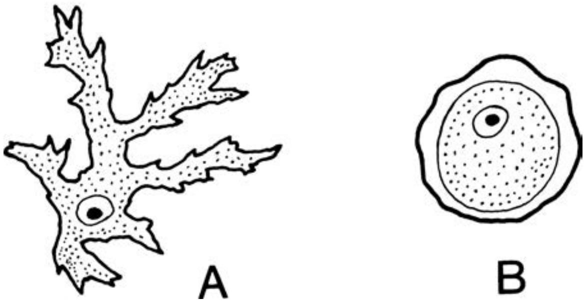
Balamuthia spp. produce virulence factors that enhance binding to and penetrating the blood brain barrier. These organisms can cause cell death by direct phagocytosis as well as through various toxins and proteases capable of destroying the extracellular matrices. Human-to-human transmission has been documented through solid organ transplantation in 2009 and 2010 (34).

Life Cycle and Morphology

The life cycle of *B. mandrillaris* has two stages, cysts and trophozoites. The trophozoites can gain entry to the body through the respiratory tract or through a skin defect. Trophozoites are capable of hematogenously disseminating to the CNS. This pathogen is capable of producing GAE which is a very rare cause of fulminant life-threatening meningoencephalitis.The life cycle is similar to that seen with *Acanthamoeba* spp.; like *Acanthamoeba* spp., *Balamuthia* does not have a flagellated stage in its life cycle as do organisms classified as *N. fowleri* (Fig. 24.20). Unlike *Acanthamoeba*, which is widely distributed in the environment and can be isolated from soil, water, and even air, *B. mandrillaris* is more difficult to isolate and to culture, with a generation time ranging from 20 to 50 h (35).

Morphology of Trophozoites. Trophozoites of *B. mandrillaris* are usually irregular in shape, and actively feeding amebae may measure from 12 to 60 µm in length (normal, 30 µm) (Fig. 24.21). As a eukaryotic cell, *B. mandrillaris* possesses a nucleus but may possess more than one nucleolus. In tissue culture, broad pseudopodia are usually seen; however, as the monolayer cells are destroyed, the trophozoites develop fingerlike pseudopodia.

Figure 24.20 (A) Trophozoite and (B) cyst of *Balamuthia mandrillaris*. (Illustration by Sharon Belkin.)
doi:10.1128/9781555819002.ch24.f20



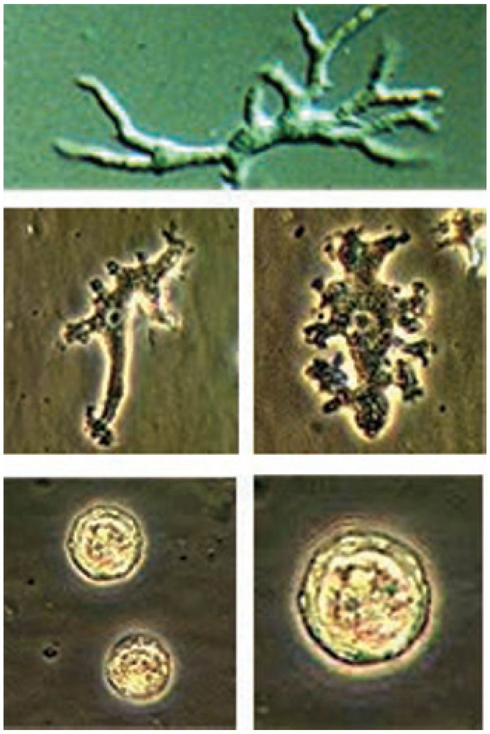


Figure 24.21 *Balamuthia mandrillaris*. (Top and middle) Trophozoites; note the finger-like pseudopodia. (Bottom) Cysts. (Courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch24.f21

Morphology of Cysts. Cysts are somewhat smaller than the trophozoites, are usually spherical, and measure from 13 to 30 µm in diameter (Fig. 24.20). Under electron microscopy, the cysts are characterized by having three layers in the cyst wall: an outer wrinkled ectocyst, a middle structureless mesocyst, and an inner thin endocyst. Under light microscopy, they appear to have two walls, an outer irregular wall and an inner round wall.

Clinical Disease

The disease is very similar to GAE caused by *Acanthamoeba* spp. and has an unknown incubation period. The clinical course tends to be subacute or chronic and is usually not associated with swimming in freshwater. No characteristic clinical symptoms, laboratory findings, or radiologic indicators have been found to be diagnostic for GAE. The neuroimaging findings show heterogeneous, hyperdense, nonenhancing, space-occupying lesions.

Whether single or multiple, they involve mainly the cerebral cortex and subcortical white matter. These findings suggest a CNS neoplasm, tuberculoma, or septic infarcts. Patients complain of headaches, nausea, vomiting, fever, visual disturbances, dysphagias, seizures, and hemiparesis. There may also be a wide range in terms of the clinical course, from a few days to several months. If the route of entry is through broken skin, painless nodules may be observed, developing into lesions containing trophozoites while the patient is alive.

Unlike *Acanthamoeba* encephalitis, *Balamuthia* amebic encephalitis has been found in immunocompetent individuals (individuals who were negative for syphilis, diabetes mellitus, malignancies, and fungal, HIV type 1, HIV type 2, and mycobacterial infections and had normal CD4- and CD8-positive T-lymphocyte counts and B-lymphocyte counts). These findings confirm the virulent nature of this pathogen. In immunocompetent hosts, an inflammatory response is mounted and amebae are surrounded by macrophages, lymphocytes, and neutrophils. However, with rare exceptions, these patients also tend to die of severe CNS disease.

Both trophozoites and cysts of *B. mandrillaris* are found in many of the same CNS tissues as are *Acanthamoeba* spp. Although differentiation of these two organisms in tissue by light microscopy is difficult, *B. mandrillaris* may have more than one nucleolus in the nucleus in some tissue sections (1) (Fig. 24.22). Generally, electron microscopy and histochemical methods are required for definitive identification of *B. mandrillaris*. PCR or an immunofluorescence test using species-specific sera is the most reliable means of distinguishing between *Acanthamoeba* and *Balamuthia* spp.

Magnetic resonance imaging and computerized tomography are useful and will exhibit brain lesions, which are found in the parietal lobe, anterior lobe, temporal lobe, and cerebellum. Lesions have been described as calcified and as forming a mass-like structure. Biopsy may reveal a necrotic cortex and the faint outline of perivascular monocytes. Giemsa stain shows both trophozoites and cysts and may be used to stain wet mounts, while calcofluor white preferentially stains cysts (has a binding affinity for cellulose, chitin, and potentially other glycans), which may aid in identification. However, without an early diagnosis and high index of suspicion, prognosis remains poor, with a case-fatality rate of >98%.

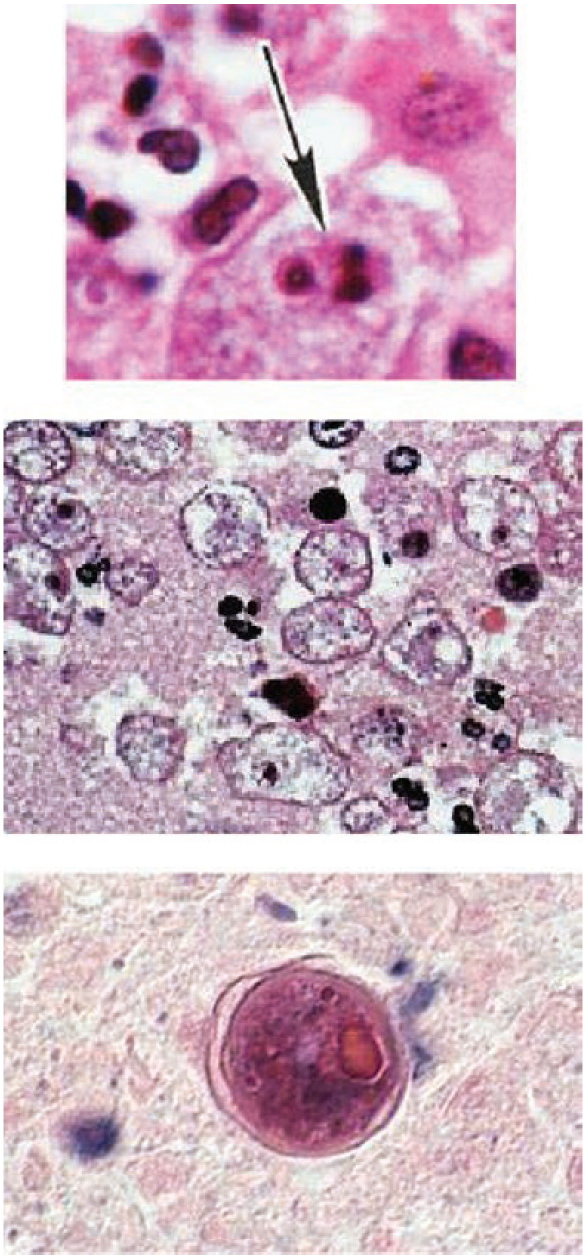

Figure 24.22 *Balamuthia mandrillaris*. (Top and middle) Trophozoites in brain. (Bottom) Cyst in brain (hematoxylin and eosin). (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch24.f22

Diagnosis

It is interesting that attempts to isolate the organisms from some humans with GAE have not been successful, and *B. mandrillaris* has also been shown not to grow well on *E. coli*-seeded nonnutrient agar plates. In the diagnostic laboratory, these organisms can be cultured in mammalian cell cultures; some success has been obtained with monkey kidney cells and with MRC, HEp-2, and diploid macrophage cell lines. Using human brain microvascular endothelial cells, investigators have cultured *B. mandrillaris* postmortem from brain and CSF from a case of granulomatous amebic meningoencephalitis (36). A cell-free growth medium is also now available (1). The trophozoites are characterized by extensive branching and a single nucleus (occasionally binucleate forms are seen) with a central karyosome. Occasionally, a few elongated forms with several contractile vacuoles are seen. The cysts have a single nucleus (occasionally, binucleate forms are seen) and have the typical double wall, with the outer wall being thick and irregular. The identity of *B. mandrillaris* can be confirmed using immunofluorescence staining assays and PCR methods.

Serum antibodies to *B. mandrillaris* have been found in both adults and children; however, testing is not currently available for routine use. Although the mouse model is rarely used and is somewhat impractical, mice infected with *Acanthamoeba* spp. or *B. mandrillaris* may die of acute disease within 5 to 7 days or chronic disease after several weeks. In either case, amebae can be seen in the mouse brain after culture or histologic examination.

Based on sequence analysis of mitochondrial small-subunit rRNA genes, primers have been developed that amplify a *Balamuthia*-specific PCR product. These primers will be useful not only for retrospective analyses of preserved tissues but also for possible organism identification *in vivo* (2). Genotyping studies indicate that lethal infections caused by *B. mandrillaris* are due to a single species with a global distribution. Apparently, there is no correlation between a particular mitochondrial sequence and the genus of the infected vertebrate. The mitochondrial sequence from the mandrill isolate is identical to that obtained from a human (6).

Treatment

In vitro studies indicate that *B. mandrillaris* is susceptible to pentamidine isethiocyanate and that patients with this infection may benefit from this treatment in combination with other drugs. However, pentamidine is associated with adverse effects including nephrotoxicity, leukopenia, elevated liver enzymes, and hypoglycemia. Also, pentamidine does not cross the normal, intact blood-brain barrier well (18). Other studies indicate that sulfadiazine, azithromycin, clarithromycin, flucytosine, and miltefosine have amebicidal activity (18). In one immunocompetent patient who survived, treatment included combination antibiotics (pentamidine, 300 mg intravenously once a day; sulfadiazine, 1.5 g four times a day; fluconazole, 400 mg once a day; and clarithromycin, 500 mg three times a day), with no neurologic sequelae seen (21). See chapter 36 for additional information.

Epidemiology and Prevention

Routes of CNS entry may include ameba penetration of the olfactory neuroepithelium via the nasal route. However, hematogenous dissemination from a primary lung (ameba entry via the respiratory tract) or skin (ameba entry through breaks in the skin followed by exposure to contaminated soil, e.g., working in gardens) entry is thought to be more common. Current recommendations are similar to those for *Acanthamoeba* spp. Although attempts to isolate *B. mandrillaris* from soil samples related to previous encephalitis cases were unsuccessful, there was always some question regarding the designation “free-living” amebae. However, following the death of a 3-year-old Northern California resident from amebic encephalitis caused by *Balamuthia*, environmental samples were collected around the child’s home and outdoor play areas. An ameba, consistent with *Balamuthia*, was isolated from the soil found in a potted plant in the home (3). Thus, the isolation of *Balamuthia* amebae from soil affirms its status as a free-living ameba; like *Acanthamoeba* and *Naegleria*, *Balamuthia* is also an opportunistic pathogen.

From the information presented above, it is clear that *B. mandrillaris*, formerly regarded as having no pathogenic potential, will continue to be identified as the etiologic agent of fatal meningoencephalitis in humans as well as animals (Fig. 24.20 to 24.22). This opportunistic infection may also continue to cause disease in individuals who are immunocompromised, as well as those who are immunocompetent.

Sappinia (*diploidea*) *pedata*

The genus *Sappinia* is a newly recognized human pathogen causing amebic encephalitis; there are two species, *S. diploidea* and *S. pedata*. An infection with *S. pedata* has been well documented in a single patient, who survived the infection, while it is not known if *S. diploidea* can cause human infections (37, 38). Trophozoites measure from 40 to 70 µm and have a distinctive double nucleus (Fig. 24.23). Transmission electron microscopy confirms that the trophozoites contain two nuclei attached to each other by connecting perpendicular filaments. The trophozoites ingested host blood cells and stained brightly with Giemsa and PAS stains. Cysts were not seen, but their presence in the human host was not excluded, and they have been seen in culture. These and other morphologic characteristics led to the diagnosis of *S. diploidea*, a demonstrated human pathogen, for the first time. However, based on molecular techniques (real-time PCR assays based on 18S rRNA gene sequences), the organism was reidentified as *S. pedata*. The assay specific for *Sappinia* can be incorporated into the multiplex PCR assay described by

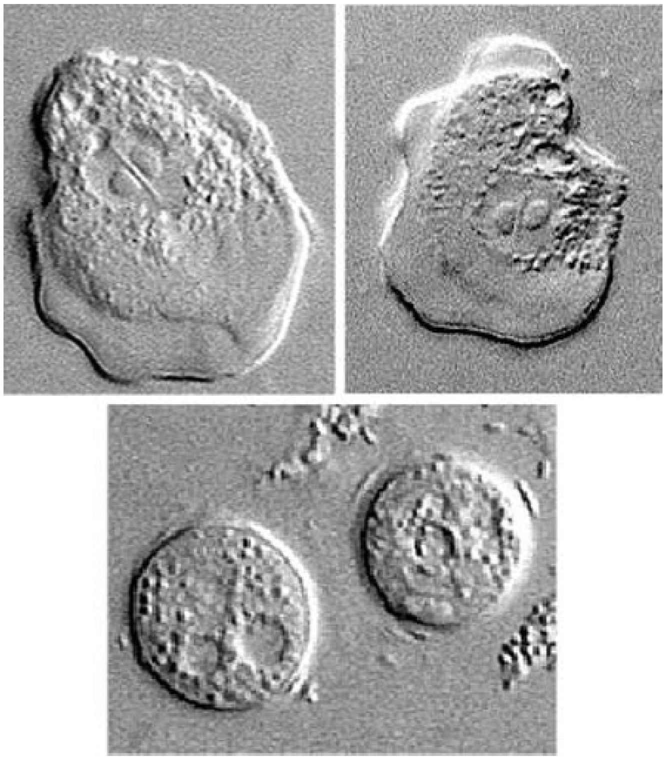

Figure 24.23 *Sappinia* sp. using differential interference contrast (DIC) microscopy. (Upper) Trophozoites; note the presence of two nuclei, connected to each other by connecting filaments. (Lower) Cysts. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch24.f23

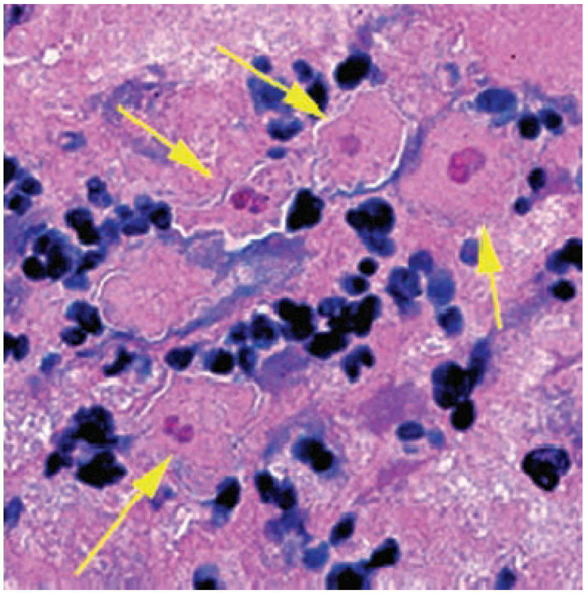

Figure 24.24 *Sappinia pedata*. Four trophozoites (arrows) seen in brain tissue. Note the presence of two nuclei within some of the trophozoites where both are in the same plane of focus. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch24.f24

TABLE 24.8 Summary of information on the newly recognized pathogenic free-living ameba *Sappinia pedata*[a]

Characteristic	Comments
Patient	38-year-old man
Symptoms	Visual disturbances, headache, seizure
Brain scan	Solitary tumor-like mass in posterior left temporal lobe
Surgical excision	Necrotizing hemorrhagic inflammation
Histologic findings	Central necrotic and hemorrhagic inflammations; acute and chronic inflammatory cells without granulomas or eosinophils; trophozoites present in viable brain parenchyma on mass periphery without inflammatory response
Organisms present	Amebic trophozoites
Trophozoite characteristics	Large (40–70 μm), 2 nuclei per trophozoite
Stained trophozoites	Bright; Giemsa, periodic acid-Schiff stains
Cysts	Obtained in culture; not found in tissue
Therapy after surgery	Azithromycin, pentamidine, itraconazole, flucytosine

[a] Information from reference 37.

Qvarnstrom et al., which distinguishes *Acanthamoeba*, *B. mandrillaris*, and *N. fowleri* for simultaneous detection of the four genera of free-living amebae that cause infections in humans (39).

The patient was a 38-year-old man who complained of visual disturbances and headache; he also had a seizure. He had reported a sinus infection prior to the onset of symptoms. Brain scans revealed a solitary tumor-like mass in the posterior left temporal lobe. On biopsy, the mass demonstrated necrotizing hemorrhagic inflammation, which contained free-living amebae (Fig. 24.24). After surgical excision of the tumor-like mass, the patient was treated with a sequential regimen of antiamebic drugs, including azithromycin, pentamidine, itraconazole, and flucytosine. Characteristics of this case are summarized in Table 24.8.

Protozoa from Other Body Sites

Trichomonas vaginalis
Toxoplasma gondii

Trichomonas vaginalis

Trichomonas vaginalis was first isolated in 1836 from the purulent discharge from female genital organs. The infection occurs worldwide and has been found in the population whenever the appropriate specimens have been examined for the presence of the organism. It is estimated that 5 million women and 1 million men in the United States have trichomoniasis, with the annual incidence of new cases estimated at 7.4 million (1). The annual incidence of trichomoniasis worldwide is estimated to be more than 275 million cases, which does not include the number of asymptomatic cases that are not treated. In North America, more than 8 million new cases are reported yearly, with an estimated rate of asymptomatic cases being as high as 50% (1). Trichomoniasis is now the primary nonviral sexually transmitted infection (STI) worldwide. In women, disease manifestations may include vaginitis, cervicitis, urethritis, pelvic inflammatory disease, and adverse birth outcomes. *T. vaginalis* infection may also increase risk of HIV transmission, the incidence and severity of cervical and prostate cancer, and increased infertility. Some of the most recent developments in our understanding of *T. vaginalis* pathobiology include the increased association with HIV in terms of exposure to STIs and a positive association with aggressive prostate cancers (2).

Population genetic analysis has shown that *T. vaginalis* is a genetically diverse parasite that consists of two types present in equal proportions worldwide. Parasites belonging to the two types (type 1 and type 2) differ significantly in the rate at which they harbor the *T. vaginalis* virus, a double-stranded RNA virus implicated in parasite pathogenesis, and in their sensitivity to the widely used drug metronidazole (3). The extensive clinical variability and disease sequelae are matched by significant genetic diversity in the organism itself; this strongly suggests a connection between the genetic identity of isolates and their clinical manifestations (4).

T. vaginalis has the largest protozoan genome known, potentially encoding approximately 60,000 proteins. To what degree these genes are expressed is not well known, and only a few transcription factors and promoter domains have been identified.

Figure 25.1 Life cycle of *Trichomonas vaginalis*. doi:10.1128/9781555819002.ch25.f1

Life Cycle and Morphology

T. vaginalis exists as flagellate and ameboid trophozoites and the pseudocystic stages (5, 6) (Fig. 25.1). Pseudocyst forms of *T. vaginalis* isolated from cervical neoplasia patients demonstrated distinct, different, and significant *in vitro* growth profiles when grown in cultures from day 1 up to day 5 as compared with the same life cycle stages isolated from noncervical neoplasia but symptomatic patients. The exposure of oxygen-adapted parasites to human epithelial cells primarily induces cytoskeletal rearrangement and proliferation, with a rapid transition from spindle-shaped flagellates to tissue-feeding and actively dividing ameboids (6). As an extracellular parasite residing in the urogenital tract, *T. vaginalis* must adhere to epithelial cells as an initial step towards colonizing the host and establishing infection. The flagellate trophozoite is 7 to 23 µm long and 5 to 15 µm wide (Fig. 25.1; Table 25.1). The axostyle is usually extremely obvious, and the undulating membrane stops halfway down the side of the trophozoite (Fig. 25.2 and 25.3). The nuclear chromatin is uniformly distributed, and there are many siderophil granules that are particularly evident along the axostyle. The axostyle is thought to anchor the parasite to vaginal epithelial cells. The cytoskeleton is composed of tubulin and actin fibers.

There are five flagella, with the fifth being incorporated within the undulating membrane. Different conditions alter the shape of the trophozoites; in axenic culture the trophozoite tends to be more pear shaped and oval, but it may appear more ameboid when attached to vaginal epithelial cells. When environmental conditions are unfavorable, the organisms may tend to round up and internalize the flagella.

The life cycle has been described but is not totally defined. In growth-phase culture, large, round forms of the organism are seen, some without flagella, some with flagella and a dividing nucleus, and some with flagella and multiple nuclei. These forms are probably developmental stages that appear prior to the typical mononuclear flagellates that generally reproduce by longitudinal binary fission. The urogenital trichomonads vary in size and shape. Physicochemical conditions (e.g., pH, temperature, oxygen tension, and ionic strength) affect the shape of trichomo-

TABLE 25.1 Characteristics of *Trichomonas vaginalis* (primarily trophozoites)[a]

Shape and size: trophozoite	Pear shaped; 7–23 µm long (avg, 13 µm), 5–15 µm wide
Shape and size: pseudocyst	Round, no motility, apparently no true cyst wall
Shape and size: ameboid form	Various, pseudopod extension, flagella still visible
Motility	Jerky, rapid
No. of nuclei and visibility	1; not visible in unstained mounts
No. of flagella (usually difficult to see)	3–5 anterior, 1 posterior
Other features	Seen in urine, urethral discharges, and vaginal smears; undulating membrane extends half the length of the body; no free posterior flagellum; axostyle easily seen
Infective stage	Trophozoite
Usual location	Vagina (male, urethra)
Striking clinical findings	Leukorrhea, pruritus vulva (thin, white urethral discharge in male)
Other sites of infection	Urethra (prostate in male)
Stage usually recovered during clinical phase	Trophozoite only (no cyst)

[a] Adapted from references 1, 5, and 7.

Figure 25.2 *Trichomonas vaginalis* trophozoite. (Illustration by Sharon Belkin.) doi:10.1128/9781555819002.ch25.f2

doi:10.1128/9781555819002.ch25.f3

nads; however, shape tends to be more uniform among cells grown in nonliving culture media than among those observed in vaginal secretions and urine (7) (Fig. 25.4).

Glucose Metabolism. *T. vaginalis* is a primitive eukaryotic organism; however, its metabolism is similar to that of primitive anaerobic bacteria (8). Carbohydrate metabolism is described as being fermentative under both anaerobic and aerobic conditions because glucose is incompletely oxidized. Carbohydrate metabolism occurs in the cytoplasm and an organelle called the hydrogenosome, which is similar to the mitochondria of higher eukaryotes. Within the cytoplasm, glucose is converted to phosphoenolpyruvate and subsequently to pyruvate via the typical Embden-Meyerhof-Parnas pathway. Pyruvate, which is generated through glycolysis, undergoes further metabolism in the hydrogenosome. The pyruvate:ferredoxin oxidoreductase has retained diversity in the usage of alternative keto acids for energy production by using a wide variety of substrates. Also, *T. vaginalis* has alternative enzymes that are active in metronidazole-resistant parasites; these alternative pathways are clearly important for the survival of the organism (8). Although *T. vaginalis* is not very energy efficient, it can adapt its metabolism to variable carbon sources. The organism has a high maintenance energy, expending up to half its carbon flow on maintaining internal homeostasis. This ability is critical since the vaginal environment is constantly changing in terms of pH, hormones, menses, and the nutrient supply (8).

Surface carbohydrates have also been implicated in the adhesion of *T. vaginalis* to epithelial cells. The most abundant surface glycoconjugate from the parasite has been described as a lipophosphoglycan, which has also revealed a role in immune interaction. However, extensive studies have demonstrated that *T. vaginalis* lipophosphoglycan-like material does not contain significant amounts of phosphate in the glycan core and should probably be renamed *T. vaginalis* lipoglycan (9).

Lipid Metabolism. *T. vaginalis* contains cholesterol, phosphatidylethanolamine, phosphatidylcholine, and sphingomyelin as its major phospholipids; apparently the organism is unable to synthesize fatty acids and sterols and must rely on exogenous sources of lipid moieties to survive. It has been postulated that *de novo* glycolipid and glycophosphosphingolipid synthesis occurs in trichomonads.

Amino Acid Metabolism. Although carbohydrates are the preferred source of nutrients, amino acids can sustain survival and growth. Under normal culture conditions, *T. vaginalis* consumes large amounts of arginine and smaller amounts of methionine for energy production. There appears to be some form of equilibrium that is maintained between the free amino acids within the cell and its external environment.

Nucleotide Metabolism. The organism is unable to synthesize purines and pyrimidines; adenine and guanine or their nucleosides are required for growth, as are thymidine, cytidine, uracil, and/or uridine (8). It also appears that there may be two nucleoside carriers, a characteristic that has also been found in *Leishmania donovani*.

Humans are the only natural host for *T. vaginalis*, and normal body sites for these organisms include the vagina and prostate. Apparently, the organisms feed on the mucosal surface of the vagina, where bacteria and leukocytes are found (1). The preferred pH for good growth in females is slightly alkaline or acidic (pH 6.0 to 6.3 optimal), not the normal pH of the healthy vagina. Although the organisms can be recovered in urine, in urethral discharge, or after prostatic massage, the pH preference of the organisms in the male has not been determined. Often, the organisms are recovered in the centrifuged urine sediment from both male and female patients.

doi:10.1128/9781555819002.ch25.f4

Clinical Disease

T. vaginalis is site specific and usually cannot survive outside the urogenital system. Although the incubation period is not well defined, *in vitro* studies provide a range of 4 to 28 days. After introduction, proliferation begins, with resulting inflammation and large numbers of trophozoites in the tissues and the secretions. As the infection becomes more chronic, the purulent discharge diminishes, with a decrease in the number of organisms. The onset of symptoms such as vaginal or vulval pruritus and discharge is often sudden and occurs during or after menstruation as a result of the increased vaginal acidity. In acute infections, diffuse vulvitis is seen and is due to copious leukorrhea. The discharge is frothy, yellow or green, and mucopurulent; however, only about 10 to 12% of women exhibit this frothy discharge. Small punctate hemorrhagic spots can be seen on the vaginal and cervical mucosa; this has been called a “strawberry appearance” and is seen in about 2% of patients. In general, symptoms include vaginal discharge (42%), odor (50%), and edema or erythema (22 to 37%) (1). Other complaints include dysuria and lower abdominal pain. Vaginal trichomoniasis may be associated with bacterial vaginosis, candidiasis, gonorrhea, and syphilis. Concurrent infections with herpes simplex virus and human papillomavirus are also seen.

In chronic infections, symptoms may be very mild with pruritus and some pain during sexual intercourse, while the vaginal secretion may be scanty and mixed with mucus. Individuals with these symptoms are the major source of transmission. From 25 to 50% of infected women may be asymptomatic and have a normal vaginal pH of 3.8 to 4.2 and normal vaginal flora. Although there is a carrier form, about 50% of these women will develop clinical symptoms during the following 6 months.

Although vaginitis is the most common finding in women with trichomoniasis, other complications include pyosalpinx (distention of a fallopian tube with pus), endometritis, infertility, low birth weight, and cervical erosion. There is also an association with increased HIV transmission and cervical dysplasia (1, 10). In a study of Malawian men, there was no difference in the rate of HIV seropositivity in men with and without *T. vaginalis* infection. However, for HIV-positive men with symptomatic urethritis, the median HIV RNA concentration in seminal plasma was significantly higher in patients with trichomoniasis than in those without trichomoniasis (1).

About 20% of women with vaginal trichomoniasis have dysuria, a symptom that may occur before any additional symptoms appear. Infection in the male may be latent, with essentially no symptoms, or may be present as self-limited, persistent, or recurring urethritis. *T. vaginalis* has been detected in 10 to 20% of subjects with nonspecific urethritis and in 20 to 30% of those whose sexual partners had vaginitis. Once established, the infection persists for a long time in females but only for a short time (usually about 10 days or less) in males.

The prevalence of *T. vaginalis* in males has not been studied as extensively as in females. Estimates vary from 4 to 20% of men with urethritis to 20 to 40% of male sexual partners of infected females. *T. vaginalis* is the cause of 11% of all cases of nongonococcal urethritis in males (8).

Respiratory distress was found in a full-term, normal male infant with *T. vaginalis* who had severe respiratory difficulties after delivery. A wet preparation of thick, white sputum showed few leukocytes and motile flagellates, which were identified as *T. vaginalis*. This study supports previous data indicating that this organism may cause neonatal pneumonia (1, 8, 11).

Factors that influence the inflammatory response are not clearly defined but may include hormonal levels, coexisting vaginal flora, and the strain and concentration of the organisms present. Lymphocytes from patients with active trichomoniasis show a proliferative response when incubated in the presence of secretory and cellular products of *T. vaginalis*. This finding indicates that delayed hypersensitivity reactions may act to modify inflammatory responses.

Several mechanisms are used by *T. vaginalis* to maintain the infection in the female urogenital tract. Recognition and binding to vaginal epithelial cells by adhesins that resemble metabolic enzymes are the first step (Table 25.2). Immune responses are evaded by masking the organisms with host proteins, shedding of trichomonad proteins into the secretions, and degradation of all immunoglobulin subclasses and complement (8). Parasites undergo phenotypic variation between surface and cytoplasmic expression of a number of immunogenic proteins against which host antibody is directed. Phenotypic variation occurs in response to iron-regulated proteins, virus-induced and repressed proteins, erythrocyte binding proteins and hemolysins, proteinases, and adhesins and contributes to the organism's overall antigenic diversity and complexity (12). Subpopulations of

TABLE 25.2 Virulence factors associated with *Trichomonas vaginalis* pathogenesis[a]

Capability	Virulence factor(s)
Nutrient acquisition and adherence	Receptors for nutrient acquisition Adhesin that is time, temperature, pH dependent Adhesin proteins, which are receptors to host extracellular matrix proteins Carbohydrates, which provide basis for ligand-receptor binding Presence of cysteine proteinases required Microfilaments concentrated on side of parasite that attaches Laminin may be target for adhesion
Cysteine proteinases	Enzymes that are lytic factors in hemolysis of erythrocytes Required for adherence to epithelial cells
Contact-independent mechanisms	Cell detaching factor (CDF) causes cytopathic effects in cell culture (not seen in nonpathogen *Pentatrichomonas hominis*) CDF levels correlate with severity of clinical disease
Damage of target cell plasma membrane	Pores created in erythrocyte membranes
Interaction with vaginal flora	Normal vaginal pH 4.5; *T. vaginalis* thrives in less acidic pH (pH > 5) Rise in pH produces concomitant reduction or loss of protective lactobacilli
Immune system evasion	Surface coating with host proteins Shedding of immunogens Cysteine proteinase degradation of IgG and IgA and complement Epitope phenotypic variation Continuous secretion of large amounts of highly immunogenic soluble antigens short-circuits antibody response
Regulation of virulence genes	General nutrient limitations Environmental factors (iron) Parasite factors (double-stranded RNA virus)

[a] Adapted from references 1, 2, and 12.

trichomonads express high- or low-iron-regulated proteins depending on the iron status of microenvironments within the vagina. Thus, the expression of virulence genes is controlled by both parasite and host environmental factors. Populations of *T. vaginalis* from fresh clinical isolates probably comprise a heterogeneous population, thus guaranteeing that some organisms will be able to infect the host. Based on current knowledge, it appears that interference with trichomonad mucin receptors and proteinases may be a strategy to prevent colonization with this parasite.

Diagnosis

Unfortunately, clinical manifestations are not reliable criteria for the diagnosis of trichomoniasis; demonstration of the parasite is required for accurate diagnosis of infection. It was demonstrated in the early 1980s that if the classic features such as "strawberry cervix" and frothy discharge were used alone in the diagnosis of trichomoniasis, 88% of infected women would not be diagnosed and 29% of uninfected women would be incorrectly diagnosed as having trichomoniasis (8).

Wet Mounts. The identification of *T. vaginalis* is usually based on the examination of wet preparations of vaginal and urethral discharges and prostatic secretions. This examination must be performed within 10 to 20 min of sample collection, or the organisms lose motility and may be very difficult to see. Several specimens may have to be examined to detect the organisms, and the sensitivity of this technique may vary between 40% and >80%. The specimen should be diluted with a drop of saline and examined under low power with reduced illumination for the presence of actively moving organisms; urine sediment can be examined in the same way. As the jerky motility of the trophozoite diminishes, it may be possible to see the movement of the undulating membrane, particularly under high dry power. Specimens should never be refrigerated (Fig. 25.5).

Since the morphology of nonpathogenic *Pentatrichomonas hominis* from stool samples is very similar to that of pathogenic *T. vaginalis*, it is important to ensure that the specimen is not contaminated with fecal material.

Stained Smears. Diagnostic tests other than wet preparations, such as permanent stains and fluorescent stains, can also be used. Organisms may be difficult to recognize in permanent stains; however, if a dry smear is submitted to the laboratory, Giemsa or Papanicolaou stain can be used (Fig. 25.6 and 25.7). Chronic *Trichomonas* infections may cause atypical cellular changes that can be misinterpreted, particularly on the Papanicolaou smear. The organisms are routinely missed on Gram stains (Fig. 25.6). Unfortunately, *T. vaginalis* does not always appear in its typical pear-shaped form but instead may resemble polymorphonuclear leukocytes. The number of false-positive and false-negative results reported on the basis of stained smears strongly suggests that the results should be confirmed by observation of motile organisms either from the direct wet mount or from appropriate culture media (1).

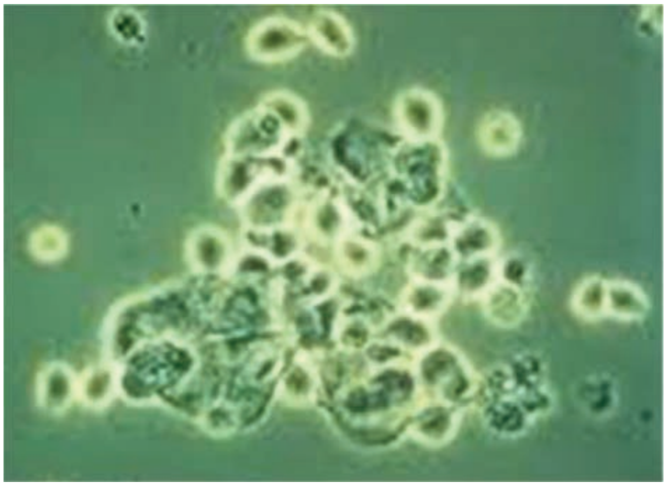

Figure 25.5 *Trichomonas vaginalis* wet mount (courtesy of the CDC Public Health Image Library).
doi:10.1128/9781555819002.ch25.f5

Culture. If culture techniques are used, it is mandatory that the specimen be collected correctly, immediately inoculated into the proper medium, and properly incubated. If these requirements are not met, the findings may represent a false-negative result. Although culture is more sensitive than wet mounts, this approach is not routinely used because of cost and inconvenience. To improve these parameters, a more convenient plastic envelope method is being widely used (13) (Fig. 25.8). This envelope approach allows both immediate examination and culture in one self-contained system. The system is commercially available as the InPouch TV (BIOMED Diagnostics, San Jose, CA), which serves as the specimen transport container, the growth chamber during incubation, and the "slide" during microscopy. Once it is inoculated, it requires no opening for examination, and positive growth occurs within 5 days. The sensitivity of this system is reported to be superior to that of other available culture methods (1, 8, 13). Also, no detectable differences were seen with the timing of the inoculation of the top or bottom pouch (13). This delayed-inoculation technique allows the initial reading of the wet mount and then inoculation of the culture pouch if the wet mount is negative. The InPouch TV test is the gold standard for clinical culture for *T. vaginalis* screening. The

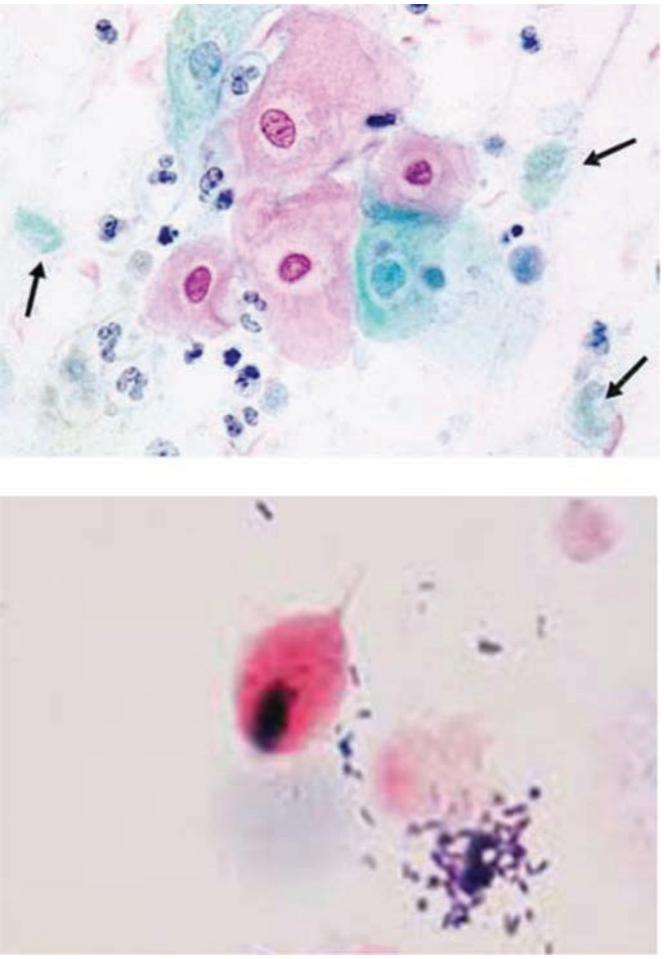

Figure 25.6 *Trichomonas vaginalis.* (Upper) Papanicolaou stain; (lower) Gram stain. doi:10.1128/9781555819002.ch25.f6

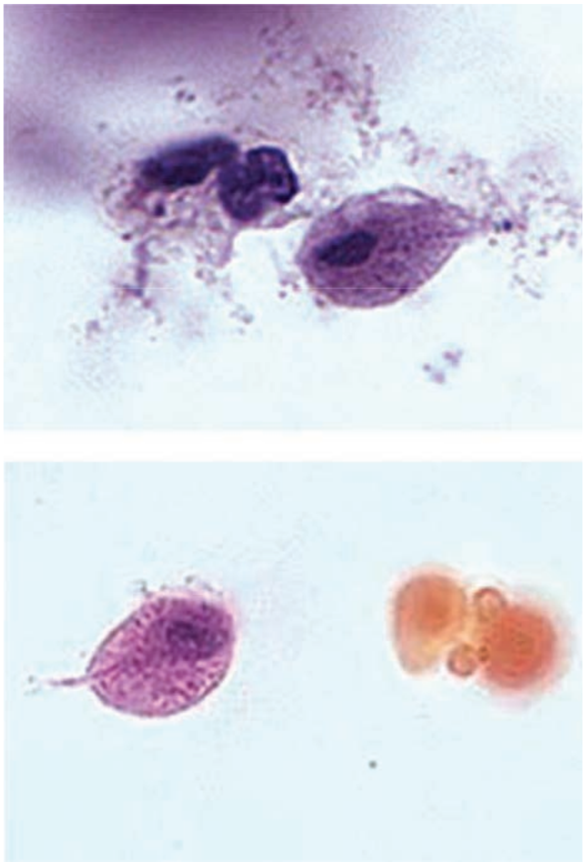

Figure 25.7 *Trichomonas vaginalis.* Giemsa stains of vaginal preparations (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch25.f7

current package insert recommends an examination period of 3 days. In a review of 2,499 InPouch tests spanning 13 years, the authors observed that examination up to 3 days will detect only 82.8% (95% confidence interval [CI], 79.0 to 86.2%) of positive specimens (14).

Various studies have been published regarding newer medium formulations and comparisons, including the use of modified Columbia agar (15). Although the results of this study were excellent, the specimens were processed at bedside, an approach that is often not practical for specimen collection. Cell culture methods use a variety of cell lines to recover *T. vaginalis* from clinical specimens, and they include McCoy cells. This approach has been reported to detect the organism at a concentration as low as 3 organisms/ml (8). However, this approach is not as practical as other available culture options and is rarely used in the routine clinical laboratory setting. Similarities in the results of these various diagnostic methods, particularly culture methods, have to be reviewed within the context of delivery systems and compliance with the proper use of transport options.

Antigen Detection. Screening patients for the presence of *T. vaginalis* has been somewhat limited by the available tests, many of which tend to be insensitive or expensive or require delays before the result is reported. A rapid diagnostic test for *T. vaginalis* infection has been developed and has proven to be much more sensitive than the wet-mount examination (Table 25.3). When compared with culture (InPouch), the XenoStrip-Tv (Xenotope Diagnostics, Inc., San Antonio, TX) was 76.7% sensitive and 99.8% specific and 79.4% sensitive and 97.1% specific in two different studies (16). Rapid test performance did vary with the day of the culture-positive result, with a 71% decline in XenoStrip sensitivity for every additional day of delay until cultures were positive. This product is easy to

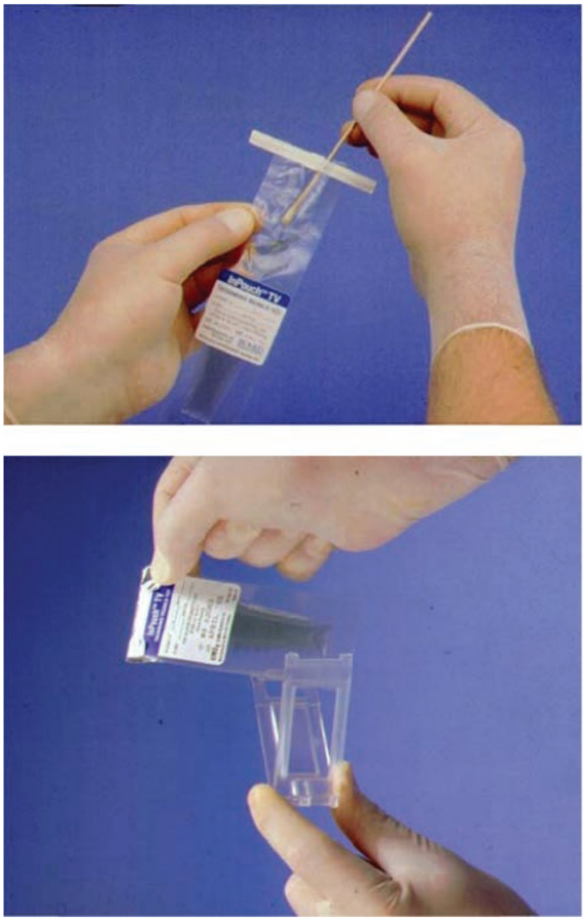

Figure 25.8 InPouch TV diagnostic system for culturing *Trichomonas vaginalis*. (Upper) The swab containing a specimen from the patient is being inserted into the liquid medium within the plastic pouch; (lower) the pouch is inserted into the plastic holder. (Photographs courtesy of BIOMED Diagnostics.) See also chapter 32. doi:10.1128/9781555819002.ch25.f8

use, is more sensitive than the wet mount, and should be considered as an alternative to the wet mount, particularly for point-of-care diagnosis when microscopy may be impractical (17).

Another rapid detection system for *T. vaginalis* uses an immunochromatographic capillary-flow (dipstick) assay, which provides results in 10 min. Compared with wet mount and culture, this system, OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, MA), showed 83.3% sensitivity and 98.8% specificity, while the wet mount has a sensitivity of 71.4% and a specificity of 100% (Fig. 25.9). This test also detected *T. vaginalis* in samples that required 48 to 72 h of incubation before becoming culture positive (18, 19). Compared to culture alone, OSOM was 83.5% sensitive and 99.0% specific.

Antibody Detection. Various techniques have been used to demonstrate antibodies against *T. vaginalis*; they include agglutination, complement fixation, indirect hemagglutination, gel diffusion, fluorescent-antibody assay, and enzyme-linked immunosorbent assay (ELISA). However, there are a number of reasons why this approach has not been used routinely. In some cases, an antibody response is not seen, due to test sensitivity or the timing of the test procedure. Also, antitrichomonal antibodies persist for long periods after therapy, and so current and past infections cannot be differentiated.

Molecular Testing. The use of PCR methods has led to improvements in *T. vaginalis* detection; nonviable organisms and target sequences can also be detected. In addition to various culture and transport options, there are currently several other products available, including the Affirm VPIII probe (Becton Dickinson, Cockeysville, MD), the Quik-Tri/Can latex agglutination test (PanBio Integrated Diagnostics, Baltimore, MD), and the T.VAG DFA (Light Diagnostics, Temecula, CA). The Affirm VP system uses synthetic oligonucleotide probes for the detection of both *Gardnerella vaginalis* and *T. vaginalis* from a single vaginal swab (8). A PCR-based ELISA with urine as the clinical specimen gave sensitivity and specificity data (compared with wet mount or culture) as 90.8% and 93.4%, respectively, in women and 92.7% and 88.6%, respectively, in men (21, 22). For clinical settings in which vaginal specimens are not available and culture is not an option, urine-based PCR-ELISA may be another option. In some settings, self-obtained vaginal swabs may be useful for PCR, and it appears that PCR may be more sensitive than culture for the diagnosis of *T. vaginalis* in males (1). Based on your patient population, client base, number of requests, and cost, these tests may be relevant for your laboratory test menu.

The results of the GenProbe Aptima *T. vaginalis* assay were compared with the Affirm VPIII *T. vaginalis* test. In the absence of an independent reference standard for trichomonal vaginitis, a positive result in either assay was deemed to represent true infection. The diagnostic accuracy of the combined NAA-based test construct was approximately 20 to 25% higher than that of the Affirm VPIII when modeled in populations with various prevalences of infectious vaginitis (22).

A battery of highly sensitive and specific PCR assays has been developed that detects *T. vaginalis* in urine. A protocol for differentiating among human *Trichomonas* species was also developed; these procedures could also be used for the validation of commercial nucleic acid amplification tests (23).

KEY POINTS—LABORATORY DIAGNOSIS

Trichomonas vaginalis

1. Wet-preparation (motile organisms) examination is recommended; the specimen should be examined immediately. If this is not possible, other methods should be considered.
2. Fluorescent stains and culture have also been recommended.
3. The newer rapid methods may not be as sensitive as culture or PCR, but organisms can be detected, often 48 to 72 h prior to cultures becoming positive for *T. vaginalis*.
4. If dry smears are submitted to the laboratory, they can be fixed with absolute methanol, allowed to dry, and stained like a thin blood smear (Giemsa stain).
5. Serologic tests are not routinely available.

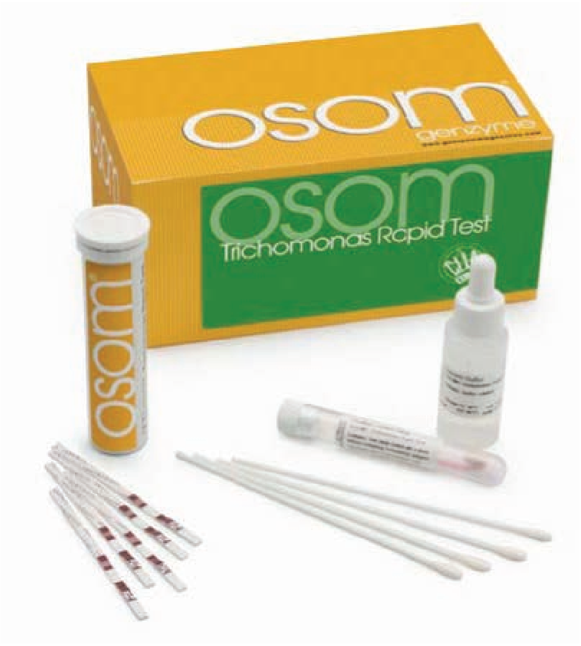

Figure 25.9 *Trichomonas vaginalis*. Direct antigen detection strip used for rapid testing (OSOM Trichomonas Rapid Test; courtesy of Genzyme Diagnostics, Cambridge, MA). doi:10.1128/9781555819002.ch25.f9

Treatment

Metronidazole is recommended for the treatment of urogenital trichomoniasis, although resistance to both metronidazole and other 5-nitroimidazoles has been reported (24). It is also recommended that all sexual partners of the patient be treated simultaneously to avoid immediate reinfection. Metronidazole-resistant *T. vaginalis* has been implicated in an increased number of cases; unfortunately, metronidazole is currently the only drug approved for the treatment of trichomoniasis in the United States (11). Although vaginal metronidazole creams and pessaries are available, their cure rate compared with oral drug administration is poor. Metronidazole can be taken as single or multiple doses, as well as administered intravenously. Additional information on therapy can be found in chapter 36.

One review reported that metronidazole reduced the risk of persistent infection in women with *T. vaginalis* infection but increased the incidence of preterm birth (25).

TABLE 25.3 Summary of commercially available kits for immunodetection of *Trichomonas vaginalis*

Diagnostic kit	Manufacturer and/or distributor[a]	Type of test	Sensitivity (%), specificity (%)	Comments
Affirm VPIII	Becton-Dickinson	DNA probe	93, 99	*Trichomonas vaginalis*, *Gardnerella vaginalis*, *Candida* spp.
Aptima *Trichomonas vaginalis* (ATV)	Hologic	Nucleic acid amplification test (NAAT)	94–100, 96–100	*Trichomonas vaginalis* (vaginal swab, endocervical swab, PreservCyt solution)
Quik-Trich	PanBio Integrated Diagnostics	Latex agglutination	95, 99	*Trichomonas vaginalis*
OSOM Trichomonas Rapid Test	Genzyme Diagnostics	Dipstick	83.3, 98.8	*Trichomonas vaginalis*; *T. vaginalis* detected in samples that required 48 to 72 h of incubation prior to becoming positive
Trichomonas vaginalis DFA[b] kit	Light Diagnostics—Chemicon	DFA[b]	97, 99	96.1% agreement with wet mount, but more positives found with DFA
XenoStrip-Tv	Xenotope Diagnostics	Dipstick	76.7, 99.8	*Trichomonas vaginalis*

[b] DFA, direct fluorescent antibody.

Neonatal infection depends on maternal estrogen levels, which wane after the 3rd to 6th week of life; after this time, the infection may disappear. However, if required, treatment of neonates should be postponed until the 6th to 8th week of age and then given if the infant is symptomatic (8).

Although the cure rate is excellent, treatment failure can be due to several factors including noncompliance and reinfection. Published case reports of *T. vaginalis* strains that are clinically resistant to metronidazole are increasing; in the late 1990s, it was estimated that approximately 5 to 10% of all patient isolates demonstrated some level of resistance to metronidazole (26). Resistance can be linked to progressive decrease and eventual loss of the pyruvate: ferredoxin oxidoreductase, so that the drug-activating process is averted. The development of resistance in *T. vaginalis* is also accompanied by decreased expression of ferredoxin (11). Refractory cases are defined as cases in which two standard courses of therapy fail to cure the patient, and these cases can be very difficult to treat. Refractory cases are treated with higher (often double) doses of metronidazole for an extended period; this is effective approximately 80% of the time. Treatment protocols are now available for marginal, low, moderate, and high levels of metronidazole resistance. Therefore, the need for metronidazole susceptibility testing has become more important for clinically relevant patient care. Different methods are used as pharmacological screening procedures for new drugs, including simple cell enumeration. However, this approach is highly subjective. Another approach, which involves determination of acid phosphatase activity as the screening procedure, has been recommended. Compared with microscopy procedures, there are some clear advantages to these newer colorimetric methods, including greater speed and efficiency and less subjectivity (27). Other metabolic routes of *T. vaginalis* have also been used to develop susceptibility testing methods for determining antitrichomonal activity (27).

Demographic data and *T. vaginalis* isolates were collected from women attending six STI clinics participating in the STD Surveillance Network (SSuN). SSuN is a sentinel site surveillance network which, through the implementation of common protocols for collecting, reporting, and analyzing enhanced surveillance data, aims to improve the capacity of national, state, and local STI programs to detect, monitor, and respond rapidly to trends in STIs. *T. vaginalis* specimens from women undergoing physical examinations were systematically collected, either consecutively or on selected days of the week, during 2009 and 2010. A low prevalence of *in vitro* metronidazole resistance was seen. Minimum lethal concentrations of tinidazole were lower than those of metronidazole, and no tinidazole resistance was detected (28).

Epidemiology and Prevention

Trichomoniasis has been found in every continent and climate, with no season variability. It has a cosmopolitan distribution within all racial groups and throughout all socioeconomic levels. The annual incidence of trichomoniasis is estimated to be more than 275 million cases worldwide. The incidence can exceed 50% in patients attending STI clinics and depends on age, sexual activity, number of sexual partners, other STIs, sexual customs, phase of the menstrual cycle, and sensitivity of patient examination and specimen collection and testing.

Humans are the only natural host for *T. vaginalis*. Risk factors for trichomoniasis have also been investigated. The associations between HIV and trichomoniasis may relate to increased shedding of HIV due to local inflammation produced by *T. vaginalis*, increased susceptibility to HIV as a result of breaks in the mucosal barriers, a higher prevalence of STIs in HIV-infected individuals, and/or an increased susceptibility to HIV due to immunosuppression. Transmission of HIV is enhanced by coinfection with *T. vaginalis*, and treatment of trichomoniasis reduces the levels of HIV RNA (1).

A symbiotic relationship between *T. vaginalis* and *Mycoplasma hominis* has been documented; such a symbiosis may indicate a potential role of *T. vaginalis* in the transmission of bacterial infection (29). These findings suggest that this relationship between the two organisms may provide the bacteria with the ability to resist the host defense mechanisms and therapy.

Infection is acquired primarily through sexual intercourse, hence the need to diagnose and treat asymptomatic males. The organism can survive for some time in a moist environment such as damp towels and underclothes; however, this mode of transmission is thought to be very rare. Evidence implicating *T. vaginalis* as a potential contributor to poor outcomes in both women and men continues to accumulate. In women, this infection may play a role in the development of cervical neoplasia, postoperative infections, and potential problems with pregnancy. It is also seen as a factor in atypical pelvic inflammatory disease and infertility. In men, trichomoniasis causes nongonoccocal urethritis and contributes to male infertility. The importance of this infection needs to be recognized beyond the limits of the STI clinics (10, 30).

Vaccines. As with many STIs, infection with *T. vaginalis* does not produce long-term immunity. Although the antibody response to this organism is well documented, the antibodies provide only limited protection, and antibody titers disappear after therapy. Vaccine development has shown some promise; potential targets include a 100-kDa protein that is immunogenic across a number of *T. vaginalis* isolates, as well as essential adherence molecules such as adhesins, mucinases, and cysteine proteinases (11). Although several vaccine trials were held during the 1960s and the late 1970s, subsequent studies led to doubts about the efficacy of the vaccines. Later studies using a murine model have shown promise, and a bovine *Trichomonas foetus* model in cattle has also yielded promising results. A whole-cell *Trichomonas foetus* vaccine is now commercially available for cattle and provides protection, as well as accelerating the eradication of infection.

Summary. *T. vaginalis* is one of the neglected parasitic infections designated by the Centers for Disease Control and Prevention (CDC) which have been targeted as priorities for public health action. With the introduction of newer diagnostic testing, more attention can be devoted to surveillance, prevention, and treatment. Because of the increasing burden of trichomoniasis in certain obstetric populations, the question of whether screening and treatment during pregnancy improve perinatal outcomes should be readdressed. In addition, the association with pelvic inflammatory disease and HIV acquisition is troubling. No longer can we afford to continue to disregard this destructive parasite by not screening at-risk patients.

Toxoplasma gondii

Toxoplasma gondii is worldwide in distribution, is closely related to other coccidia, and also has certain similarities to malarial parasites. The parasites were first discovered in 1908, by Charles Nicolle and Louis Manceaux at the Pasteur Institute, in the North African rodent called the gundi, hence the species name *gondii*. At the same time, Alfonso Splendore described the organism from laboratory rabbits at the Portuguese Hospital in São Paulo, Brazil. However, the complete life cycle was not determined until 1970 (31). Although serologic evidence indicates a high rate of human exposure to the organism, the disease itself is relatively rare. *T. gondii* can infect many vertebrates as well as humans, but the definitive host is the house cat and other members of the *Felidae* family.

Life Cycle and Morphology

The life cycle is shown in Fig. 25.10. Humans can acquire the infection in several ways, either by the accidental ingestion of oocysts shed in cat feces or by the ingestion of rare or raw meats, particularly pork, lamb, or venison. Transmission can also occur *in utero*, by transfusion, and during organ transplantation (32–34). Toxoplasmosis should be considered as a possible cause of multiorgan failure after liver transplantation. The inclusion of serologic testing should be considered in routine donor testing. The most common means of infection is probably through ingestion of rare or raw meats. The oocysts shed in cat feces are 9 to 11 μm wide by 11 to 14 μm long and contain two sporocysts, each containing four sporozoites (Fig. 25.11). Cats shed oocysts after ingestion of any of the three infectious stages of *T. gondii*. Cats become infected from eating birds, small rodents, or other sources of raw meat. In the tachyzoite-induced life cycle of *T. gondii* in cats, the animals can shed up to 360 million oocysts per day and will shed for 4 to 6 days (34).

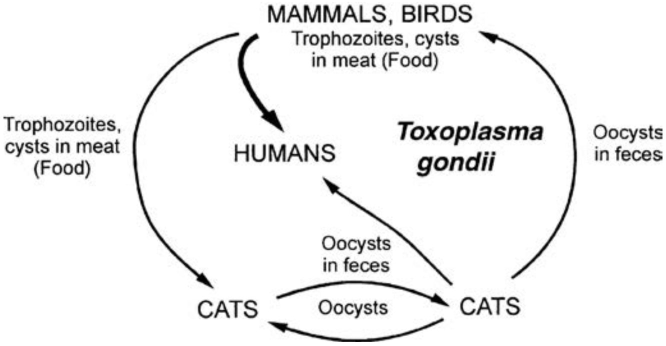

Figure 25.10 Life cycle of *Toxoplasma gondii*. The active forms (trophozoites) are also referred to as tachyzoites, while the resting stages within the cysts are called bradyzoites (very slow-growing trophozoites). doi:10.1128/9781555819002.ch25.f10

There are three infectious stages of *T. gondii*: the tachyzoites (in groups or clones), the bradyzoites (in tissue cysts), and the sporozoites (in oocysts). Tachyzoites rapidly multiply in any cell of the intermediate host (many other animals and humans) and in nonintestinal epithelial cells of the definitive host (cats). Bradyzoites are found within the tissue cysts and multiply very slowly; the cyst may contain few to hundreds of organisms, and intramuscular cysts may reach 100 μm in size. Although the tissue cysts may develop in visceral organs such as the lungs, liver, and kidneys, they are more prevalent in neural and muscular tissues, including the brain, eyes, and skeletal and cardiac muscle. Intact tissue cysts can persist for the life of the host and do not cause an inflammatory response (31).

The organisms are obligate intracellular parasites and are found in two forms in humans. The actively proliferating trophozoites or tachyzoites are usually seen in the early, more acute phases of the infection. The resting forms or cysts are found primarily in muscle and brain, probably as a result of the host immune response. The cysts contain the more slowly growing trophozoites or bradyzoites. Bradyzoites encyst approximately 8 to 10 days after entry into the host and differ from tachyzoites in being more resistant to pepsin, having a longer generation time, containing cytoplasmic vacuoles which may serve as carbohydrate stores, and being the only stage to initiate the enteroepithelial cycle and transform into oocysts in the feline intestine.

The trophozoites (tachyzoites) are crescent shaped and are 2 to 3 μm wide by 4 to 8 μm long (Fig. 25.12 and 25.13). One end tends to be more rounded than the other. Tachyzoites are the dissemination form. They are able to invade virtually all vertebrate cell types, where they multiply in a parasitophorous vacuole. Giemsa is the stain of

choice; the cytoplasm stains pale blue and the nucleus stains red and is situated toward the broad end of the organism.

The cysts are formed in chronic infections, and the organisms within the cyst wall are strongly periodic acid-Schiff positive (Fig. 25.14). Bradyzoites result from the conversion of tachyzoites into a slow-dividing stage and form tissue cysts. These cysts are more or less spheroid in brain cells or elongated in muscular cells. During the acute phase, there may be groups of tachyzoites that appear to be cysts; however, they are not strongly periodic acid-Schiff positive and have been termed pseudocysts.

The cycle occurring in cats includes asexual multiplication and sexual reproduction in the small intestinal epithelial cells (31, 34). Sexual reproduction occurs only in felids (domestic and wild cats). The final stage of the reproductive cycle is the oocyst, which is passed in the feces. The shedding of oocysts begins 3 to 7 days after the ingestion of tissue cysts and may continue for up to 20 days. Infected cats can shed more than 100 million oocysts in their feces. They can infect a wide range of intermediate hosts—virtually all warm-blooded animals, from mammals to birds—when ingested with food or water. Oocysts are also infective for cats, although less efficiently. After defecation, development of infective sporozoites inside the oocysts requires 1 to 5 days and depends on environmental conditions. The developmental cycle in the cat takes approximately 19 to 48 days after infection with the oocysts but only 3 to 10 days after the ingestion of meat infected with cysts, e.g., a mouse.

The number of cats in the United States is estimated at around 70 million, with the number of feral cats probably being greater than that of domestic cats. Of the cats

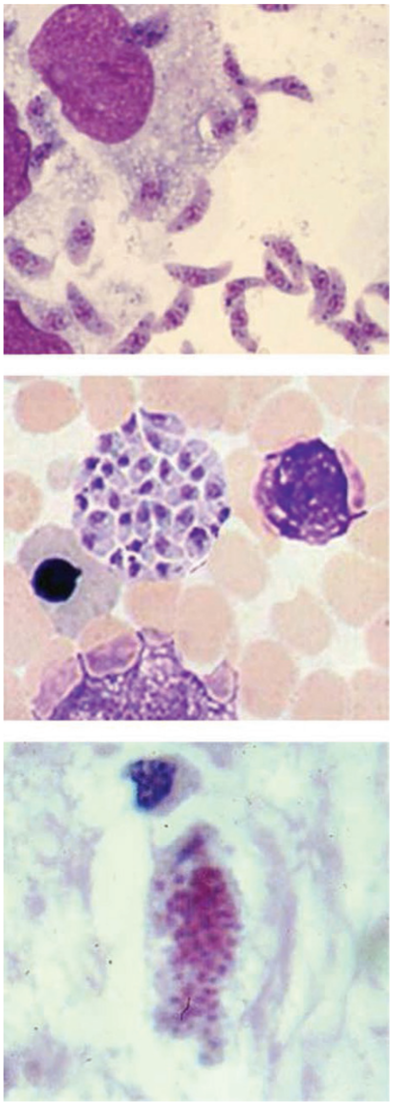

Figure 25.13 *Toxoplasma gondii*. (Top) Tachyzoites from mouse peritoneal fluid; (middle) tachyzoites seen within human bone marrow; (bottom) bradyzoites seen in human tissue. doi:10.1128/9781555819002.ch25.f13

examined within the United States, 1% had *T. gondii* oocysts in their feces. However, this may be because the period of shedding is usually only 1 to 2 weeks during the life of the cat and the oocysts are quite small, measuring approximately 10 µm. Consequently, the use of routine fecal examinations to determine whether cats are positive for *T. gondii* is somewhat limited and is not particularly helpful in determining whether the animal is shedding oocysts.

Clinical Disease

Approximately 25 to 30% of the world's human population is infected by *Toxoplasma*. Actually, the prevalences vary widely between countries and often within a given country or between different communities in the same region. Low seroprevalences (10 to 30%) have been observed in North America, in Southeast Asia, in northern Europe, and in Sahelian countries of Africa. Moderate prevalences (30 to 50%) have been found in countries of central and southern Europe, and high prevalences have been found in Latin America and in tropical African countries (35).

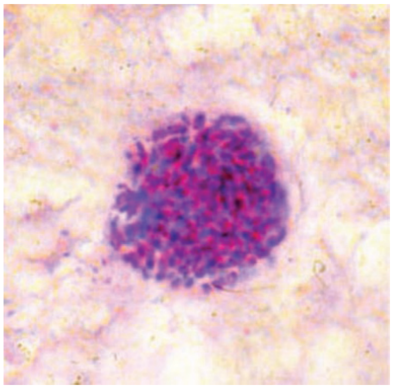

Figure 25.14 *Toxoplasma gondii*. Tissue cyst, PAS stain. Each cyst contains 50 to 5,000 bradyzoites, which replicate following cyst rupture, unless destroyed by cellular immunity. doi:10.1128/9781555819002.ch25.f14

When the tachyzoites are actively proliferating, they invade cells adjacent to the original infected cell as it ruptures. This process creates continually expanding focal lesions. Once the cysts are formed, the process becomes quiescent, with little or no multiplication and spread. In the immunocompromised or immunodeficient patient, a cyst rupture or primary exposure to the organisms often leads to lesions. The organisms can be disseminated via the lymphatics and the bloodstream to other tissues. Disintegration of cysts may give rise to clinical encephalitis in the presence of apparently adequate immunity.

The large number of people who are serologically positive for *T. gondii* suggests that the majority of infections are benign, with most people exhibiting few (e.g., cold or light case of the flu) or no symptoms. The most severe symptoms are seen with congenital, transplacental infections or infections in compromised patients (Tables 25.4

TABLE 25.4 People at risk for severe toxoplasmosis

Category	Comments
Infants born to mothers who are first exposed to *Toxoplasma* infection several months before or during pregnancy	Mothers who are first exposed to *Toxoplasma* more than 6 months before becoming pregnant are not likely to pass the infection to their children.
Persons with severely weakened immune systems	Infection that occurred at any time during life can reactivate.

TABLE 25.5 Toxoplasmsosis: mechanisms of human infection

Mechanism	Comments
Infection through cysts	Any meat from warm-blooded animals and birds (lamb, pork, beef, chicken, etc.)
Cyst resistance	Cysts remain infectious in refrigerated carcasses (1–6°C) or minced meat for up to 3 weeks; freezing at –12°C or lower for at least 3 days is usually acceptable, although it depends on the thickness of the meat
Solid organ transplantation	Infection transmitted through a cyst-containing donor organ; heart transplants higher risk than liver, lung, or kidney patients
Infection through oocysts	Risk of infection in cats increases when weather is warm and moist; single cat can shed >100 million oocysts, which require 1–5 days to sporulate and become infective; direct cat contact not considered major risk; oocysts may remain infective in cat litter up to 14 days; once sporulated can survive viable for more than 1 yr
Contamination of water	Remain viable for long periods and can resist freezing and moderately high water temperatures; not killed by routine chemical/physical treatments currently used by water treatment plants; freshwater runoff may contaminate seawater; viable oocysts found in various species of shellfish (oysters, clams, mussels)
Contamination of soil, vegetables, fruits	Contact with soil; particularly high risk in children
Infection through tachyzoites	Fragile stage outside of the host; not as likely as other means of infection, but linked to drinking of unpasteurized goat's milk
Congenital infection	Tachyzoites colonize placental tissues and gain access to the fetus in about 30% of cases; decreasing seroprevalence of toxoplasmosis in industrialized countries may have consequences for the risk of infection during pregnancy
Infection through injection	Rare, but possible via needlestick injuries or scratching while manipulating tachyzoites from the RH strain[a]; blood transfusion and/or bone marrow possible

[a] The RH type I strain has been extensively used for defining the biology of *Toxoplasma*, ranging from active invasion and replication to host cell entry, and for molecular genetic analyses. RH was initially isolated from a 1939 case of toxoplasmic encephalitis by Albert Sabin and was subsequently cloned by Elmer Pfefferkorn for *in vitro* culture in 1977.

and 25.5). Toxoplasmosis can be categorized into four groups: (i) disease acquired in immunocompetent patients, (ii) disease acquired or reactivated in immunosuppressed or immunodeficient patients, (iii) congenital disease, and (iv) ocular disease.

Acquired Infections in Immunocompetent Individuals. In approximately 90% of cases, no clinical symptoms are seen during the acute infection. However, 10 to 20% of patients with acute infection may develop painless cervical lymphadenopathy. This presentation is benign and self-limited, with symptoms resolving within weeks to months. Acute visceral manifestations are seen in rare cases. In one study from French Guiana over a period of 6.5 years, 13 of 16 patients had consumed game in the 2 weeks prior to the onset of symptoms and in eight cases the game was undercooked (36). Although other cases have been reported during the last decade, very few were reported in detail. In reviewing the possible link between *T. gondii* and schizophrenia, it appears that some cases of acute toxoplasmosis in adults are associated with psychiatric symptoms such as delusions and hallucinations (37).

Infections in Immunocompromised Patients. Infections in immunocompromised patients can lead to severe complications; underlying conditions that may influence the course of the disease include various malignancies (such as Hodgkin's disease, non-Hodgkin's lymphomas, leukemias, and solid tumors), collagen vascular disease, organ transplantation, and AIDS. In immunocompromised patients, the central nervous system (CNS) is primarily involved, with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions. More than 50% of these patients show an altered mental state, motor impairment, seizures, abnormal reflexes, and other neurologic sequelae. Studies show that even in these groups, most patients receiving chemotherapy for toxoplasmosis will improve significantly or have complete remission. However, in those with AIDS, therapy must be continued for long periods to maintain a clinical response.

In genotyping studies, it appears that the type of *T. gondii* strain does not predominantly influence the pathogenesis of toxoplasmosis in immunocompromised patients. Thus, regardless of the strain genotype, there remains the need for specific prophylaxis in these patients infected by *T. gondii* (38).

Transplant recipients. In transplant recipients, disease severity depends on previous exposure to *T. gondii* by the donor and recipient, the type of organ transplanted, and the level of immunosuppression of the patient. Disease can be due to reactivation of a latent infection or an acute primary infection acquired directly from the transplanted organ (39). Stem cell transplant recipients are particularly susceptible to severe toxoplasmosis, primarily due to reactivation of a previously acquired latent infection. If stem cell transplant recipients have a positive serologic test prior to transplantation, they are known to be at risk for severe disseminated toxoplasmosis (40). All potential transplant recipients should be tested for *Toxoplasma*-specific IgG antibodies to determine their antibody status. An individual with acute acquired infection often produces detectable IgG and IgM antibodies, while those with reactivation may or may not have an increase in the levels of IgG antibodies and normally do not demonstrate an IgM response. Seronegative cardiac transplant recipients who receive an organ from a seropositive donor may develop toxoplasmic myocarditis; this disease presentation may also mimic organ rejection.

AIDS patients. Patients who become infected with *T. gondii* risk developing disease when their CD4$^+$ T-lymphocyte count falls below 100,000/ml. Fever and malaise usually precede the first neurologic symptoms; headache, confusion, seizures, or other focal signs strongly suggest the diagnosis of toxoplasmosis.

Toxoplasma encephalitis (TE) was reported as a life-threatening opportunistic infection among patients with AIDS prior to the use of highly active antiretroviral therapies. This condition is fatal if untreated. Most AIDS patients with TE have detectable IgG antibodies to *T. gondii*; however, <5% may not have antibody in their serum. Psychiatric manifestations of *T. gondii* are also seen in immunocompromised individuals with AIDS in whom latent infections have become reactivated. Altered mental status occurs in approximately 60% of patients, with symptoms including delusions, auditory hallucinations, and thought disorders (37). A characteristic imaging finding of toxoplasmosis is the "asymmetric target sign." Typically, any abscess forms a ring-enhancing lesion; however, in toxoplasmosis, there is an enhancing, eccentrically situated nodule within this ring. This sign can be seen by postcontrast computed tomography and magnetic resonance imaging and is virtually pathognomonic (Fig. 25.15). Unfortunately, it is only present in approximately one-third of patients, and in the remaining patients *Toxoplasma* lesions within the brain have a variable appearance depending on the degree of immunosuppression.

Disseminated toxoplasmosis should be considered in the differential diagnosis of immunocompromised patients with culture-negative sepsis, particularly if combined with neurologic, respiratory, or unexplained skin lesions. Examination of Wright's-stained peripheral blood smears or antitoxoplasma immunoperoxidase studies of skin biopsy specimens may be diagnostic (31).

In histologically confirmed cases of TE, when the majority of the patients received some therapy, the overall prognosis has been poor, with the median survival following initiation of therapy being 4 months. No beneficial or harmful effects could be attributed to the use of corticosteroids, and toxicity attributed to pyrimethamine-sulfonamide therapy was reported for many patients. A clinical relapse of TE has been seen in approximately half of the patients discharged from the hospital.

Although an inflammatory process is observed during TE in HIV-positive patients, the major cause of CNS lesions is probably uncontrolled parasite multiplication rather than immunopathologic changes. Also, *T. gondii* is capable of enhancing HIV-1 replication within reservoir host cells and, simultaneously, HIV-1 itself undermines acquired immunity to the parasite, promoting reactivation of chronic toxoplasmosis.

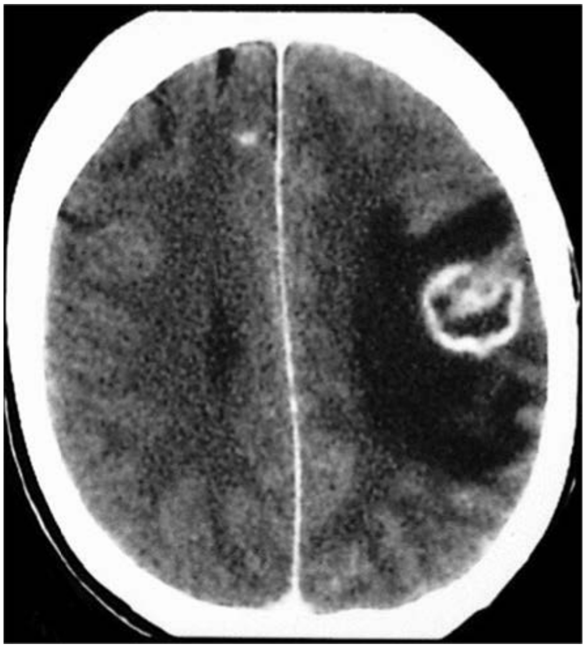

Figure 25.15 *Toxoplasma gondii.* CNS toxoplasmosis in patient with AIDS. Postinfusion computer tomography scan shows a moderately sized ring enhancing lesion with an eccentric nodule, which also enhanced. The corticomedullary location and marked surrounding edema are characteristic of toxoplasmosis. (Courtesy of P. Harrison, Vancouver; http://tmcr.usuhs.edu/tmcr/chapter45/imaging4.htm.) doi:10.1128/9781555819002.ch25.f15

Respiratory disease due to *T. gondii* has also been recognized in immunocompromised patients, and the few cases that have been found in HIV-positive patients have been in association with CNS disease. The finding of pulmonary toxoplasmosis in the absence of neurologic findings in HIV-positive patients emphasizes the importance of considering this organism as the cause of pulmonary disease in such patients with respiratory symptoms.

Congenital Infections. Congenital infections result from the transfer of parasites from the mother to the fetus when she acquires a primary infection during pregnancy. In 90% of patients, no clinical symptoms are apparent during acute infection. Congenital infections may be particularly severe if the mother acquires the infection during the first or second trimester of pregnancy. At birth or soon thereafter, symptoms in these infants may include retinochoroiditis, cerebral calcification, and occasionally hydrocephalus or microcephaly. Symptoms of congenital CNS involvement may not appear until several years later.

The risk of congenital toxoplasmosis depends on the timing of the mother's acute infection. Transmission to the fetus increases with gestation age: 15 to 25% in the first trimester, 30 to 45% in the second, and 60 to 65% in the third. However, the severity of congenital disease decreases with gestation age. Signs of infection at delivery are present in 21 to 28% of those infected in the second trimester and in ≤11% of those infected in the third trimester. Overall, 10% are born with severe disease. Congenital transmission can occur even if the mother is immune, although this is rare; reinfection of the mother during pregnancy is possible, particularly if she comes in contact with large numbers of infective cysts and/or oocysts.

The characteristic symptoms of hydrocephalus, cerebral calcifications, and chorioretinitis resulting in mental retardation, epilepsy, and impaired vision represent the most severe form of the disease. Cerebral lesions may calcify, providing retrospective signs of congenital infection.

In the case of seroconversion by the mother during pregnancy, prenatal diagnosis is usually performed by analysis of amniotic fluid. However, it is important to remember that despite the use of advanced diagnostic methods, some cases of congenital toxoplasmosis cannot be detected early. This demonstrates the importance of careful follow-up of newborns who are at risk. Treatment of the mother may reduce the incidence of congenital infection; therefore, rapid and accurate diagnosis should be emphasized.

Ocular Infections. Chorioretinitis in immunocompetent patients is generally due to an earlier congenital infection. Patients may be asymptomatic until the second or third decade; at that point, cysts may rupture, with lesions then developing in the eye. The number of people who develop chorioretinitis later in life is unknown but may represent over two-thirds of the total. Also, up to 30% of patients relapse after treatment. Chorioretinitis is usually bilateral in patients with congenitally acquired infection and is generally unilateral in patients with recently acquired infection.

Diagnosis

The diagnosis of *Toxoplasma* infection in immunocompetent individuals relies on serology. Serologic diagnosis is usually retrospective and is used to determine the immune status, such as (i) in a pregnant woman, preferably at an early stage of pregnancy; (ii) in a patient with uveitis or retinochoroiditis with no known history of congenital infection; or (iii) in a graft setting, i.e., in organ donors or transplant recipients. In patients with fever or lymphadenopathy, serologic testing allows the differential diagnosis of cytomegalovirus, Epstein-Barr virus, or HIV infections, as well as other diseases associated with lymphadenopathy (35).

Other procedures include PCR, examination of biopsy specimens, buffy coat cells, or cerebrospinal fluid, and isolation of the organism in tissue culture or in laboratory animals (Tables 25.6 and 25.7). It is difficult to demonstrate the parasite in lymph node biopsy specimens, and while some authorities think the histologic appearance is very characteristic, others consider the histologic changes to be nonspecific. However, because many individuals have been exposed to *T. gondii* and may have cysts within the tissues, recovery of organisms from tissue culture or animal inoculation may be misleading, since the organisms may be isolated but may not be the etiologic agent of disease. For this reason, serologic tests are often recommended as the diagnostic approach of choice. However, two representative situations in which the detection of organisms may be very significant are (i) tachyzoite-positive smears and/or tissue cultures inoculated from cerebrospinal fluid and (ii) in patients with acute pulmonary disease, the demonstration of tachyzoites in Giemsa-stained smears of bronchoalveolar lavage fluid, with some tachyzoites being extracellular and some being intracellular.

Emphasis on pediatric patients, particularly neonates, is seen in the extensive literature on serologic testing. An algorithm for the diagnosis and treatment of neonatal toxoplasmosis is seen in Fig. 25.16; a summary of risk management issues in pregnancy can be seen in Fig. 25.17. An understanding of the difficulties in test interpretation is helpful. First, all newborns from mothers who are antibody positive will have passively transferred maternal IgG. These titers can be quite high but may not indicate infection in the baby. The detection of IgM antibodies, which do not cross the placental barrier, provides a much more accurate indication of infection in the newborn. There can still be situations in which a false-negative (IgG saturation of antigen receptors) or false-positive (presence of rheumatoid factor and antinuclear antibody) result is possible. There is evidence to indicate that in certain instances, the presence of IgM antibody titers in single serum specimens cannot be used to indicate recent exposure, particularly since IgM can persist beyond 2 years (35, 39, 41). Interpretation of serologic tests for IgM can be seen in Fig. 25.18. A current means of confirming or ruling out a recent infection is the determination of IgG avidity, a method which relies on the increased affinity of the antibody for its target antigen during the course of natural immunity following infection.

In the United States, the first FDA-approved test (Vidas Toxo IgG avidity assay; bioMérieux) was approved in 2011. A high avidity ratio excludes an infection acquired in the preceding 4 months with most commercial tests, ruling out an infection acquired during gestation when the test is performed during the first trimester of pregnancy. In routine practice, avidity testing allows the avoidance of unnecessary spiramycin treatment in pregnant women and

TABLE 25.6 Clinical use of immunodiagnostic tests[a]

Questions to answer	Tests to use	Interpretation	Comments
Is the patient currently infected?	IgG assays	If IgG positive = infected If IgG negative, retest in 3 weeks if acute infection suspected	A single specimen is satisfactory to determine antibody status. Situations where baseline information is helpful: (i) women of childbearing age tested prior to conception; (ii) before initiation of immunosuppressive therapy; (iii) after determination of HIV-1-positive status; (iv) organ donors prior to transplantation.
Has the patient recently acquired the infection?	IgM and IgA assays	If IgG positive and IgM negative = infected for more than 6 months If IgG positive and IgM positive = infection within last 2 years, or false-positive IgM result	Specimens drawn 2 wk apart may or may not be helpful; often an increase in IgG or IgM titer is not possible; titers may already have reached a plateau when first sample is drawn.
How recently was the infection acquired by the patient?	IgG avidity, differential agglutination	If IgG avidity high = infected at least 12 wk earlier If IgG avidity low = recent infection possible; some people have persistent low IgG avidity for months after infection	If IgG avidity is low, draw second sample 3 weeks after first sample; send both specimens to *Toxoplasma* reference laboratory for confirmation of IgG, IgM, and IgG avidity results and possibly differential agglutination and IgA and IgE testing.
Is evidence of active infection present?	PCR, culture, antigen detection	*Toxoplasma* isolated from 95% of placentas of congenitally infected newborns when mother has not been treated and from approximately 81% when the mother has received therapy	Attempts should be made to isolate *T. gondii* from the placenta, amniotic fluid, and cord blood to confirm the diagnosis.

[a] Adapted from references 33 and 39.

unjustified long-term repeated follow-ups of fetuses and infants, provided that the test is performed before the fourth month of pregnancy (35). The ARCHITECT Toxo IgG assay (Abbott), using recombinant antigens, showed excellent specificity and sensitivity for acute phase as well as past infection specimens. The ARCHITECT Toxoplasmosis panel can be reliably used to rule out acute *T. gondii* infection in pregnant women (42).

The Sabin-Feldman dye test, one of the first methods used to diagnose toxoplasmosis, is based on the fact that in the presence of immune serum, *T. gondii* loses its affinity for methylene blue stain. Because this test uses live *Toxoplasma* trophozoites, however, most laboratories do not provide it routinely. A specific guide to the interpretation of serologic titers for toxoplasmosis is provided in Table 25.8. Interpretation of toxoplasmosis serology in pregnant women can be seen in Fig. 25.19.

The serologic diagnosis of toxoplasmosis is very complex and has been discussed extensively in the literature; a number of additional procedures, some of which are automated, have been developed and reported in the last few years (43). These methods include enzyme immunoassays, some of which are automated (20), ELISAs (39, 41, 44, 45), direct agglutination (39), an immunosorbent agglutination assay (39), an indirect immunofluorescence assay, immunocapture (39), and immunoblotting (46). Evaluations of various commercial assays have also been discussed (39, 47).

A great deal of molecular biology-based work involving PCR for the diagnosis of toxoplasmosis and strain typing has also been done (35, 40, 46, 48–51). This technology may be useful in situations where knowledge of recent infection is necessary. PCR has also been used to detect *T. gondii* in deparaffinized ocular tissue sections, cerebrospinal fluid, blood, and bronchoalveolar fluid; however, the absence of *Toxoplasma* DNA does not exclude toxoplasmosis. PCR can be very helpful in evaluating fetal infection; certainly the time needed to detect parasites is much shorter than when using mouse or tissue culture approaches. Sensitivity depends on the clinical presentation; it is higher when confirming congenital toxoplasmosis from amniotic fluid but lower in patients with infection reactivation such as HIV-positive patients.

TABLE 25.7 General comments on the performance and interpretation of serologic results for the diagnosis of toxoplasmosis[a]

---

1. Specific IgM normally develops early, within 1–2 wk after primary infection.
2. Specific IgG normally develops within 4 wk after primary infection.
3. Production and increase in titers usually peak within 4–8 wk, but in individual cases the increase in IgM may continue for some weeks and IgG for several months.
4. The antibody result from a single serum sample gives no clear indication of when the infection occurred.
5. A rise in titer (IgG) should be demonstrated between 2 or more samples tested in the same test run; a 4-tube antibody increase is required to support the diagnosis of acute febrile toxoplasmosis. If serum is taken during late infection or for the presence of lymphadenopathy, titers in excess of 1:1,000 should be present.
6. The presence of IgM does not confirm a very recent infection; a positive IgM result has low predictive value for identifying primary *T. gondii* infection.
7. The amount of specific IgM may decrease to below the detection level in less than 3 mo after infection; however, IgM may be detectable for many months after the primary infection (can be detected as long as a year or more after primary infection). IgM antibody can persist for 6 mo in the conventional test but as long as 6 yr in the capture test.
8. IgG avidity gradually increases after primary infection. Low or equivocal avidity results can persist for months to >1 yr after primary infection. High-avidity test results seen in individuals infected for at least 3 to 5 mo.
9. For congenital infections, an IgG titer of >1:1,000 indicates a tentative diagnosis, pending confirmation of a positive IgM test, the exclusion of rheumatoid factor and antinuclear antibody, and the isolation of *Toxoplasma*, if possible. Passively transferred antibody shows a 10-fold decay every 3 mo; during infection, high antibody titers are stable or will increase.
10. Specific IgA results are not particularly helpful. A negative result does not exclude, nor does a positive result confirm, a recent primary infection.
11. Termination of pregnancy may be offered to women who seroconvert in the first 8 wk of pregnancy and to those infected in the first 22 wk of pregnancy when fetal infection is confirmed. A more conservative approach is based on abortion only if there is ultrasonographic evidence of hydrocephalus.
12. In the context of recurrent pregnancy loss, intravenous immunoglobulin therapy can cause confusion in the interpretation of serologic results for the diagnosis of toxoplasmosis; the appearance of anti-*Toxoplasma* antibodies may lead to the conclusion that seroconversion has occurred. Also, if positive serologic results are seen, the woman may be incorrectly considered immune.

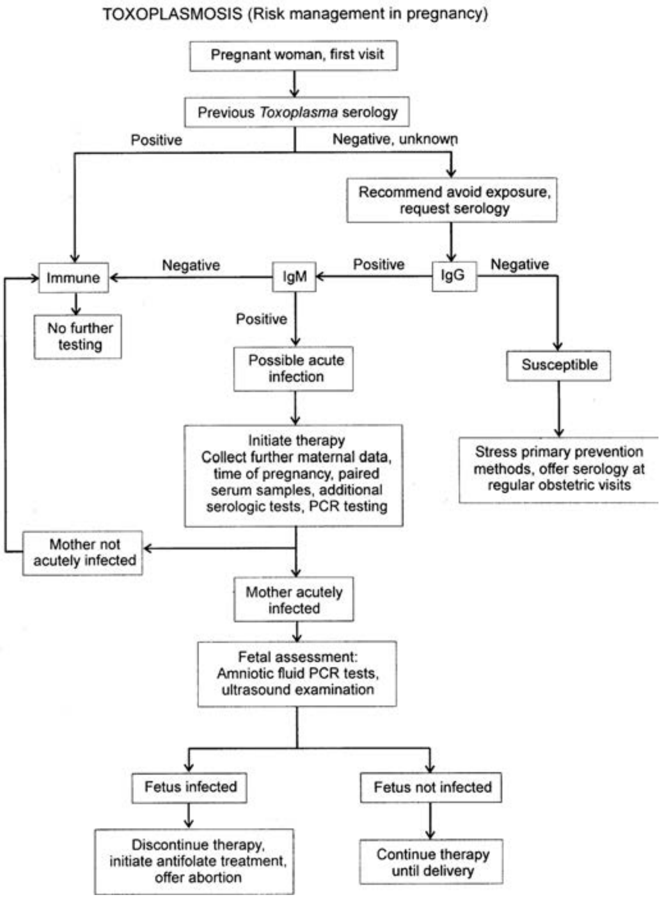
Antigen detection has improved during the last few years; however, this approach still appears to lack sensitivity when used with human samples. Antigen detection may be helpful in diagnosing the compromised patient in whom antibody titers are low or absent. This serologic approach can also clarify low titers, i.e., those found in early acute infection or chronic infection. This test capability can also be very helpful in patients with monoclonal gammopathies, whose titers to *T. gondii* may be extremely high but may not be causing the clinical condition. See Algorithm 25.1.

KEY POINTS—LABORATORY DIAGNOSIS

Toxoplasma gondii

1. Serologic results are normally used to diagnose toxoplasmosis. Results of all other procedures must be interpreted in light of the serologic findings.
2. *T. gondii* identified in histologic preparations or isolated in animals or in tissue culture systems may or may not be the causative agent of the symptoms (many individuals harbor the organisms in their tissues but have no symptoms).



TOXOPLASMOSIS (Risk management in pregnancy)
Pregnant woman, first visit
Previous *Toxoplasma* serology
Positive
Negative, unknown
Recommend avoid exposure, request serology
Immune
Negative
IgM
Positive
IgG
Negative
No further testing
Positive
Possible acute infection
Susceptible
Initiate therapy Collect further maternal data, time of pregnancy, paired serum samples, additional serologic tests, PCR testing
Stress primary prevention methods, offer serology at regular obstetric visits
Mother not acutely infected
Mother acutely infected
Fetal assessment: Amniotic fluid PCR tests, ultrasound examination
Fetus infected
Fetus not infected
Discontinue therapy, initiate antifolate treatment, offer abortion
Continue therapy until delivery

Figure 25.17 Toxoplasmosis: risk management in pregnancy. doi:10.1128/9781555819002.ch25.f17

Treatment

It is generally recommended that the following conditions be treated: clinically active disease, diagnosed congenital toxoplasmosis, and disease in symptomatic compromised patients. Drugs that have been found to be effective, either alone or in combination, include sulfonamides and pyrimethamine (actively multiplying tachyzoites). Clindamycin and spiramycin have also been used in certain circumstances.

Pregnant Patients. Therapy for pregnant patients who acquire the infection and for newborns with *Toxoplasma* antibody is somewhat controversial. However, prophylactic therapy is often recommended for the newborn until it can be demonstrated that IgM antibody is not present. Spiramycin has been used to treat women infected in pregnancy, since it is potentially less toxic for the fetus. Apparently this drug is concentrated in the placenta but does not cross the barrier freely, and drug levels in the neonate are low. Spiramycin has also been used to treat congenitally infected infants every other month, alternating with sulfadiazine-pyrimethamine treatment.

Women who develop toxoplasmosis during the first trimester of pregnancy should be treated with spiramycin (3 to 4 g/day). After the first trimester, if there is no documented transmission to the fetus, spiramycin can be continued until term. Spiramycin is not currently available in the U.S. but can be obtained at no cost from Aventis through IND from the FDA (301-796-1600) following confirmation of the diagnosis by a recognized laboratory (i.e., Palo Alto Medical Foundation, Toxoplasmosis Laboratory; 650-853-4828) (24). If transmission has occurred *in utero*, therapy with pyrimethamine and sulfadiazine should be started (24). Pyrimethamine is a potential teratogen and should be used only after the first trimester (52). Congenitally infected newborns should be treated with pyrimethamine every 2 or 3 days and a sulfonamide daily for about 1 year (24, 53).

AIDS Patients. Although a combination of pyrimethamine and a sulfonamide is the standard regimen for treating TE in AIDS patients, the use of these drugs can be contraindicated in patients with a history of bone marrow suppression and severe allergic reactions to sulfonamides. It is also important to realize the potential danger of using high doses of sulfadiazine, which may lead to the development of sulfadiazine-induced crystalluria; to prevent crystalluria, patients should be adequately hydrated and their urinary pH should be maintained above 7.5. The use of oral clindamycin and pyrimethamine is effective (24). Data also suggest that a combination of trimethoprim and sulfamethoxazole (TMP-SMX, cotrimoxazole) may be as effective as pyrimethamine-sulfadiazine in AIDS patients with TE. It is interesting that treatment of cerebral toxoplasmosis protects against *Pneumocystis* pneumonia in AIDS patients; the decreased risk is probably due to chronic suppressive treatment with pyrimethamine and sulfonamides.

Approximately 10 to 50% of patients who are seropositive for antibodies to *T. gondii* have CD4$^+$ T-lymphocyte counts of <100/mm^3. Detection of IgG antibodies indicates prior infection and possible presence of tissue cysts. Since TE may result from reactivation of tissue cysts, prophylaxis with TMP-SMX or dapsone plus pyrimethamine with leucovorin is recommended for these patients. HIV-infected persons who are seronegative for *Toxoplasma* IgG should be counseled to protect themselves from primary infection by eating well-cooked meats and washing their hands after possible soil contact. Cats kept as pets should be fed commercial or well-cooked food, should be kept indoors, and should have their litter box changed each day. An algorithm for prevention of TE can be seen in Fig. 25.20. TE continues to occur among patients not receiving prophylaxis. It is estimated that at least half of the cases could be

Stable IgG titers?
Yes
No
Infection acquired more than 2 months before first sampling
Infection acquired less than 2 months before first sampling
Fetal risk must be appreciated according to gestational age

Figure 25.18 Chart for the analysis of conventional antibody tests for *Toxoplasma gondii* by the IgM technique. Interpretation depends on the type of test used. In the IgM-indirect immunofluorescence assay test, a titer of 1:64 would support a diagnosis of infection acquired 1 to 3 months earlier. In the double-sandwich IgM-ELISA (IgM capture), titers of 1:256 and higher should be expected in the first 4 months of infection. (Adapted from references 33, 39, and 41.) doi:10.1128/9781555819002.ch25.f18

prevented by better motivation of physicians and increased compliance by patients.

Ocular Toxoplasmosis. The management of ocular toxoplasmosis depends on the severity of the clinical presentation. Most specialists treat patients whose visual acuity has progressed to worse than 20/200, who have lesions in the peripapillary, perifoveal, or maculopapillary bundle regions, or who have severe vitreous inflammation. However, most do not treat patients whose visual acuity is 20/20, who have lesions in the far peripheral retina, or who have trace to mild vitreous inflammation. Various therapeutic regimens are used; however, almost all specialists, when asked, indicated that they used corticosteroids in the initial treatment regimen. In general, most indicated that they would modify treatment during pregnancy, in newborns, and in AIDS patients. Additional information can be found in chapter 36.

Epidemiology and Prevention

Human infection can be acquired through ingestion or handling of infected meat or through ingestion of infective oocysts, which can remain viable within cool, moist soil for a year or longer (Tables 25.5, 25.9). Certainly, hand

TABLE 25.8 Guide to interpretation of serologic tests for the diagnosis of toxoplasmosis[a]

	Infection status[c] of patients with titer[d] of:				
Clinical condition[b]	**0 (negative)**	**1:2–1:16**	**1:32–1:128**	**1:256–1:512**	**> 1:1,024**
Asymptomatic	Susceptible to infection	Infection in the past, probably immune	Infection in the past, probably immune	Infection in the past, probably immune	Recent infection or reinfection
Pregnancy	Susceptible to infection	Infection in the past, probably immune	Infection in the past, probably immune	Infection in the past, probably immune	Need to monitor neonate for infection
Newborn, asymptomatic or with jaundice	No	No	Diagnosis unlikely	Diagnosis unlikely	Possible, perform testing for IgM
Newborn with encephalitis	No	No	No	Diagnosis unlikely	Diagnosis may be correct if titer is stable or rises; perform testing for IgM
Lymphadenopathy	No	No	No	Diagnosis unlikely	Diagnosis possible
Fever with pneumonia, myocarditis, or hepatitis	No	No	Diagnosis unlikely	Diagnosis unlikely	Diagnosis possible; perform testing for IgM
Retinochoroiditis	No	Diagnosis possible	Diagnosis possible	Diagnosis possible	Diagnosis possible
Encephalitis	No	No	Diagnosis unlikely	Diagnosis unlikely	Possible; perform testing for IgM
Encephalitis (immunosuppressed patient)	Nondiagnostic	Diagnosis unlikely (may be tranfusion related)	Diagnosis possible	Diagnosis possible	Diagnosis likely; perform testing for IgM

[a] Adapted from reference 41.

[b] Patients are immunocompetent except where stated otherwise.

[c] 0, Susceptible to infection; the patient is not immune and is susceptible to a primary infection. 1:2–1:16, No; with these titers, toxoplasmosis should not be diagnosed. 1:32–1:128, Diagnosis unlikely; these titers would be the lowest found in typical forms of the syndrome. 1:256–1:512, Diagnosis possible; these titers would be characteristic but not necessarily diagnostic. >1:1,024, Diagnosis likely; these titers would probably be diagnostic for toxoplasmosis; perform testing for IgM as the presence of antibody may be informative.

3) Hand washing after soil contact

TABLE 25.9 Prevention of infection with *Toxoplasma gondii*

Prevention	Comments
Do not eat raw or undercooked meat or eggs	An example would be hollandaise sauce, prepared from raw eggs; pork, lamb, and venison particularly involved
Cured and smoked meat and sausages are considered safe	As an additional precaution, freeze at –20°C for a minimum of 1 day; however, some sausages are eaten almost raw after adding salt and spices (incidence of *T. gondii* in certain populations can be very high)
Consume only pasteurized or ultra-heat-treated milk and dairy products	Remember to consider ingredients of dairy products
When handling raw meat, avoid contaminating face, other food, utensils, cutting boards, or countertops	Hand washing and cleaning utensils, sinks, cutting boards, and countertops sufficient
Wash or peel fruits prior to eating them uncooked	Washing of smooth fruits is much easier than of berries; irradiation at 0.5 kGy is effective in "killing" coccidian oocysts on fruits and vegetables
Control insect pests and their access to food	Keep foods covered and/or refrigerated
Wear gloves when gardening or handling sand where cats usually defecate	Wash hands after removing gloves
If living with cats, change litter boxes every day and rinse them with boiling water	In one day, oocysts in cat feces will not have time to mature—extended periods in litter boxes will lead to fully infectious oocysts
Monitor and limit cat food sources	Infection in cats can be reduced by not allowing them to eat raw meat, birds, and rodents; use dry or canned cat food; in some areas of the world, ingestion of infected chicken viscera can lead to oocyst shedding and spread of *T. gondii* in the environment
Avoid handling stray cats and kittens	May be outdoor cats or may have consumed raw meat
Administer feline *T. gondii* vaccine to farm cats on swine operations	Reduction of exposure of finishing pigs to *T. gondii*; promising intervention to reduce risk of contaminating pork

washing is highly recommended when there has been potential exposure to the oocysts. It is recommended that meat be cooked so that the internal temperature reaches 150°F (66°C). The question of the house cat always arises; indoor cats fed on dry, canned, or boiled food are unlikely to be infected. However, cats that go outside and have access to other infected animals (birds or mice) may shed oocysts in their feces; therefore, other preventive measures, including changing the litter box daily and disinfecting the pan with boiling water, have been recommended. Also, the feces should not be placed onto the soil but, rather, should be disposed of either in the toilet or within bags.

Until recently, waterborne transmission of *T. gondii* was considered uncommon, but several large outbreaks linked to contaminated municipal water sources have led to a reassessment of this potential mode of transmission (33, 54). Considering the importance of using autofluorescence in environmental detection of oocysts, it has now been established that *T. gondii* oocysts fluoresce with the same pale blue color as can be seen with *Cyclospora cayetanensis* and other organisms. Apparently, morphologic differences among coccidian oocysts provide fluorescent details sufficient for identification when testing environmental water samples (55).

Since primary infection with *T. gondii* leads to specific and definitive protection against reinfection, the feasibility of developing a vaccine continues to be investigated. To protect humans, indirect procedures such as vaccination of the definitive host, i.e., the cat, or direct procedures by immunization with nonliving vaccines may be required.

Toxoplasma Types

Most *Toxoplasma* strains in North America and Europe fall into three clonal lineages known as types 1 (I), 2 (II), and 3 (III). South American strains are more genetically diverse and comprise distinct genotypes. The majority of human infections that have been studied in North America and Europe are caused by type II strains, which are also common in agricultural animals from these regions. However, several diverse genotypes of *T. gondii* are associated with severe infections in humans in South America.

In North America, type 2 strains are associated with congenital infections and AIDS patients. These same type 2 strains are also associated with human infections in Europe, whereas other diverse genotypes are found in other parts of the world.

Type 1 has been identified in patients in China, being the major type prevalent in mainland China, and has also been found in Columbia, Sri Lanka, Vietnam, and the U.S.; thus it is widespread in Asia and South and North America.

In a more recent study, PCR-RFLP genotype #1 (type II clonal), #2 (type III), #3 (type II variant), and #10 (type I) are found worldwide. Genotypes #2 and #3 dominate in Africa, genotypes #9 (Chinese 1) and #10 are prevalent in Asia, genotypes #1, #2, and #3 are prevalent in Europe, and genotypes #1, #2, #3, #4, and #5 dominate in North America (#4 and #5 are collectively known as type 12). In Central and South America, there is no clear dominance of any genotype even though a few have relatively higher frequencies. Statistically there are significant differences among populations in Africa, Asia, Europe, North America, and Central and South America, with only Europe and North America exhibiting similar diversity (56).

Malaria and Babesiosis

Malaria

Babesiosis

Malaria

Malaria represents one of the oldest documented diseases of humans, and even today, organisms in the genus *Plasmodium* kill more people than do any other infectious microorganisms. Egyptian mummies more than 3,000 years old have been found with enlarged spleens, most probably due to malaria. Deadly periodic fevers and splenomegaly have been mentioned, dating from as early as 2700 BCE, in both Egyptian and Chinese writings.

Based on the lack of malaria records in the New World prior to the arrival of European explorers, conquistadors, and colonists, it is assumed that Europeans imported *Plasmodium malariae* and *Plasmodium vivax* to the Americas. Apparently, the arrival of *Plasmodium falciparum* coincided with the importation of African slaves, and by the early 1800s malaria was found worldwide.

Malaria has probably had a greater impact on world history than any other infectious disease. It has been responsible for the outcome of wars, population movements, and the growth and development of various nations throughout the world. Before the American Civil War, malaria was found as far north as southern Canada; however, there has been a gradual decline, and by the early 1950s it was no longer an endemic disease within the United States. It is still a very common disease in many parts of the world, particularly in tropical and subtropical areas (Table 26.1, Fig. 26.1).

Of the five species that infect humans, *P. vivax* and *P. falciparum* account for 95% of infections. Some estimates indicate that *P. vivax* may account for 80% of the infections. This species also has the widest distribution, extending throughout the tropics, subtropics, and temperate zones. *P. falciparum* is generally confined to the tropics, *P. malariae* is sporadically distributed, and *P. ovale* is confined mainly to central West Africa and some South Pacific islands.

We usually associate malaria with patients having a history of travel within an area where malaria is endemic. However, other situations that may result in infection involve the receipt of blood transfusions, use of hypodermic needles contaminated by prior use (as with, for example, drug addicts), possibly congenital infection, and transmission within the United States by indigenous mosquitoes that acquired the parasites from imported infections (1).

With the exception of tuberculosis, malaria kills more people than any other communicable disease in the world. More than 300 million to 500 million individuals throughout the world are infected with malaria, and 1.5 million to 2.7 million people a year, most of whom are children, are being killed by the disease. More people are dying from malaria today than 30 years ago. Malaria is endemic in over 100 countries in which 2,400 million people live; this is approximately 50% of the world's population (2). The African countries, where 90% of the malaria deaths occur, are ravaged by warfare, and the richer nations that fund most malaria research are cutting budgets. Malaria prevention is difficult and no drug is universally effective. Vaccine development studies are under way but malarial vaccines are not yet widely used.

Although over 1,000 cases of malaria are reported to the Centers for Disease Control and Prevention each year, the actual number of cases may be much larger. There has been a definite increase in the number of cases of *P. falciparum* malaria reported, which may be related to increased resistance to chloroquine. In 2011, 1,925 cases were reported in the United States, which represents an increase of 14% from 2010 and the largest number of reported cases since 1971 (1). Of these cases, 1,920 cases were classified as imported, 1 laboratory-acquired case, 1 transfusion-related case, 2 congenital cases, and 1 cryptic case. Over 49% of the cases were *P. falciparum*, with 22% *P. vivax*, 2.6% *P. malariae*, 2.6% *P. ovale*, and 1% mixed infections. During 2011, no cases of *P. knowlesi* were reported in the United States, although 23% of the cases overall were undetermined to the species level. There were 91 cases involving military personnel.

It is important for both physicians and laboratorians within areas where malaria is not endemic to be aware of the difficulties related to malaria diagnosis and the fact that symptoms are often nonspecific and may mimic other

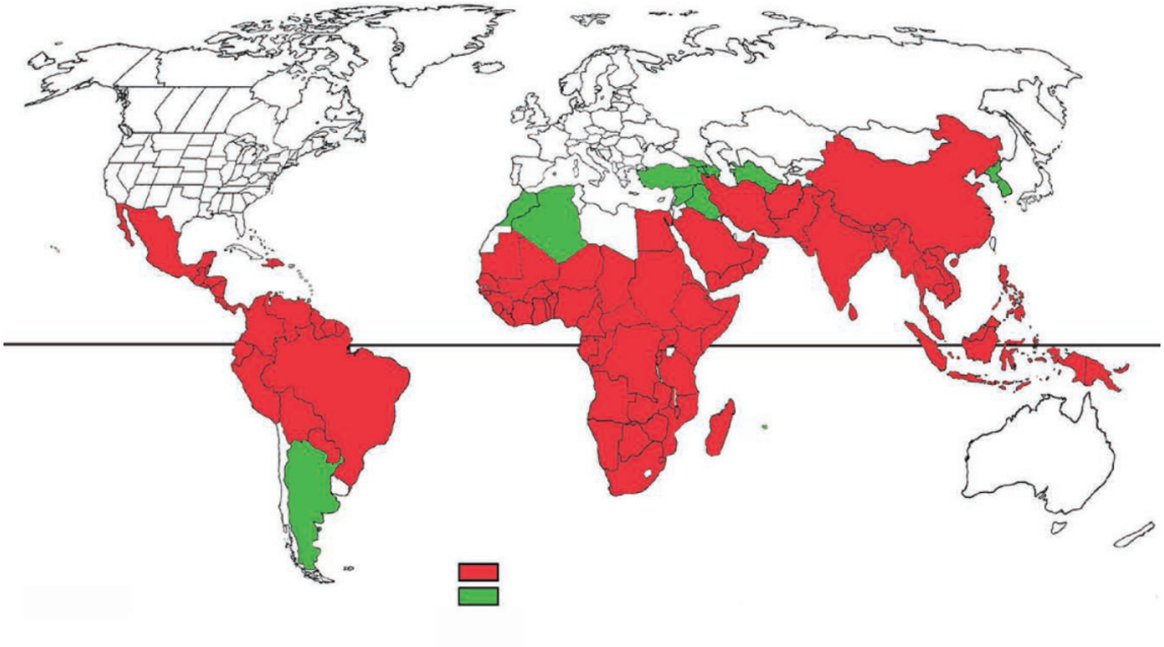

Figure 26.1 Countries where malaria is endemic; green indicates regions where *Plasmodium vivax* only is endemic (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch26.f1

problems. It is important for physicians to recognize that travelers are susceptible to malarial infection when they go to a country where malaria is endemic, and they should receive prophylactic medication. It is also important to remember that 80% of the *P. falciparum* cases acquired by American civilians are contracted in sub-Saharan Africa; currently there are 40 cities in Africa with over 1 million inhabitants, and by 2025 over 800 million people will live in urban areas. Malaria has always been a rural disease in Africa; however, it appears that the urban poor are at a much higher risk of contracting malaria than was previously recognized. These changes also have the potential to affect travelers to Africa.

With the tremendous increase in the number of people traveling from the tropics to malaria-free areas, the number of imported malaria cases is also on the rise. There have been reports of imported infected mosquitoes transmitting the infection among people who live or work near international airports. It is also possible that mosquitoes can reach areas far removed from the airports (3). This situation has been termed "airport malaria," i.e., malaria that is acquired through the bite of an infected anopheline mosquito by persons with apparently no risk factors for the disease. Unfortunately, unless a careful history is obtained, the diagnosis of malaria can be missed or delayed. Tests to exclude malaria should be considered for patients who work or live near an international airport and who present with an acute febrile illness. The potential danger of disseminating the mosquito vectors of malaria via aircraft is well recognized; however, modern disinfection procedures have not yet eliminated the risk of vector transportation. Not only can insects survive nonpressurized air travel, but also they may be transported further by car or other means after arriving at the airport. Contraction of airport malaria is certainly an unusual event, particularly considering that the number of air travelers is well over 1 billion annually. However, in addition to asking a patient, "Where have you been, and when were you there?" one should ask, "Where do you live?"

Potential contributing factors to malaria-related fatalities in U.S. travelers include (i) failure to seek pretravel advice, (ii) failure to prescribe correct chemoprophylaxis, (iii) failure to obtain prescribed chemoprophylaxis, (iv) failure to adhere to the chemoprophylaxis regimen, (v) failure to seek medical care promptly for their illness, (vi) failure to obtain an adequate patient history, (vii) delay in diagnosis of malaria, and (viii) delay in initiating treatment of malaria (4). One or more of these potential problems can lead to the death of the patient.

Life Cycle and Morphology

Pre-Erythrocytic Cycle. The vector for malaria is the female anopheline mosquito. When the vector takes a blood meal, sporozoites contained in the salivary glands of the

mosquito are discharged into the puncture wound (Fig. 26.2 and 26.3). Within an hour, these infective stages are carried via the blood to the liver, where they penetrate hepatocytes and begin to grow, thus initiating the pre-erythrocytic or primary exoerythrocytic cycle. Detailed study of sporozoite entry into the hepatocytes indicates that the process involves parasite-encoded surface proteins and host molecules. The sporozoites become round or oval and begin dividing repeatedly. This schizogony results in large numbers of exoerythrocytic merozoites.

Erythrocytic Cycle. Once these merozoites leave the liver, they invade the red blood cells (RBCs), thus initiating the erythrocytic cycle (Fig. 26.4 and 26.5). A secondary or

dormant schizogony may occur in *P. vivax* and *P. ovale* organisms, which remain quiescent in the liver until a later time. These resting stages have been termed hypnozoites (5). Delayed schizogony does not occur in *P. falciparum* and probably does not occur in *P. malariae* or *P. knowlesi*.

Recrudescence. The situation in which the RBC infection is not eliminated by the immune system or by therapy and the number in the RBCs begins to increase again with subsequent clinical symptoms is called a recrudescence. All species may cause a recrudescence.

True relapse. The situation in which the erythrocytic infection is eliminated and a relapse occurs later because of a new invasion of the RBCs from liver merozoites, called a recurrence or true relapse, theoretically occurs only in *P. vivax* and *P. ovale* infections.

Once the RBCs and reticulocytes have been invaded, the parasites grow and feed on hemoglobin. Within the RBC, the merozoite (or young trophozoite) is vacuolated, ring shaped, more or less ameboid, and uninucleate. The excess protein, an iron porphyrin, and hematin left over from the metabolism of hemoglobin combine to form malarial pigment (some workers use the term "hemozoin"; however, the term "malarial pigment" is used throughout this chapter).

Schizogony. Once the nucleus begins to divide, the trophozoite is called a developing schizont. The mature schizont contains merozoites (whose number depends on the species), which are released into the bloodstream. Many of the merozoites are destroyed by the immune system, but others invade RBCs, in which a new cycle of erythrocytic schizogony begins.

After several erythrocytic generations, some of the merozoites do not become schizonts but, rather, begin to undergo development into the male and female gametocytes. Whether this development is predetermined genetically or occurs as a response to some specific stimulus is unknown (6). It is likely that cells are committed to sexual development in the preceding round of asexual schizogony within the pre-erythrocytic schizont rather than differentiating following invasion of an RBC by uncommitted merozoites. Data also suggest that genetic and environmental factors may predispose *Plasmodium* spp. to switch from asexual to sexual development. Apparently, sexual commitment is highest in merozoites derived directly from the liver schizont, and there is a progressive loss of commitment with increasing numbers of asexual cycles. Environmental stimuli may relate directly to an increase in parasite density; there may also be some direct links between sublethal doses of chloroquine and an increase in gametocytogenesis, particularly in chloroquine-resistant parasites.

The asexual and sexual forms just described circulate in the bloodstream during infections by four of the *Plasmodium* species. However, in *P. falciparum* infections, as the parasite continues to grow, the RBC membrane becomes sticky and the cells tend to adhere to the endothelial lining of the capillaries of the internal organs. Thus, only the ring forms and the gametocytes (occasionally mature schizonts) normally appear in the peripheral blood.

Sporogony. If gametocytes are ingested when the mosquito takes a blood meal, they mature into gametes while in the mosquito gut. The male microgametes undergo nuclear division by a process called exflagellation, in which the microgametes break out of the RBC, become motile, and penetrate the female macrogamete, with the fertilized stage being called the zygote (Fig. 26.6). This zygote then becomes elongate and motile and is called the ookinete. This stage migrates to the mosquito midgut, secretes a thin wall, and grows into the oocyst, which extends into the insect's hemocele. Within a few days to 2 weeks, the oocyst matures, with the formation of hundreds to thousands of sporozoites. When the oocyst ruptures, the sporozoites are released into the hemocele and dispersed throughout the body, and some make their way into the salivary glands. When the mosquito next takes a blood meal, the sporozoites are injected with saliva into the host (Fig. 26.7).

Life Cycle within a Tube of Blood (EDTA). Unfortunately, when blood tubes are held at room temperature, especially with the cap removed, the process of exflagellation can occur within the blood. Subsequently, when the blood films are prepared, these microgametocytes can be confused with *Borrelia* spp. (7, 8). While the organisms are within the tube of blood, the life cycle continues, unlike the situation when fingerstick blood films are prepared. Thus, any delay in thick and thin blood film preparation can result in a loss of organisms, as well as multiple artifact problems.

Clinical Disease

From the time of the original mosquito bite until a week or more later, the patient remains asymptomatic. During this time, the organisms are undergoing multiplication (pre-erythrocytic cycle) in the liver. When the liver merozoites invade the RBCs, several broods begin to develop; however, one will eventually dominate and suppress the others, thus beginning the process of periodicity; this periodicity is very rarely seen in an immunologically naive patient early in the infection. Therefore, these patients with no prior exposure to malaria tend to be symptomatic early with a very low parasitemia and most often do not present as a possible malaria patient. Once the cycle is synchro-

nized, the simultaneous rupture of a large number of RBCs and liberation of metabolic waste by-products into the bloodstream precipitate the paroxysms of malaria.

Clinical symptoms of malaria include anemia, splenomegaly, and the classic paroxysm, with its cold stage, fever, and sweats. Although the febrile paroxysms strongly suggest infection, many patients who are seen in medical facilities, particularly in the early stages of the infection, do not exhibit the typical fever pattern. They may have fever or several small, random peaks each day. Since the symptoms associated with malaria are so nonspecific, the diagnosis should be considered in any symptomatic patient with a history of travel to an area where malaria is endemic. During the primary infection in a nonimmune host, the early fever episodes can affect density-dependent regulation of the parasite population, maintaining cycles of parasitemia and promoting synchronous parasite growth. The typical paroxysm begins with the cold stage and rigors lasting 1 to 2 h. During the next few hours, the patient spikes a high fever and feels very hot, and the skin is warm and dry. The last several hours are characterized by marked sweating and a subsequent drop in body temperature to normal or subnormal.

Anemia seen in malarial infections can be caused by a number of mechanisms, including (i) direct RBC lysis as a function of the life cycle of the parasite, (ii) splenic removal of both infected and uninfected RBCs (coated with immune complexes), (iii) autoimmune lysis of coated infected and uninfected RBCs, (iv) decreased incorporation of iron into heme, (v) increased fragility of RBCs, and (vi) decreased RBC production from bone marrow suppression.

Malaria can mimic many other diseases, such as gastroenteritis, pneumonia, meningitis, encephalitis, or hepatitis. Other possible symptoms include lethargy, anorexia, nausea, vomiting, diarrhea, and headache. Leukopenia can also be seen in malaria, as can an occasional elevated white blood cell (WBC) count with a left shift. Eosinophilia and thrombocytopenia may also be seen but are much less frequent. A clinical comparison of some of the features of the five different malarias is presented in Table 26.2. Information on the pathogenesis of malaria is provided in Fig. 26.8 and Tables 26.3 to 26.5.

***Plasmodium vivax*.** The primary clinical attack usually occurs 7 to 10 days after infection, although there are strain differences, with a much longer incubation period being possible. In some patients, symptoms such as headache, photophobia, muscle aches, anorexia, nausea, and sometimes vomiting occur before organisms can be detected in the bloodstream. In other patients, the parasites can be found in the bloodstream several days before symptoms appear (Tables 26.6 and 26.7).

During the first few days, the patient may not exhibit a typical paroxysm pattern but, rather, may have a steady low-grade fever or an irregular remittent fever pattern. Once the typical paroxysms begin, after an irregular periodicity, a regular 48-h cycle is established. An untreated primary attack may last from 3 weeks to 2 months or longer. The paroxysms become less severe and more irregular in frequency and then stop altogether. In 50% of patients, relapses occur after weeks, months, or up to 5 years (or more).

Severe complications are rare in *P. vivax* infections, although coma and sudden death or other symptoms of cerebral involvement have been reported. These patients can exhibit cerebral malaria, renal failure, circulatory collapse, severe anemia, hemoglobinuria, abnormal bleeding, acute respiratory distress syndrome, and jaundice (8, 9). Studies have confirmed that these were not mixed infections with *P. falciparum* but single-species infections with *P. vivax*. Recent data demonstrate that the infection comes

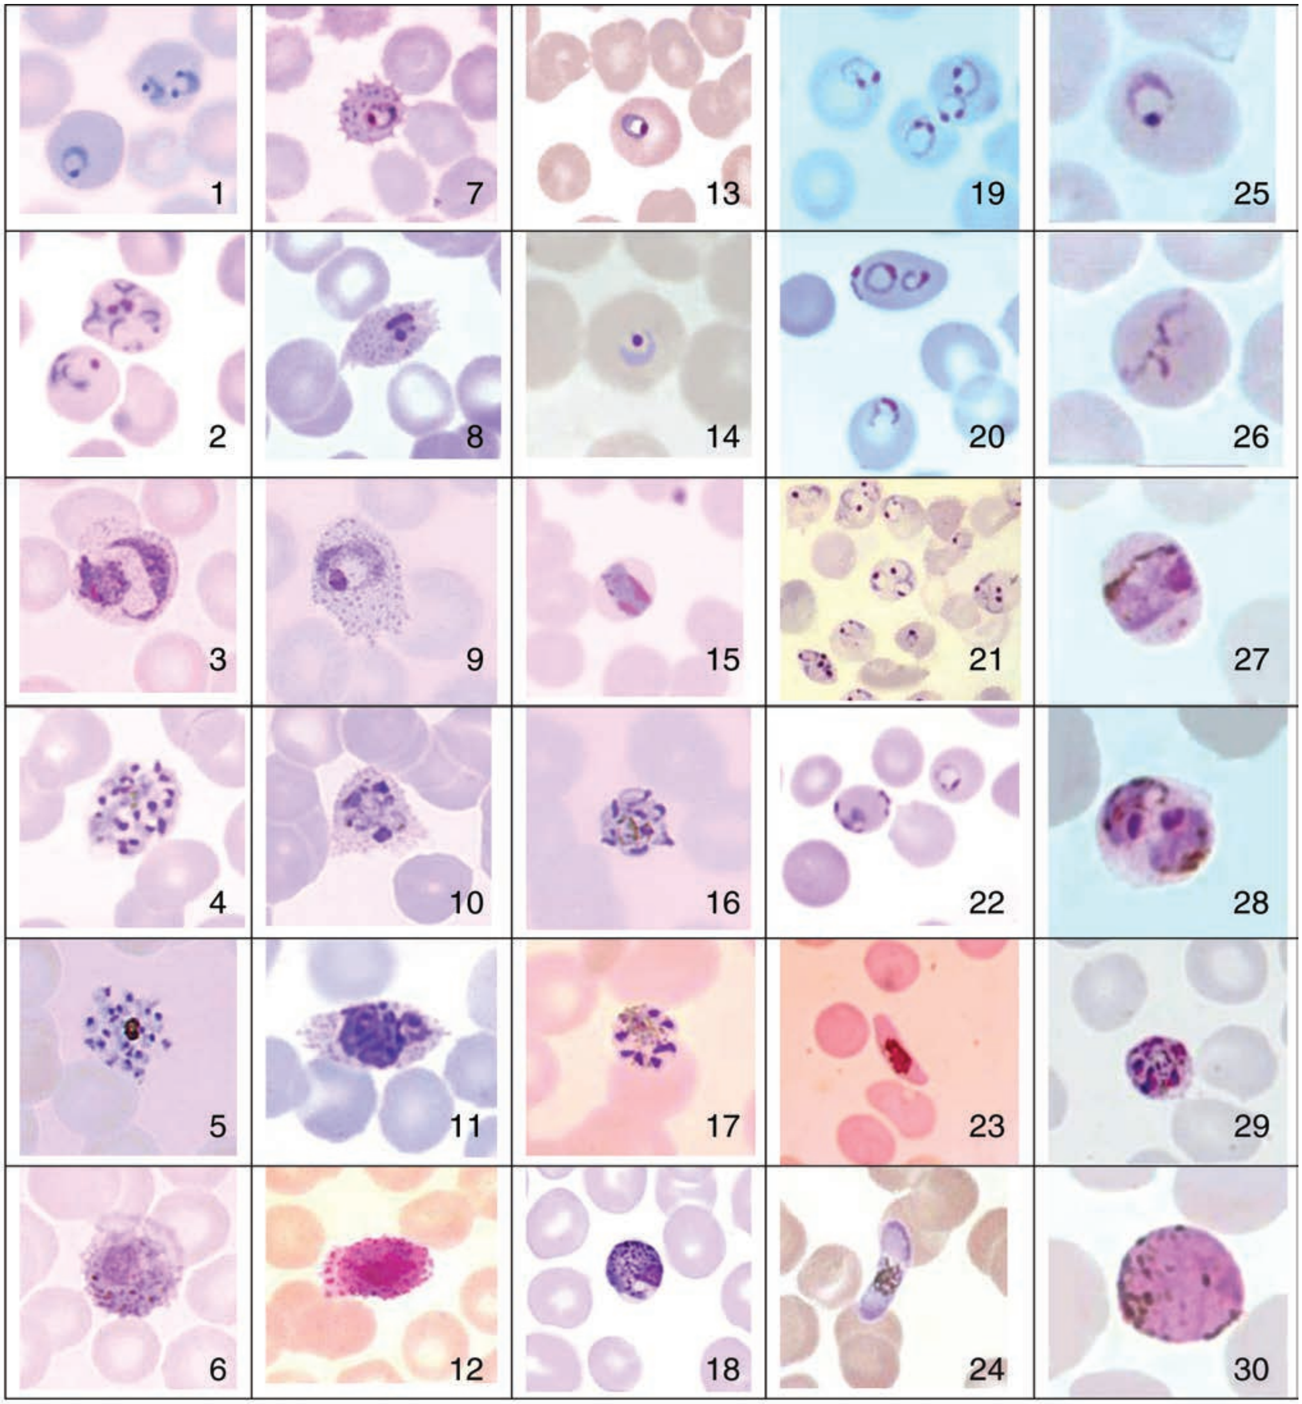
---

Figure 26.4 Morphology of malaria parasites. *Plasmodium vivax* (reading down): (1) early trophozoite (ring form); (2) late trophozoite with Schüffner's dots (note enlarged RBC); (3) late trophozoite with ameboid cytoplasm (very typical of *P. vivax*); (4) late trophozoite with ameboid cytoplasm; (5) mature schizont with 18 merozoites and clumped pigment; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Plasmodium malariae*: (1) early trophozoite (ring form); (2) early trophozoite with thick cytoplasm; (3) early trophozoite (band form); (4) late trophozoite (band form) with heavy pigment; (5) mature schizont with nine merozoites arranged in a rosette; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Plasmodium ovale*: (1) early trophozoite (ring form) with Schüffner's dots; (2) early trophozoite (note enlarged RBC); (3) late trophozoite in RBC with fimbriated edges; (4) developing schizont with irregularly shaped RBC; (5) mature schizont with eight merozoites arranged irregularly; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. *Plasmodium falciparum*: (1) early trophozoite (accolé or appliqué form); (2) early trophozoite (one ring is in the headphone configuration with double chromatin dots); (3) early trophozoite with Maurer's dots; (4) late trophozoite with larger ring and Maurer's dots; (5) mature schizont with 24 merozoites; (6) microgametocyte with dispersed chromatin; (7) macrogametocyte with compact chromatin. **Note:** Without the appliqué form, Schüffner's dots, multiple rings per cell, and other developing stages, differentiation among the species can be very difficult. It is obvious that the early rings of the four species shown in this figure can mimic one another very easily. *Remember: one set of negative blood films cannot rule out a malaria infection.* doi:10.1128/9781555819002.ch26.f4

with a significant burden of morbidity and associated mortality.

Since *P. vivax* infects only the reticulocytes, the parasitemia is usually limited to around 2 to 4% of the available RBCs (Fig. 26.9). Splenomegaly occurs during the first few weeks of infection, and the spleen progresses from being soft and palpable to hard, with continued enlargement during a chronic infection. If the infection is treated during the early phases, the spleen returns to its normal size.

Leukopenia is usually present; however, leukocytosis may be present during the febrile episodes. Concentrations of total plasma proteins are unchanged, although the albumin level may be low and the globulin fraction may be elevated. The increase in the concentration of gamma glob-



ulins is caused by the development of antibodies. The level of potassium in serum may also be increased as a result of RBC lysis.

***Plasmodium ovale*.** Molecular methods have confirmed the existence of two distinct nonrecombining species of *Plasmodium ovale* (classic type *Plasmodium ovale curtisi* and variant type *Plasmodium ovale wallikeri*). In one study, a significant finding was more severe thrombocytopenia among patients with *P. ovale wallikeri* infection than among those with *P. ovale curtisi* infection. Recent epidemiologic studies conducted by using PCR techniques have found *P. ovale* infections in most of sub-Saharan Africa, Southeast Asia, and the Indian subcontinent, including prevalence as high as 15% according to results of studies conducted in rural Nigeria and Papua New Guinea. In addition, severe complications such as spleen rupture, severe anemia, or acute respiratory distress syndrome may occur in patients with *P. ovale* malaria. Thus, the global burden of *P. ovale* infection might have been underestimated.

Although *P. ovale* and *P. vivax* infections are clinically similar, *P. ovale* malaria is usually less severe, tends to relapse less frequently, and usually ends with spontaneous recovery, often after no more than 6 to 10 paroxysms (Tables 26.6 and 26.7). Relapses occur as early as 17 days after treatment of the primary attack to as late as 255 days. Delayed primary attacks occur when the primary attack has been eliminated, usually with antimalarial drugs. Such infections have been reported after 4 years (Fig. 26.10).

The incubation period is similar to that seen in *P. vivax* malaria, but the frequency and severity of the symptoms are much lower, with a lower fever and a lack of typical rigors. *P. ovale* infects only the reticulocytes (as does *P. vivax*), so that the parasitemia is generally limited to around 2 to 4% of the available RBCs (10).

The geographic range has been thought to be limited to tropical Africa, the Middle East, Papua New Guinea, and Irian Jaya in Indonesia. However, infections with *P. ovale* in Southeast Asia may be the cause of benign and relapsing malaria in this region. In both Southeast Asia and Africa, two different types of *P. ovale* circulate in humans. Human infections with variant-type *P. ovale* are associated with higher parasitemias and thus have possible clinical relevance (11).

The Duffy blood group does not appear to be a controlling factor for infections with *P. ovale* as it does with *P. vivax*. There appears to be no difference in susceptibility to infection between Caucasians and African-Americans. Because of the resistance of individuals with negative Duffy blood group to infection with *P. vivax* and the high prevalence of negativity in populations of West Africa, surveys reporting *P. vivax* may actually represent infections with *P. ovale*.

***Plasmodium malariae*.** *Plasmodium malariae* invades primarily the older, more mature RBCs, so that the number of infected cells is somewhat limited (Fig. 26.11). The incubation period between infection and symptoms may be much longer than that seen with *P. vivax* or *P. ovale* malaria, ranging from about 27 to 40 days. Parasites can be found in the bloodstream several days before the initial attack, and the prodromal symptoms may resemble those of *P. vivax* malaria. A regular periodicity is seen from the beginning, with a more severe paroxysm, including a

Figure 26.5 Morphology of malaria parasites. Morphology of malaria parasites. Column 1 (top to bottom), *Plasmodium vivax* (note enlarged infected RBCs): (1) early trophozoite (ring form) (note one RBC contains two rings—not that uncommon); (2) older ring, note ameboid nature of rings; (3) late trophozoite with Schüffner's dots (note enlarged RBC); (4) developing schizont; (5) mature schizont with 18 merozoites and clumped pigment; (6) microgametocyte with dispersed chromatin. longer cold stage and more severe symptoms during the hot stage. Collapse during the sweating phase is not uncommon (Tables 26.6 and 26.7).

Proteinuria is common in patients with *P. malariae* infection; in children it may be associated with clinical signs of the nephrotic syndrome. It has been suggested that kidney problems may result from deposition within the glomeruli of circulating antigen-antibody complexes in an antigen excess situation seen with a chronic infection. Apparently, the nephrotic syndrome associated with *P. malariae* infections is unaffected by the administration of steroids. A membranoproliferative type of glomerulonephritis with relatively sparse proliferation of endothelial and mesangial cells is the most common type of lesion seen in *P. malariae* infection. Granular deposits of IgM, IgG, and C3 are seen in immunofluorescence assays (12, 13). Since chronic glomerular disease associated with *P. malariae* infections is usually not reversible with therapy, genetic and environmental factors may play a role in the nephrotic syndrome.

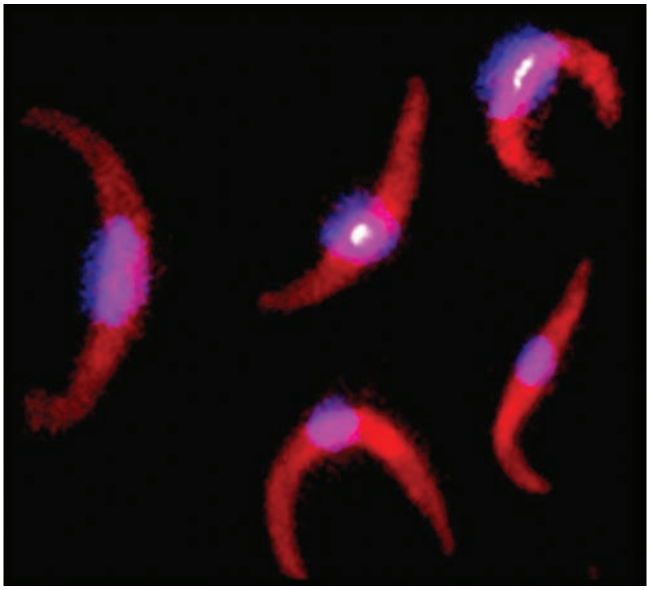

Figure 26.7 Malarial sporozoites from the mosquito vector.
doi:10.1128/9781555819002.ch26.f7

The infection may end with spontaneous recovery, or there may be a recrudescence or series of recrudescences over many years. These patients are left with a latent infection and persisting low-grade parasitemia for many, many years. *P. malariae* does not relapse from persistent liver stage parasites. However, the blood stage parasites persist for extremely long periods, perhaps for the life of the human host. There have been many reports of people who have left zones of endemicity whose infections have recrudesced, under stress, after many years of dormancy, or who have donated blood and the recipient has developed an infection. It is documented that these cases can recrudesce as long as 50 to 70 years after the original infection. Because almost all of these long-term infections have been detected following transfusion donations, it is believed that the parasites have persisted in the blood at very low densities with the patients remaining asymptomatic the entire time.

Plasmodium falciparum**.** *P. falciparum* tends to invade all ages of RBCs, and the proportion of infected cells may exceed 50%. Schizogony occurs in the internal organs (spleen, liver, bone marrow, etc.) rather than in the circulating blood. Ischemia caused by the plugging of vessels within these organs by masses of parasitized RBCs produces various symptoms, depending on the organ involved (Fig. 26.12). It has been suggested that a decrease in the

TABLE 26.2 *Plasmodium* spp.: characteristics of the five infections[a]

Infection parameter	*P. vivax*	*P. ovale*[b]	*P. malariae*	*P. falciparum*	*P. knowlesi*[c]	Comments

Figure 26.8 Pathogenesis of malaria. (Adapted from Markell EK, Voge M, *Medical Parasitology*, 5th ed, WB Saunders Co, Philadelphia, PA, 1981.) doi:10.1128/9781555819002.ch26.f8

ability of the RBCs to change shape when passing through capillaries or the splenic filter may lead to plugging of the vessels.

The onset of a *P. falciparum* malaria attack occurs 8 to 12 days after infection and is preceded by 3 to 4 days of vague symptoms such as aches, pains, headache, fatigue, anorexia, or nausea. The onset is characterized by fever, a more severe headache, and nausea and vomiting, with occasional severe epigastric pain. There may be only a feeling of chilliness at the onset of fever. Periodicity of the cycle is not established during the early stages, and the presumptive diagnosis may be totally unrelated to a possible malaria infection. If the fever does develop a synchronous cycle, it is usually a cycle of somewhat less than 48 h (Tables 26.6 and 26.7, Fig. 26.13).

An untreated primary attack of *P. falciparum* malaria usually ends within 2 to 3 weeks. True relapses from the liver do not occur, and after a year, recrudescences are rare.

Severe or fatal complications of *P. falciparum* malaria can occur at any time during the infection and are related to the plugging of vessels in the internal organs, with the symptoms depending on the organ(s) involved (Table 26.3). The severity of the complications in a malaria infection may not correlate with the parasitemia seen in the peripheral blood, particularly in *P. falciparum* infections. Acute lung injury is more likely to occur in patients with very severe, multisystemic *P. falciparum* malaria than in other malaria patients. When patients present with acute lung injury and septic shock, bacterial coinfection should be suspected and treated empirically.

Disseminated intravascular coagulation is a rare complication of malaria; it is associated with a high parasite burden, pulmonary edema, rapidly developing anemia, and cerebral and renal complications. Vascular endothelial damage from endotoxins and bound parasitized blood cells may lead to clot formation in small vessels.

Cerebral malaria is most often seen in *P. falciparum* malaria, although it can occur in the other types as well.

TABLE 26.3 Malaria pathophysiology[a]

Factor	Comments[b]
Parasite virulence factors	Multiplication capacity: rapidly expanding biomass outstrips host defenses; immunity reduces multiplication RBC selectivity: age of RBC determines level of parasitemia; less so for *P. falciparum* and *P. knowlesi*, both of which can infect all ages of RBCs Cytoadherence, rosetting: all four species can induce rosetting; *P. falciparum* causes cytoadherence; possible cytoadherence also likely in *P. knowlesi* infections Cytokine release: *P. falciparum* varies in ability to induce TNF release, even those derived from single genotype; anti-inflammatory cytokines IL-1ra and IL-10 associated with *P. knowlesi*; overall cytokine levels lower than those for patients with *P. falciparum* Antigenicity: in areas of endemic infection, parasites not recognized by the host will have relative growth advantage Drug resistance: antimalarial drugs widely available, self-medication common, selective pressure against drug-sensitive parasites
Parasite multiplication	At the onset of fever, approximaely 10^8 parasites in the body; corresponds to 20–20,000 parasites/µl of blood; in areas of endemic infection, patients may tolerate parasitemias up to 10,000/µl of blood without feeling ill; *P. falciparum* and *P. knowlesi* have ability to infect all RBCs and may exceed 50%
Parasite biomass	Loose positive correlation between parasitemia and prognosis in *P. falciparum* and *P. knowlesi* malaria; positive correlation between number of sequestered parasitized RBCs and severity of *P. falciparum* malaria
Toxicity and cytokines	Question of true toxin versus paroxysmal cytokine release due to nonspecific reaction to amount of particulate debris released into the circulation at schizont rupture; high concentrations of cytokines appear to be harmful, while lower levels probably benefit the patient; they are responsible for the typical symptoms of fever and malaise
RBC deformability	As the parasite grows, the normally flexible biconcave disk becomes more spherical and rigid, and the surface becomes irregular and covered with small protrusions; reduction in deformability results from reduced membrane fluidity, increasing sphericity, and enlarging, viscous intraerythrocytic parasite; also occurs in uninfected RBCs in acute malaria
Sequestration and pathology	RBCs adhere to microvascular endothelium (cytoadherence) and disappear from peripheral circulation (i.e., sequestration); greatest involvement is in brain, heart, kidney, intestines, and adipose tissue, least prominent is in skin; consequences of microcirculatory obstruction are reduced oxygen/substrate supply (anaerobic glycolysis and lactic acidosis)
Coma	Coma associated with 15–20% mortality; however, both adults and children recover without sequelae; thought to be metabolic or anesthetic encephalopathy (may involve neurotransmitter abnormalities and NO)
Intracranial pressure	Mild generalized increase in systemic vascular permeability in severe malaria; majority of patients with cerebral malaria do not have cerebral edema; all children with cerebral malaria (at some time) have elevated ICP; background rise in ICP probably results from increase in cerebral blood volume, independent of permeability
Immunological factors	Unlikely that cerebral malaria is due to immune-mediated damage; fatal falciparum malaria has lack of extravascular pathology; in cases of hypergammaglobulinemia, most antibody is not directed against malaria antigens; description suggests a "smoke screen" with broad-spectrum and nonspecific activation that interferes with the development of a specific cellular immune response; exception may be nephrotic syndrome caused by *P. malariae* and antigen-antibody immune complex formation in the kidneys
Renal failure	Basic pathology is acute tubular necrosis; urine sediment unremarkable, sodium level in urine low, blood pressure normal; no proof, but renal microvascular obstruction due to sequestration in kidneys may be responsible; glomerulonephritis is very rare in acute malaria, and renal necrosis does not occur; renal complications more common with *P. malariae* and *P. knowlesi*
Pulmonary edema	Pulmonary function usually normal; pregnant women with severe falciparum malaria at risk for sudden, acute pulmonary edema (resulting from a sudden increase in pulmonary capillary permeability); cause not known
Respiratory distress syndrome	Acute and late-onset respiratory distress syndrome seen; included in WHO guidelines for severe malaria in the nonimmune (immunologically naive, no prior exposure to malaria), *P. falciparum*, *P. knowlesi*
Cardiovascular function	Pump function not a problem in severe malaria; may be autonomic dysfunction in acute malaria (postural hypotension associated with impaired cardioacceleration), but may be common to all febrile infections

(continued)

TABLE 26.3 Malaria pathophysiology[a] *(continued)*

Factor	Comments[b]
Fluid space; electrolyte changes	Patients may be dehydrated; mild hyponatremia and hypochloremia are common, but potassium levels are usually normal (in spite of hemolysis); after rehydration, total body water and extracellular volume are normal
Anemia	In general, degree of anemia corresponds to duration and severity of infection; obligatory destruction of RBCs due to life cycle; accelerated destruction of nonparasitized RBCs correlates with disease severity; condition is compounded by bone marrow dysfunction; factors that trigger removal of nonparasitized RBCs not fully explained; RBC survival reduced in malaria (not affected by corticosteroids); reduced oxygen carriage; past explanation of death due to congestive cardiac failure may be due to tissue hypoxia and severe metabolic acidosis
Coagulopathy and thrombocytopenia	Accelerated coagulation cascade activity with accelerated fibrinogen turnover; moderate thrombocytopenia common in *P. falciparum* and *P. vivax* malaria, caused by splenic clearance; DIC no longer considered important in pathogenesis of malaria
Blackwater fever	Massive intravascular hemolysis and passage of dark red, brown, or usually black urine; occurs when patients with G6PD deficiency take oxidant drugs (whether or not they have malaria), when G6PD-deficient patients have malaria and receive treatment with quinine or artemisinin derivatives, and when some patients with normal G6PD levels are treated with quinine or artemisinin derivatives; blackwater fever is not usually accompanied by renal failure, although renal impairment is common; can be seen with all species (more severe with *P. falciparum*)
Spleen	Rapid splenic enlargement for removal of parasitized RBCs; may also modulate cytoadherence, but mechanism is not known
Gastrointestinal tract	Minor ulceration of stomach and duodenum common in severe malaria; may be reduced splanchnic perfusion (malabsorption of sugars, fats, and amino acids); may be increased gut permeability
Liver	Hepatic dysfunction usually seen in severe malaria; jaundice common (hemolytic, hepatic, cholestatic components); reduced clotting factor synthesis, metabolic drug clearance, and biliary excretion; failure of glyconeogenesis (lactic acidosis and hypoglycemia); liver blood flow may be reduced or may be elevated
Acidosis	Consistent feature; arterial, capillary, venous, and CSF lactate concentrations rise in direct proportion to disease severity; majority of lactic acid produced in malaria derives from host rather than parasite; also feature of severe *P. knowlesi* infection
Hypoglycemia	Closely associated with hyperlactatemia; hypoglycemia leads to nervous system dysfunction and is associated with residual neurological deficit in survivors of cerebral malaria; does not tend to be an issue with *P. knowlesi* malaria
Placenta	Pregnancy increases susceptibility to malaria (suppression of systemic and placental cell-mediated immune responses); intense sequestration of *P. falciparum*-infected RBCs in placenta and maternal anemia; leads to placental insufficiency and fetal retarded growth; maternal mortality approaches 50%, and fetal death usual; high incidence of cerebral malaria, hypoglycemia, and pulmonary edema; *P. vivax* also linked to reductions in birth weight, suggesting that systemic effects of malaria may be more important than previously recognized
Coincident infections	Patients vulnerable to other infections, including other species of malaria; relationship to HIV also questionable; chronic hepatitis B virus carriage also associated with increased risk of severe malaria

[a] Adapted from references 2, 9, 10, 12, 23, and 75–78.

[b] CSF, cerebrospinal fluid; DIC, disseminated intravasular coagulopathy; G6PD, glucose-6-phosphate dehydrogenase; ICP, intracranial pressure; IL, interleukin; NO, nitric oxide; TNF, tumor necrosis factor.

If the onset is gradual, the patient may become disoriented or violent or may develop severe headaches and pass into coma. Some patients, even those who exhibit no prior symptoms, may suddenly become comatose. Physical signs of central nervous system (CNS) involvement are quite variable, and there is no real correlation between the severity of the symptoms and the peripheral blood parasitemia. It has been shown that patients with cerebral malaria were infected with RBC rosette-forming *P. falciparum* and that plasma from these patients generally had no antirosetting activity. A rosette usually consists of a parasitized RBC surrounded by three or more uninfected RBCs (Fig. 26.14A). Interaction with adjacent uninfected RBCs in rosettes appears to be mediated by knobs seen on the parasitized RBC (Fig. 26.14B) (14). In contrast, *P. falciparum* parasites from patients with mild malaria lacked the rosetting phenotype or had a much lower rosetting rate. Also, antirosetting activity has been detected in the plasma of these patients. These findings strongly support the idea that RBC rosetting contributes to the pathogenesis of cerebral malaria while antirosetting antibodies offer protection against these clinical sequelae.

Interplay among many factors, including free oxygen radicals and other mediators of inflammation, is likely to

TABLE 26.4 *Plasmodium* pathogenesis and sequelae

Clinical situation and condition	Comments[a]	Reference(s)
Chronic malaria in West Africa	West Africa; SLVL and hyperreactive malarial splenomegaly have clinical and immunological features in common. Dysregulated immune response to repeated malaria infections results in a stimulated, proliferating pool of B cells; environmental and other factors promote the development of SLVL. Several infectious agents have been associated with B-cell non-Hodgkin's lymphomas.	79
Clinically severe malaria; 489 patients in Zimbabwe	Malaria and blood group A patients had lower hemoglobin levels; also at higher risk of coma than patients in other blood groups	80
64 *P. falciparum* patients in eastern Sudan; plasma samples and seasonal agglutination of infected RBCs	First demonstration of marked seasonal fluctuations in capacity of sera to agglutinate parasitized RBCs; may reflect drop in levels of agglutinating antibodies between seasons or shifts in antigens being recognized from one transmitting season to the next	81
Cerebral malaria (*P. falciparum*); 250,000 Vietnam veterans	CM results in multiple, major, substantially underappreciated neuropsychiatric symptoms in Vietnam veterans (poor dichotic listening, "personality changes," depression, and, in some cases, partial seizure-like symptoms). History of malaria needs to be assessed in workup of any Vietnam veteran; positive response could dramatically change diagnosis and therapy. VEGF and its receptor-related molecules are overexpressed in the brain tissues of CM patients. Factors associated with CM are (from most important): pulmonary edema, splenomegaly, fever, high parasitemias, dyspnea, hepatomegaly, higher systolic blood pressure, higher body mass index.	82–84
Bone marrow transplantation in recipient of multiple blood transfusions	*P. falciparum* trophozoites and gametocytes found on peripheral blood smears	85
Problem with donors living in high-risk areas	11/420 patients (2.6%) positive for *P. falciparum* (mean time 22 + 44 days)	86
Both donor and recipient checked prior to BMT	Recommendation for treatment prior to harvest and conditioning of cells, regardless of smear results; patient infection with *P. falciparum* 11 days after stem cell transplant; critical to check donor/recipient in areas of endemicity	87, 88
Case of unrelated donor	Case of *P. vivax* infection, donor asymptomatic 11 months prior to donation	89
Relapse of primary unidentified infection	Case of *P. vivax* infection after BMT	90
Case of pancytopenia after 70 days	Case of *P. vivax* infection after BMT; always consider malaria in the differential	91
Severe *P. falciparum* malaria; 24 adults (NO)	No support for the hypothesis that excessive NO production contributes to the pathogenesis of severe falciparum malaria. However, local changes in NO production (CNS) might not be reflected in total production or levels in the CSF.	92, 93
NO production varies throughout childhood (African children)	NO levels high in infancy, decrease after first year of life, then increase again after 5 yr of age. Elevated NO in both infants and older children may be related to age and malaria infection, respectively, and may be one of the mediators of anti-disease immunity in these two age groups.	94
NO production related to anemia (Tanzania)	NO production was inversely associated with hemoglobin concentration; thus, it is not a predictor of anemia after correction of age/gender data.	95
Cerebral malaria (*P. falciparum*)	Identification of rare *P. falciparum* parasites expressing a panadhesive phenotype linked to RBC rosetting (correlate of CM)	96
	Parasitized RBCs may bind integrin $\alpha_v\beta_3$ on microvascular endothelial cells; sequestration leads to cerebral malaria.	97
	Binding of parasitized RBCs to cerebral endothelial cells leads to functional changes in the blood-brain barrier in CM.	98
Adhesion phenomena (*P. falciparum*)	Cytoadherence begins at 12 h and peaks at 28 h; rosette formation (16–20 h); rosette formation and immunoglobulin binding rate of about 50% (24–36 h)	99
Molecular mechanisms of cytoadherence (*P. falciparum*)	Cytoadherence may activate intracellular signaling pathways in both endothelial cells and infected RBCs, leading to gene expression of mediators such as cytokines, which could modify the outcome of the infection.	100, 101
RBC deformability (*P. falciparum*)	Reduced deformability of uninfected RBCs at high shear stresses and subsequent splenic removal of these cells may be an important contributor to anemia of severe malaria.	92

(continued)

TABLE 26.4 *Plasmodium* pathogenesis and sequelae *(continued)*

Clinical situation and condition	Comments[a]	Reference(s)
Eosinophil activity (*P. falciparum*)	Appears that low eosinophil counts may be due to tissue sequestration and destruction rather than decreased production; levels of eosinophilia granule proteins in plasma correlated with levels of TNF and soluble IL-2 receptor, implicating inflammatory responses and T-cell activation as causes of eosinophil activation	102
Fatal malaria (*P. falciparum*) in African children	Three clinical syndromes: severe anemia, CM, malaria-associated hyperapnea (increased rate and depth of breathing); "respiratory distress" may be misleading, malaria hyperapneic syndrome (severe systemic acidosis) may not be recognized in conscious children	103
Frequent parasitemias with *P. falciparum* (asymptomatic); children in Tanzania	Asymptomatic (especially polyclonal) *P. falciparum* infection protects against clinical disease due to new parasites.	104
Maternal and infant mortality (*P. falciparum*)	Accumulation of large numbers of infected RBCs in maternal blood spaces of placenta may be mediated by adhesion of infected RBCs to molecules on the syncytiotrophoblast surface. Parasites infecting pregnant women may be antigenically distinct from those common in childhood disease.	105
P. vivax malaria	Although *P. vivax* is seldom fatal, it is a major cause of morbidity. *P. vivax*-infected RBCs form rosettes like those seen in *P. falciparum* infections.	9, 106
P. malariae malaria	Blood stage parasites may persist for the life of the host; immune complexes in kidneys may cause structural glomerular damage.	12
P. ovale malaria	Two types of *P. ovale* based on nucleotide deletions and substitutions in the 18S rRNA gene; these parasites have been found to coexist in Vietnam, Thailand, and Myanmar; generally least severe of 5 human species of malaria	10
P. knowlesi malaria	Endemic in Malaysian Borneo; very short life cycle (24 h); early infection mimics *P. falciparum*, older stages mimic *P. malariae*; can infect all ages of RBCs with high parasitemias like those seen in *P. falciparum* malaria; can result in fatal outcome	75

[a] BMT, bone marrow transplantation; CM, cerebral malaria; CSF, cerebrospinal fluid; IL-2, interleukin-2; NO, nitric oxide; SLVL, splenic lymphoma with villous lymphocytes; TNF, tumor necrosis factor; VEGF, vascular endothelial growth factor.

be involved in the pathogenesis of cerebral malaria (2, 15). Sequestration often predisposes to cerebral symptoms but in ways not necessarily restricted to obstruction of blood flow. Tumor necrosis factor alpha and other pyrogenic cytokines play a role in the regulation of parasite density in the host; cerebral malaria is also thought to be related to excessive tumor necrosis factor alpha.

Magnetic resonance imaging of the brains of patients with cerebral malaria shows that the volume of the brain is increased. This increased volume probably results from sequestration of parasitized RBCs and compensatory vasodilatation rather than from edema. Brain stem herniation may occur, but its temporal relation to brain death in patients with cerebral malaria is still unclear. Ultrastructural study of the brain in patients with fatal *P. falciparum* infections reveals that sequestration of parasitized RBCs in cerebral microvessels is much higher in the brains of patients with cerebral malaria (cerebrum, cerebellum, and medulla oblongata) than in the brains of patients with noncerebral malaria. There were 26.6 times more parasitized RBCs in the brain microvasculature than in the peripheral blood (2).

Extreme fevers, 107°F (ca. 41.7°C) or higher, may develop in a relatively uncomplicated attack of malaria or may develop as another manifestation of cerebral malaria. Without vigorous therapy, the patient usually dies. Cerebral malaria is considered to be the most serious complication and the major cause of death from infection with *P. falciparum*; this complication accounts for up to 10% of all *P. falciparum*-infected patients admitted to the hospital and for 80% of fatal cases.

Bilious remittent fever involves the liver, with symptoms including abdominal pain, nausea, and severe and persistent vomiting, with the vomitus containing evidence of bile or fresh blood. There may also be severe diarrhea or dysentery with resulting dehydration. The liver is large and tender, the skin becomes icteric, and the urine contains bile.

Diarrhea or dysentery without liver involvement or jaundice is also seen, with malabsorption characterized by decreased absorption of D-xylose and vitamin B_{12} and a low carotene level. Jejunal biopsy reveals edema, round cell infiltration of the lamina propria, and blunting of villi, which have also been found on postmortem examinations.

Algid malaria symptoms include circulatory collapse; low blood pressure; hypothermia; rapid, thready pulse; and pale, cold, clammy skin. There may be severe abdominal pain, vomiting and diarrhea, and muscular cramps. At postmortem examination, the adrenal glands are congested, necrotic, and hemorrhagic. In the subacute stage

TABLE 26.5 Immunopathology of malaria[a]

Pathology	Identified or possible mechanisms[b]
Autoimmunity	Autoantibodies Antinuclear antibodies
Immunosuppression	Antigenic competition Decreased lymphocyte production Disruption of spleen function Macrophage dysfunction Polyclonal activation and immune system "exhaustion"
Hypergammaglobulinemia	Ag-induced cytokine production (IL-6)
Anemia	Anti-RBC antibodies Decrease in RBC production (effect of TNF) Increased RBC destruction Iron deficiency
Thrombocytopenia	Increased platelet removal Coating of platelets with malarial antigen; subsequent platelet destruction
Hyperactive malarial splenomegaly	Genetic predisposition Hypogammaglobulinemia Chronic increase of lymphocyte proliferation
Nephrotic syndrome	Immune complex (Ag-Ab) deposition on kidney glomeruli Autoimmunity

[a] Adapted from references 78, 107, and 108.
[b] Ab, antibody; Ag, antigen; IL, interleukin; TNF, tumor necrosis factor.

and after recovery, some patients develop signs resembling Addison's disease.

Although infrequent, blackwater fever is most often associated with *P. falciparum* malaria. Usually, there is a history of previous malarial attacks. Sudden, intravascular hemolysis results in a dramatic color change in the urine (acidic urine with a high methemoglobin content). Since the hemoglobinuria does not necessarily give rise to symptoms, the onset may be missed. Quinine sensitivity has been postulated as one possible factor leading to blackwater fever. Another has been the presence of antibodies acting as hemolysins against RBC antigens. The parasitemia may be relatively low in patients with blackwater fever. With the increased use of quinine to treat chloroquine-resistant patients who live in areas with malaria, more cases of blackwater fever may be seen in the future.

Acute renal failure may also occur unassociated with blackwater fever and hemolytic anemia. Renal anoxia is thought to lead to tubular necrosis. The nephrotic syndrome, caused by acute glomerulonephritis, has also been found in some patients with *P. falciparum* malaria.

Independent risk factors contributing to anemia in falciparum malaria in patients presenting with anemia on admission include age younger than 5 years, a palpable spleen, a palpable liver, recrudescent infections, being female, a history of prolonged history of illness (>2 days) before admission, and pure *P. falciparum* infections rather than mixed infections with *P. falciparum* and *P. vivax*. It appears that coinfection with *P. vivax* can modify the severity of the disease.

TABLE 26.6 Parasitemia determined from conventional light microscopy: clinical correlation[a]

Parasitemia (%)	No. of parasites/µl	Clinical correlation[b]
0.0001–0.0004	5–20	Number of organisms that are required for a positive TBF (sensitivity) **Note (TBF):** Examination of 100 TBF fields (0.25 µl) may miss up to 20% of infections (sensitivity, 80–90%); at least 300 TBF fields should be examined before reporting a negative result **Note (THBF):** Examination of 100 THBF fields (0.005 µl); at least 300 THBF fields should be examined before reporting a negative result; *both* TBF and THBF should be examined for every specimen submitted for a suspect malaria case. **One set (TBF + THBF) of negative blood films does not rule out a malaria infection.**
0.002	100	Naive patients may be symptomatic below this level; remember emergency room patients and travelers.
0.1	5,000	BinaxNOW (maximum sensitivity); patients with low parasitemias will often have a false-negative rapid test; if negative, then STAT thick and thin films are required.
0.2	10,000	Level above which immune patients will exhibit symptoms
2	100,000	Maximum parasitemia of *P. vivax* and *P. ovale* (infect young RBCs only) (rarely may exceed 2%)
2–5	100,000–250,000	Hyperparasitemia, severe malaria,[c] increased mortality
10	500,000	Exchange transfusion may be considered, high mortality

[a] Adapted from references 23 and 109.
[b] TBF, thick blood film; THBF, thin blood film.
[c] WHO criteria for severe malaria are parasitemia of >10,000/µl and severe anemia (hemoglobin, <5 g/liter). Prognosis is poor if >20% of parasites are pigment-containing trophozoites and schizonts and/or if >5% of neutrophils contain visible pigment.

TABLE 26.7 Malaria characteristics

Organism	Characteristics
Plasmodium vivax (benign tertian malaria)	48-h cycle Tends to infect young cells (reticulocytes) Enlarged RBCs Schüffner's dots (true stippling) after 8–10 h Delicate ring; occasionally may see 2 rings/cell (like *P. falciparum*) Very ameboid trophozoite Mature schizont contains 12–24 merozoites
Plasmodium malariae (quartan malaria)	72-h cycle (long incubation period) Tends to infect old, mature cells Normal-size to small RBCs No stippling Thick ring, large nucleus Trophozoite tends to form "bands" across the cell Mature schizont contains 6–12 merozoites (rosette or "daisy")
Plasmodium ovale	48-h cycle Tends to infect young cells (reticulocytes) Enlarged RBCs (may or may not always be oval) with fimbriated edges Schüffner's dots appear in the beginning (in RBCs with very young ring forms, in contrast to *P. vivax*) Smaller ring than *P. vivax* Trophozoite less ameboid than that of *P. vivax* Mature schizont contains average of 8 merozoites
Plasmodium falciparum (malignant tertian malaria)	36–48-h cycle Tends to infect any cell regardless of age; thus, very heavy infection may result All sizes of RBCs No Schüffner's dots (Maurer's dots: may be larger, bluish, single dots) Multiple rings/cell (only young rings, gametocytes, and occasional mature schizonts seen in peripheral blood) (in severe, very high parasitemia cases, other blood stages may be seen) Delicate rings; may have 2 dots of chromatin per ring ("headphones"), appliqué or accolé forms Crescent-shaped gametocytes; takes approximately 10 days to appear
Plasmodium knowlesi (simian malaria)	~24-h cycle Tends to infect any cell regardless of age; thus, very heavy infection may result All sizes of RBCs, but most tend to be normal size No Schüffner's dots (faint, clumpy dots later in cycle) Multiple rings/cell (may have 2–3) Delicate rings; may have two dots of chromatin/ring ("headphones"), appliqué or accolé forms Band form trophozoites commonly seen Mature schizont contains 16 merozoites, no rosettes Gametocytes round, tend to fill the cell **Note:** Early stages mimic *P. falciparum* ring forms; later stages mimic *P. malariae* band forms, etc. (often misdiagnosed as a *P. falciparum/P. malariae* mixed infection)

In African children with malaria, the presence of impaired consciousness or respiratory distress can identify those at high risk of death. Biochemical evidence of hepatic and renal dysfunction also suggests a poor prognosis; however, in contrast to adults with malaria, children with severe malaria do not always have acute renal failure.

Using several different approaches, it is estimated that approximately 100,000 infant deaths in Africa could be attributed to malaria during pregnancy, resulting in low-birth-weight babies. Antimalarial intermittent preventive treatment during pregnancy has been estimated to prevent the death of 22,000 children younger than 5 years through reduced numbers of preterm deliveries. However, if one assumes an efficacy rate of 80% in preventing placental malaria, the number of deaths prevented may be closer to 80,000.

Plasmodium knowlesi**.** In addition to the Kapit Division of Sarawak in Malaysian Borneo, there have also been reports of locally acquired *P. knowlesi* infections from Southern Thailand, the Myanmar-China border, the Philippines, and Singapore, indicating that transmission occurs in many Southeast Asian countries (Fig. 26.15). *P. knowlesi* is primarily a chronic infection of the long-tailed (*Macaca fascicularis*) and pig-tailed (*Macaca nemestrina*) macaques (Fig. 26.16). The early stages are easily confused with *P. falci-*

parum, while the later stages mimic *P. malariae* on blood film microscopy in cases of human infection. The erythrocyte invasion by *P. knowlesi* is not limited to young or old cells, which allows high parasitemia, and development of the parasite in erythrocytes is asynchronous (Fig. 26.17, Tables 26.6 and 26.7).

P. knowlesi is relatively closely related with *P. vivax*; therefore, it is not surprising that infections with these two species share some common features, such as occasional severity and marked thrombocytopenia. However, disease caused by *P. knowlesi* is somewhat more severe than disease caused by *P. vivax*, although vivax malaria can also be severe in a significant number of cases, at least in certain regions (severe malaria in ~3%, compared with 7 to 10% in individuals with *P. knowlesi* malaria).

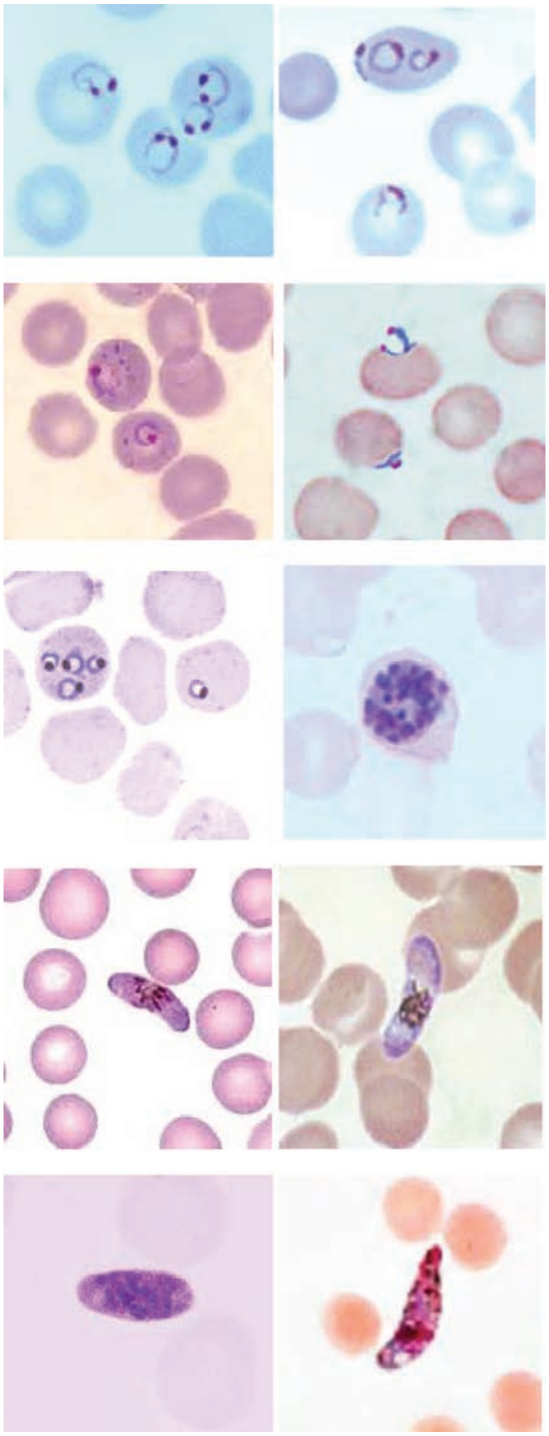

Figure 26.13 *Plasmodium falciparum*. (Top and row 2) *P. falciparum* ring forms. Note the double rings per cell, appliqué or accolé form, and headphone appearance of some rings; also note Maurer's clefts in the RBCs (row 2, left). (From reference 101 with permission.) doi:10.1128/9781555819002.ch26.f14

In Malaysia, the patients with *P. knowlesi* infection typically present with a febrile illness with daily fever and chills. Other frequent symptoms included headache, rigors, malaise, myalgia, abdominal pain, breathlessness, and productive cough. Tachypnea, pyrexia, and tachycardia were common clinical signs. Although the patients had thrombocytopenia at hospital admission or on the following day, none had clinical coagulopathy. At hospital admission, only a few of the patients had anemia, whereas mild hepatic

Figure 26.15 *Plasmodium knowlesi* infections reported in humans and macaques and limits of natural distribution of mosquito vectors and of macaques. The numbers in parentheses represent numbers of *P. knowlesi* cases reported for each Southeast Asian country or region in Malaysia. (Courtesy of reference 75.) doi:10.1128/9781555819002.ch26.f15

dysfunction was relatively common. The great majority of patients (94%) experienced no complications, and the infection responded well to chloroquine and primaquine treatment (16–18). In patients with severe infections, the most frequent complication was respiratory distress.

P. knowlesi is unique among the primate and human malarias in that it has a 24-h erythrocytic cycle, which tends to accelerate the development of complications. Information on the characteristics of knowlesi malaria in humans indicates that the levels of parasitemia vary over a wide range among different patients. The *P. knowlesi* parasitemia at hospital admission tends to be strongly and independently associated with renal dysfunction; renal failure is seen despite interventions. Unlike serious cases of *P. falciparum*, neurological symptoms with *P. knowlesi* are rare, and no cases of cerebral malaria have been reported (18). However, autopsy findings in a fatal case of *P. knowlesi* malaria indicate that *P. knowlesi*-infected red cells can sequester in capillaries of the brain, heart, and kidneys. In some of the fatal cases, a high parasitemia was seen (15%, >10%, and >10 parasites per high-power microscope field).

Since *P. knowlesi* malaria can progress rapidly to severe disease, these presumptive cases should be treated like *P. falciparum* malaria if the species identification is based on microscopic examination alone or if coinfection with *P. falciparum* cannot be excluded with certainty using PCR. It is important to remember that diagnostic results should include a comment: "Unable to rule out *P. falciparum* or *P. knowlesi*." This information alerts the physician to the possibility of severe disease and possible fatal outcomes. This approach is particularly important if the microscopic examination of blood films suggests *P. malariae* but the patient has severe disease, a high parasitemia (>0.1%), or a recent history of visiting woods or their vicinity in Southeast Asia. Unfortunately, neither the pLDH- nor aldolase-based rapid tests demonstrate sufficiently high overall sensitivity for *P. knowlesi*. More sensitive rapids are

needed in regions of *P. knowlesi* endemicity; new test development is currently under way.

Mixed Infections. Coincident infection with more than one species of malaria is more common than previously suspected. As an example, in Thailand, up to 30% of patients who present with severe *P. falciparum* malaria are also infected with *P. vivax*. Based on overlapping geographic areas where both *P. falciparum* and *P. vivax* are found, it is not surprising that dual infections occur. In Africa, dual infections with *P. falciparum* and *P. malariae* have also been found. Although the figures may be underestimates, in Gambian children the prevalence of mixed-species infection varies from <1% to >60%. There has even been a report of a rare quadruple malaria infection in a remote area in the western half of New Guinea Island (Irian Jaya Province, Indonesia); this infection was confirmed using nested PCR and species-specific primer pairs (19). In Africa, *P. ovale* occurs commonly in areas with Duffy-negative populations who are refractory to *P. vivax*, thus appearing to prevent the natural coexistence of the two species. However, the Duffy blood group-negative trait that protects many African populations from *P. vivax* infection is considered very rare or nonexistent in New Guinea. Since *P. ovale* is considered a very unusual finding outside of Africa, the natural occurrence of *P. ovale* and *P. vivax* together in the same patient is considered a very rare finding. It is also likely that this population could also become infected with the fifth human malaria, *P. knowlesi*.

Although antagonism and predominance of one *Plasmodium* species over the other in the human host have been described, differences in the methods and sensitivity of detection may have complicated the interpretation of results. It is generally accepted that *P. falciparum* predominates over *P. vivax* in mixed infections. *P. ovale* has been found in mixed infections and has been established in persons carrying *P. falciparum*, *P. vivax*, and *P. malariae* at the same time. Simultaneous patent infections with three or four *Plasmodium* species are not entirely rare findings in the blood of healthy carriers in regions of hyperendemic infection.

Interaction between *P. falciparum* and *P. vivax* is often reported to be suppressive. There are reciprocal seasonal changes in the prevalence of the two species that cannot be explained by changes in vector behavior, antimalarial drug use, or age. Changes may be due to competition for host cells, since *P. falciparum* causes dyserythropoiesis, leading to a decreased number of reticulocytes available for invasion by *P. vivax*. It is possible that some cross-species immunity may be involved. Also, patients with mixed *P. falciparum-P. vivax* infections are four times less likely to exhibit patent gametocytemia than were those with a *P. falciparum* infection alone. Thus, coinfection with *P. vivax* may attenuate infections with *P. falciparum*. Also, there appear to be no limitations to vector infections with multiple species of malaria, and transmission of more than one species to humans has been documented from a single mosquito.

Detection of mixed infections can be difficult due to different levels of parasitemia, low organism densities, and confusion among various morphologic criteria for identification to the species level; these problems have been well documented. Using PCR methods, it is likely that a higher detection rate of chronic and mixed malarial species will be possible (19).

Diagnosis

Although malaria is no longer endemic within the United States, it is considered to be life-threatening, and laboratory requests for blood smear examination and organism identification should be treated as STAT requests. Malaria is usually associated with patients having a history of travel within an area where malaria is endemic, although other routes of infection are well documented (Algorithm 26.1).

Frequently, for a number of different reasons, organism recovery and subsequent identification are more difficult than the textbooks imply. It is very important that this fact be recognized, particularly when one is dealing with a possibly fatal malaria infection.

Patient Information. When requests for malarial smears are received in the laboratory, some patient history information should be made available to the laboratorian. This information should include the following.

1. Where has the patient been, and what was the date of return to the United States? (Also, "Where do you live?" has relevance to "airport" malaria.)
2. Has malaria ever been diagnosed in the patient before? If so, what species was identified?
3. What medication (prophylaxis or otherwise) has the patient received, and how often? When was the last dose taken?
4. Has the patient ever received a blood transfusion? Is there a possibility of other needle transmission (drug user)?
5. When was the blood specimen drawn, and was the patient symptomatic at the time? Is there any evidence of a fever periodicity?

Answers to such questions may help eliminate the possibility of infection with *P. falciparum* or *P. knowlesi*, usually the only species that can rapidly lead to death.

Conventional Microscopy. Often, when the diagnosis of malaria is considered, only a single blood specimen is submitted to the laboratory for examination; however, single films or specimens cannot be relied on to exclude the diagnosis, especially when partial prophylactic medication or therapy is used. Partial use of antimalarial agents may be responsible for reducing the numbers of organisms in the peripheral blood, thus leading to a blood smear that contains few organisms, which then implies a low parasitemia when in fact serious disease is present. Patients with a relapse case or an early primary case may also have few organisms in the blood smear (Table 26.6).

It is recommended that both thick and thin blood films be prepared on admission of the patient, and at least 200

to 300 oil immersion fields should be examined on both films before a negative report is issued (20, 21). Since one set of negative films will not rule out malaria, additional blood specimens should be examined over a 36-h time frame. Although Giemsa stain is widely used for all parasitic blood work, the organisms can also be seen if other blood stains, such as Wright's stain, are used (Tables 26.7 and 26.8; Fig. 26.4 and 26.5). Blood collected with the use of EDTA anticoagulant is acceptable; however, if the blood remains in the tube for any length of time, true stippling may not be visible within the infected RBCs (*P. vivax*, as an example). Also, when using anticoagulants, it is important to remember that the proper ratio between blood and anticoagulant is necessary for good organism morphology. Heparin can also be used, but EDTA is preferred. Finger stick blood is recommended, particularly when the volume of blood required is minimal (i.e., when no other hematologic procedures have been ordered). The blood should be free flowing when taken for smear preparation and should not be contaminated with alcohol used to clean the finger prior to the stick. However, in areas of the world where automation for blood work is widely used, this method is less common than in the past.

Accurate species diagnosis is essential for good patient management, since identification to the species level may determine which drug or combination of drugs will be indicated. Some patients with *P. falciparum* infections may not yet have the crescent-shaped gametocytes in the blood. Low parasitemias with the delicate ring forms may be missed; consequently, oil immersion examination at ×1,000 is mandatory.

Parasite density generally correlates with disease severity, but peripheral parasitemia does not always reflect the number of sequestered organisms. Malaria pigment may serve as a peripheral indicator of parasite biomass, since the pigment can be seen within monocytes and polymorphonuclear leukocytes during light microscopy examination. The presence of pigment has been strongly associated with more severe disease than occurs with uncomplicated cases of malaria (Fig. 26.18). Pigmented neutrophils (polymorphonuclear leukocytes, monocytes) have been associated with cerebral malaria and with death in children with severe malaria (22).

Malaria is one of the few parasitic infections considered to be immediately life-threatening, and a patient with the diagnosis of P. falciparum *or* P. knowlesi *malaria should be considered a medical emergency because the disease can be rapidly fatal. Any laboratory providing the expertise to identify malarial parasites should do so on a 24-h basis, 7 days per week.*

Patients with malaria may appear for diagnostic blood work when least expected. Laboratory personnel should be aware of the STAT nature of such requests and the importance of obtaining some specific patient history information. The typical textbook presentation of the blood smears may not be seen by the technologist. It is very

TABLE 26.8 Plasmodia in Giemsa-stained thin blood films[a]

Characteristic	*Plasmodium vivax*	*Plasmodium malariae*	*Plasmodium falciparum*	*Plasmodium ovale*
Persistence of exoerythrocytic cycle	Yes	No	No	Yes
Relapses	Yes	No, but long-term recrudescences are recognized	No long-term relapses	Possible, but usually spontaneous recovery
Time of cycle (h)	44–48	72	36–48	48
Appearance of parasitized RBC (size and shape)	1.5 to 2 times larger than normal; oval to normal; may be normal size until ring fills half of cell	Normal shape; size may be normal or slightly smaller	Both normal	60% of cells larger than normal and oval; 20% have irregular, frayed edges
Schüffner's dots (eosinophilic stippling)	Usually present in all cells except early ring forms	None	None; comma-like red dots (Maurer's dots) occasionally present	Present in all stages including early ring forms; dots may be larger and darker than in *P. vivax*
Color of cytoplasm	Decolorized, pale	Normal	Normal, bluish tinge at times	Decolorized, pale
Multiple rings/cell	Occasional	Rare	Common	Occasional
All developmental stages present in peripheral blood	All stages present	Ring forms few, as ring stage is brief; mostly growing and mature trophozoites and schizonts	Young ring forms and no older stages; few gametocytes	All stages present
Appearance of young trophozoite (early ring form)	Ring 1/3 diameter of cell; cytoplasmic circle around vacuole; heavy chromatin dot	Ring often smaller than in *P. vivax*, occupying 1/8 of cell; heavy chromatin dot; vacuole at times "filled in"; pigment forms early	Delicate, small ring with small chromatin dot (frequently 2); scanty cytoplasm around small vacuoles; sometimes at edge of red cell (appliqué form) or filamentous slender form; may have multiple rings per cell	Ring larger and more ameboid than in *P. vivax;* otherwise similar to *P. vivax*
Appearance of growing trophozoite	Multishaped irregular ameboid parasite; streamers of cytoplasm close to large chromatin dot; vacuole retained until close to maturity; increasing amounts of brown pigment	Nonameboid rounded or band-shaped solid forms; chromatin may be hidden by coarse dark brown pigment	Heavy ring forms; fine pigment grains	Ring shape maintained until late in development; nonameboid compared with *P. vivax*
Appearance of mature trophozoite	Irregular ameboid mass; 1 or more small vacuoles retained until schizont stage; fills almost entire cell; fine brown pigment	Vacuoles disappear early; cytoplasm compact, oval, band shaped, or nearly round, almost filling cell; chromatin may be hidden by peripheral coarse dark brown pigment	Not seen in peripheral blood (except in severe infections); development of all phases following ring form occurs in capillaries of viscera	Compact; vacuoles disappear; pigment dark brown, less abundant than in *P. malariae*
Appearance of schizont (presegmenter)	Progressive chromatin division; cytoplastic bands containing clumps of brown pigment	Similar to *P. vivax* except smaller; darker, larger pigment granules peripheral or central	Not seen in peripheral blood (see above)	Smaller and more compact than *P. vivax*
Appearance of mature schizont	Merozoites, 16 (12–24), each with chromatin and cytoplasm, filling entire RBC, which can hardly be seen	8 (6–12) merozoites in rosettes or irregular clusters filling normal-size cells, which can hardly be seen; central arrangement of brown-green pigment	Not seen in peripheral blood (see above)	3/4 of cells occupied by 8 (8–12) merozoites in rosettes or irregular clusters

(continued)

TABLE 26.8 *(continued)*

Characteristic	*Plasmodium vivax*	*Plasmodium malariae*	*Plasmodium falciparum*	*Plasmodium ovale*
Appearance of macrogametocyte	Rounded or oval homogeneous cytoplasm; diffuse delicate light brown pigment throughout parasite; eccentric compact chromatin	Similar to *P. vivax*, but fewer; pigment darker and more coarse	Sex differentiation difficult; "crescent" or "sausage" shapes characteristic; may appear in "showers," black pigment near chromatin dot, which is often central	Smaller than *P. vivax*
Appearance of microgametocyte	Large pink to purple chromatin mass surrounded by pale or colorless halo; evenly distributed pigment	Similar to *P. vivax*, but fewer; pigment darker and more coarse	Same as macrogametocyte (described above)	Smaller than *P. vivax*
Main criteria	Large RBC; trophozoite irregular; pigment usually present; Schüffner's dots not always present; several phases of growth seen in one smear; gametocytes appear as early as day 3	RBCs normal in size and color; trophozoites compact, stain usually intense, band forms not always seen; coarse pigment; no stippling of RBCs; gametocytes appear after a few weeks	Development following ring stage takes place in blood vessels of internal organs; delicate ring forms and crescent-shaped gametocytes are the only forms normally seen in peripheral blood; gametocytes appear after 7–10 days	RBC enlarged, oval, with fimbriated edges; Schüffner's dots seen in all stages; gametocytes appear after 4 days or as late as 18 days

[a] Although *P. knowlesi* is not listed in this table, the overall morphology using Giemsa stain will be very similar to that seen for the other four species; see Fig. 26.5 and Table 26.2.

important that the smears be examined at length and under oil immersion. The most important thing to remember is that even though a low parasitemia may be present on the blood smears, the patient may still be faced with a serious, life-threatening disease. See Algorithm 26.1 for additional information.

Alternative Methods. Giemsa-stained thick and thin blood films have been used to diagnose malaria for many years and have always been considered the "gold standard." However, a number of alternative methods have been developed, including different approaches to microscopy, flow cytometry, biochemical methods, immunoassay, and molecular methods (Table 26.9). The aim of these procedures has been to reduce cost, reduce requirements for expensive equipment, increase sensitivity, and provide simple, rapid methods that do not require conventional microscopy (23–39).

Microhematocrit centrifugation. Microhematocrit centrifugation, using the QBC tube (glass capillary tube and closely fitting plastic insert [QBC malaria blood tubes; Becton Dickinson, Sparks, MD]), has been used for the detection of blood parasites. At the end of centrifugation of 50 to 110 μl of capillary or venous blood (5 min in a QBC centrifuge [14,387 × *g*]), parasites or RBCs containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain that induces fluorescence in the parasites. This method automatically prepares a concentrated smear that represents the distance between the float and the walls of the tube. The tube is placed into a plastic holder, a drop of oil is applied to the top of the hematocrit tube, a coverslip is added, and the tube is examined with a 40× to 60× oil immersion objective (the objective must have a working distance of 0.3 mm or greater).

Note Although a malaria infection can be detected by the microhematocrit centrifugation method (which is more sensitive than use of the thick or thin blood smear), *appropriate thick and thin blood films must be examined to accurately identify the species causing the infection.*

Fluorescent dye. Another approach uses the fluorescent dye benzothiocarboxypurine (Becton Dickinson, Mountain View, CA), which intensely stains nucleic acid. In fresh blood, the dye easily penetrates the RBC membrane and stains malarial parasites, with the asexual forms staining more intensely than the gametocytes. Under these circumstances, the WBC nuclei do not stain. However, when fixed, the dye penetrates and stains both malarial parasites and WBCs. The advantages of this alternative to Giemsa-

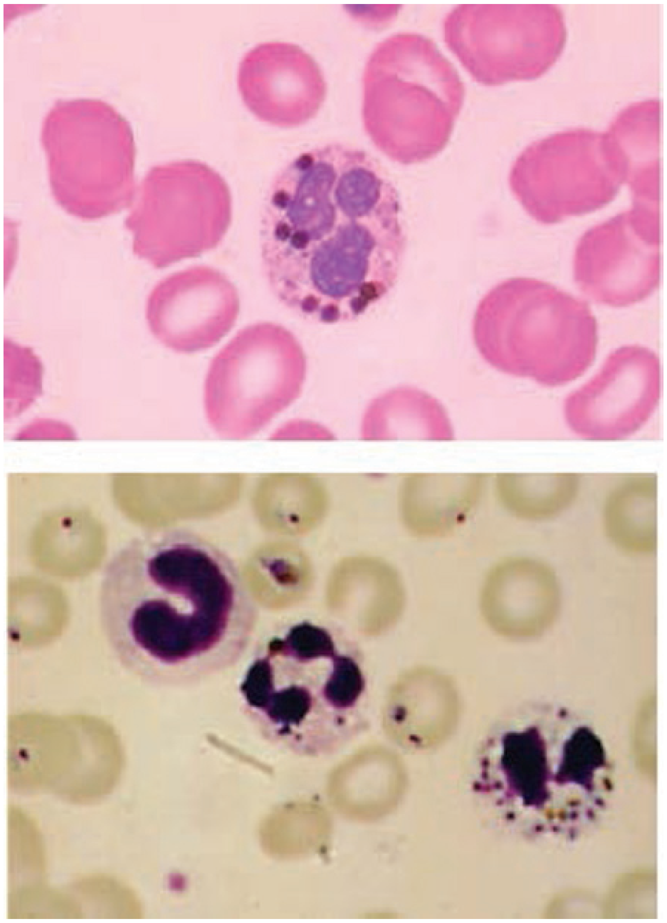

Figure 26.18 (Upper) Intracytoplasmic malaria pigment seen within a polymorphonuclear leukocyte in a specimen from a patient with malaria (courtesy of Loyda Oduber, Jaime LaRoche, Pitágoras Ureña, and Cinthia Batista, Clinical Hospital San Fernando, Panama). (Lower) Malaria pigment seen within a polymorphonuclear leukocyte (courtesy of George Healy, CDC). doi:10.1128/9781555819002.ch26.f18

stained blood films, particularly in field laboratories, are the speed of staining and evaluation and the relatively low level of training necessary to provide consistent results. Another fluorescent dye that is used is 4′,6-diamidine-2-phenylindolo-propidium iodide. However, the one disadvantage for field work is the requirement for a fluorescence microscope. Additional work is continuing on the use of benzothiocarboxypurine, and a stable prestained slide system that eliminates the need for liquid-stain application is now available.

Rapid diagnostic tests (RDTs). With the increase in drug-resistant *P. falciparum* cases in the tropics, it is no longer feasible to treat febrile patients empirically with inexpensive yet effective antimalarial agents. The substitution of newer, more expensive drugs mandates rapid, accurate, and inexpensive diagnostic procedures so that directed therapy can be provided. Immunochromatography relies on the migration of liquid across the surface of a nitrocellulose membrane. Using monoclonal antibodies prepared against a malaria antigen target that has been incorporated onto the strip of nitrocellulose, these tests are based on the capture of parasite antigen from peripheral blood. Currently, the malaria antigens used for these rapid diagnostic tests are histidine-rich protein 2 (HRP-2), parasite lactate dehydrogenase (pLDH), and *Plasmodium* aldolase (Table 26.9). These dipsticks offer the possibility of more-rapid, nonmicroscopic methods for malaria diagnosis.

A *P. falciparum* antigen detection system, the ParaSight-F test (Becton Dickinson Europe), has been very effective in field trials and has detected the HRP-2. This procedure is based on an antigen capture approach and has been incorporated in a dipstick format; the entire test takes approximately 10 min (Fig. 26.19). Another test that detects HRP-2, also in the dipstick format, is the ICT Malaria *Pf* (AMRAD ICT). This test appears to perform well and is comparable to the ParaSight-F test; however, the false-positive rate appears to be lower in this procedure. The third dipstick format procedure, OptiMAL (Flow Inc.), uses monoclonal antibodies against species-specific pLDH. Its sensitivity and specificity appear to be similar to those of the HRP-2 assays, with similar limitations at lower parasitemias. An advantage of this method is its use in follow-up for posttherapy patients to confirm a cure; the test detects only viable parasites. These rapid tests are easy to perform and interpret; however, there are a number of questions that remain concerning the relevant uses for this type of testing, especially considering the fact that the BinaxNow Malaria Test is FDA approved (Alere, Inc., Waltham, MA). A positive-control specimen is also available (Fig. 26.20).

Sensitivity remains a problem, particularly for nonimmune populations. Parasite densities of >100 parasites/μl (0.002% parasitemia) should be detected and are reasonable targets to expect from dipsticks for *P. falciparum* diagnosis. However, this level of sensitivity is at the lower end of the capability of most devices using capture methods for HRP-2 or pLDH (Table 26.6). This level of sensitivity is probably as good as clinical laboratory staff in nonspecialized laboratories with limited exposure to malaria cases could expect to provide using microscopy diagnosis. One of the potential benefits would be for inexperienced evening staff personnel for whom the dipstick identification of a life-threatening parasitemia with *P. falciparum* could prevent a missed infection. However, a negative test could not be accepted and would require confirmation by microscopic examination of both thick and thin blood films for the detection of parasitemia below the present threshold of detection by these rapid tests. Also, there are rare false

TABLE 26.9 Alternative approaches to malaria diagnosis[a]

Principle of the method	Method	Comments	Pros	Cons
Stained blood films, light microscopy[b]	TBF and THBF, after cytocentrifugation (100 µl of lysed blood centrifuged onto slide, stained with Giemsa)	Traditional method; commercially available (used in histopathology labs)	TBF used to screen larger amount of blood; THBF allows visualization of parasite within RBC; generally thought to be more sensitive than rapid antigen tests, particularly for ID to the species level	TBF unable to see parasite within RBC; THBF provides less blood per exam
Fluorescent DNA-RNA stains	TBF and THBF films (e.g., acridine orange)	Nonspecific	Sensitivity good	Requires expertise in reading
	After centrifugation (QBC)	Commercially available	Saves time, fairly sensitive	Expensive, species ID may be difficult
	Flow cytometry	Commercially available; low sensitivity	Automated counts	Low sensitivity due to "background noise"
Molecular methods	DNA-RNA hybridization	Poor sensitivity	"New approach"	Low sensitivity, cumbersome procedures
	PCR	Sensitive	Detect small numbers; species ID with mixed infections; used with blood spot collection	Lengthy procedure; automation may solve this problem
	Real-time PCR (QT-PCR)	Sensitive	Sensitivity of 20 parasites/ml of blood	Requires 500 µl of blood; takes 12 h longer than QT-NASBA
	Real-time nucleic acid sequence-based amplification (QT-NASBA)	Sensitive	Sensitivity of 20 parasites/ml of blood	Requires 50 µl of blood; takes 12 h less than QT-PCR; lends itself to testing large numbers of samples
Malaria pigment detection	Dark-field microscopy	Inferior to TBF	Pigment in WBCs sensitive indicator of prognosis	Not as sensitive as TBF
	Automated blood cell analyzers	Commercially available; detection of cases in patients not suspected as having malaria	Detects malaria pigment (WBCs, schizonts, gametocytes)	Nonspecific findings per species and parasitemia
	Depolarizing monocytes containing malarial pigment	Related to duration of symptoms before testing	Malarial pigment in monocytes	More obvious if parasitemia is ≥0.5%
	Pseudoreticulocytosis	Related to *P. falciparum*	Nuclear material from intraerythrocytic parasites	More obvious if parasitemia is ≥0.5%
Antigen detection (these tests were not developed with *P. knowlesi* in mind; other tests now under development)	HRP-2 assays: Paracheck Pf	Commercially available	Simple, rapid dipstick format; good correlation with conventional microscopy; may detect *P. falciparum* (chloroquine resistant) after patient treated for *P. vivax* (mixed infections)	*P. falciparum* only; drop in sensitivity at low levels of parasitemia (<100/µl); misses cases of only mature gametocytes (no HRP-2); false positives seen
	ICT Malaria *Pf*	Commercially available	Simple, rapid dipstick format; lower false-positive rate; good sensitivity, especially when coupled with microscopy	Some reagents must be stored at 2–8°C; cost may be a factor; more sensitive for placental malaria than microscopy

(continued)

TABLE 26.9 Alternative approaches to malaria diagnosis[a] *(continued)*

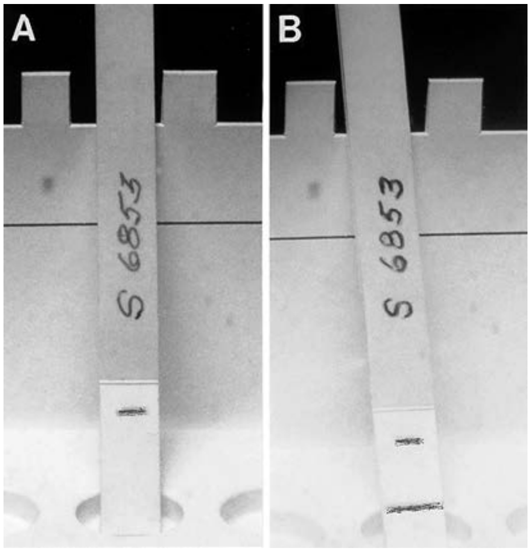
Principle of the method	Method	Comments	Pros	Cons
	MAKROmed	Commercially available	Antigen capture immunochromatographic strip format; more sensitive than conventional microscopy	Highly sensitive in detecting placental malaria, lower than expected specificity
	pLDH OptiMAL	Commercially available; test positive only with viable organisms	Simple, rapid dipstick format; also picks up *P. vivax*; few false positives; good test of cure (picks up viable parasites only)	Similar limitations at low parasitemias (<0.01%); mixed-infection ID difficult; cannot replace microscopy
	BinaxNOW (FDA-approved for use within the United States)	Commercially available; good sensitivity	Simple, rapid dipstick format; lower false-positive rate	Some reagents must be stored under refrigeration; cost may be a factor; insensitive for *P. ovale*, *P. malariae*, *P. knowlesi*

[a] Adapted from references 23–39 and 110; not all commercially available products are listed here. Very comprehensive lists of product testing to date may be found at World Health Organization (2012), http://apps.who.int/iris/bitstream/10665/77748/1/9789241504720_eng.pdf?ua=1 (accessed 4/8/2014). HRP-2, histidine-rich protein 2; ID, identification; pLDH, parasite lactate dehydrogenase; TBF, thick blood film; THBF, thin blood film; WBCs, white blood cells.

[b] Although for many years Giemsa stain has been the stain of choice, the parasites can also be seen on blood films stained with Wright's stain, a Wright/Giemsa combination stain, or one of the more rapid stains such as Diff-Quik (American Scientific Products, McGaw Park, IL), Wright's Dip Stat stain (Medical Chemical Corp., Torrance, CA), or Field's stain.

positives for patients with certain rheumatologic disorders; this is noted in the package insert and has been confirmed by users in this patient population. The U.S. military has conducted FDA-approved trials because of possible use of the devices in the field. It is very important to remember that the rapid tests currently available were not developed with the fifth human malaria, P. *knowlesi*, in mind; in some cases the tests have identified *P. knowlesi* as present, but not in all cases. Also cross-reactivity with other *Plasmodium* species has been noted. Specificity of pLDH-RDTs is decreased for *P. vivax* and *P. falciparum* due to *P. knowlesi* cross-reactivity, thus limiting their use alone in *knowlesi*-endemic areas. Sensitive *knowlesi*-specific RDTs and/or alternative molecular diagnostic tools are needed in *knowlesi*-endemic areas.

Figure 26.19 ParaSight-F test kit showing a negative test strip with a reagent control mark (A) and a positive test strip with a reagent control mark above the positive test result (B). doi:10.1128/9781555819002.ch26.f19



Overall, although they are rapid, simple, and easy to interpret, RDTs target proteins specific to *P. falciparum* or *P. vivax* or those common to all *Plasmodium* species and cannot specifically identify *P. malariae*, *P. ovale*, and *P. knowlesi*. Commercially available RDTs vary widely in diagnostic sensitivity (e.g., lacking sensitivity for some strains of *P. falciparum* and up to 50% of *P. knowlesi*) and specificity (e.g., *P. vivax* in patients with coinfections and high *P. falciparum* parasitemia levels). Lastly, RDTs cannot be used to monitor therapy, because they are qualitative. Availability of more than one test approved by FDA remains a problem.

Molecular tests. Nucleic acid amplification is the most sensitive and specific method to detect *P. falciparum*. However, PCR remains laboratory-based and requires trained personnel. Furthermore, the power dependency for the thermocycling process and the costly equipment necessary for the read-out are difficult to cover in resource-limited settings. PCR has proven to be one of the most specific

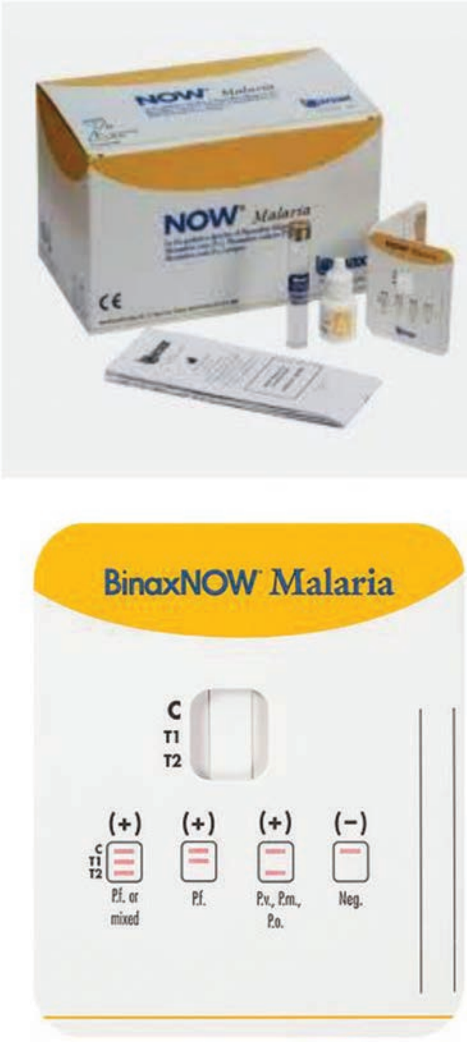


Figure 26.20 BinaxNOW Malaria test kit showing examples of possible answers. C, control line; T1, *Plasmodium falciparum* specific line; T2, panspecific line for all *Plasmodium* species (Pf, *Plasmodium falciparum*; Pv, *Plasmodium vivax*; Pm, *Plasmodium malariae*; Po, *Plasmodium ovale*). **Note:** This test was not designed to detect the presence of *P. knowlesi*; the development of newer reagents for this species is under way. (Courtesy of Alere—FDA approved for use within the United States.) doi:10.1128/9781555819002.ch26.f20

and sensitive diagnostic methods, particularly for malaria cases with low parasitemia. However, this technique has limitations in its routine use under resource-limited conditions. A number of recent studies have reported on the benefits of using PCR for detection of malaria; the high sensitivity, rapidity, and simplicity of some of the methods should be applicable to large-scale epidemiology studies, follow-up of drug treatment, and immunization trials. Detection is possible with as few as 5 or 10 parasites per μl of blood, confirming that PCR detects many more cases of low-level parasitemia than do thick blood films (36, 40).

In one study, three quantitative real-time PCR methods (qRT-PCR) were tested: qRT-PCR1 amplified a specific sequence on the *P. falciparum* Cox1 gene, qRT-PCR2 amplified a species-specific region of the multicopy 18S rDNA, and qRT-PCR3 amplified a mitochondrial DNA sequence. These three rapid, molecular qRT-PCR methods, used alone or in association, showed excellent results, with high concordance, accuracy, and reliability in malaria diagnosis (41).

In another study, the isothermal recombinase polymerase amplification method was combined with lateral flow detection as an approach to improve molecular diagnostics for *P. falciparum* in resource-limited settings. The system requires little to no instrumentation for the nucleic acid amplification reaction and the read-out is possible with the naked eye. Showing the same sensitivity and specificity as comparable diagnostic methods but simultaneously increasing reaction speed and dramatically reducing assay requirements, the method has potential to become a true point-of-care test for the malaria parasite (42).

A high-throughput multiplex 5′ nuclease quantitative PCR (qPCR) assay has been developed, with the potential to support large studies, to specifically identify *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. The analytical limit of sensitivity for each *Plasmodium* species component of the 5-plex assay was 10 to 100 copies/μl, similar to that of the 4-plex qPCR, and detection was linear from 10^1 to 10^5 copies. Based on the five-part multiplex PCR compared with microscopy, sensitivities ranged from 95.8 to 100% and specificities ranged from 98.6 to 100% (43).

In a recent study using a new loop-mediated amplification (LAMP) kit (Malaria LAMP, Eiken Chemical, Japan) in febrile returned travelers, this approach obtained diagnostic accuracy similar to that of nested PCR, and superior to that of expert microscopy. This current format of pan-*Plasmodium* genus and *P. falciparum*-specific LAMP is able to identify all *P. falciparum*-infected individuals. Nonfalciparum *Plasmodium* species are all identified but not resolved to the species level, a limitation shared with most RDT tests (44). In a companion study, the same Malaria LAMP kit was evaluated for samples from 272 outpatients at a rural Ugandan clinic and compared with expert microscopy, nested PCR, and qPCR. Compared with 3-well nested PCR, the sensitivity of both LAMP and single-well nested PCR was 90%; the microscopy sensitivity was 51%. For samples with a *P. falciparum* qPCR titer of ≥2 parasites/μl, LAMP sensitivity was 97.8% (95% confidence interval, 93.7–99.5%). Most false-negative LAMP results involved samples with parasitemia levels detectable by 3-well nested PCR but very low or undetectable by qPCR

(45). The current format has the potential to replace microscopy in developed country settings and to decrease the time lag prior to diagnosis in returning travelers.

Automated differential instruments. Hematology analyzers evaluated for malaria detection include the Cell-Dyn (Abbott Diagnostics, Santa Clara, CA), the GEN.S and LH-750 (Beckman Coulter, Miami, FL), and the XE-2100 and XS-1000*i* (Sysmex Corporation, Kobe, Kansai, Japan). The Sysmex XE-2100 is an automated hematology analyzer that uses flow cytometry, direct current impedanciometry, and radiofrequency conductance to detect and measure blood corpuscular elements. Flow cytometry may detect malaria parasites or parasite debris such as free hemozoin or hemozoin-laden macrophages as reported for Cell-Dyn instruments. For the Sysmex XE-2100, there is a gap between the manual and automated eosinophil counts (pseudoeosinophilia) and abnormal granulocyte-coded events in the DIFF scatterplot used for WBC separation based on fluorescence versus side-scatter signals in samples from *Plasmodium vivax*-infected patients. Two previously reported abnormalities, compared with thick film, had a sensitivity of 69.4% and a specificity of 100% for *P. vivax* diagnosis. These findings suggest the potential clinical utility of malaria detection by the XE-2100. However, the lack of scatterplot abnormalities in the *P. falciparum* samples, containing mainly rings, further supports the hypothesis that most abnormalities detected by the XE-2100 and other analyzers correspond to mature parasites, as found in *P. vivax* malaria. Again, the low parasitemias found in travelers (immunologically naive patients) definitely limit the potential for diagnosis using automated hematology instruments. The most common WBC and platelet flags tend to be leukopenia, atypical lymphocytes, lymphopenia, WBC abnormal scattergram, platelet clumps, thrombocytopenia, and platelet abnormal distribution. These instruments may provide valuable diagnostic parameters in areas of endemicity in detecting acute *P. vivax* malaria; however, they are not very useful for acute *P. falciparum* malaria infection.

Potential diagnostic problems with the use of automated differential instruments have been reported (37, 46). Some cases of malaria, as well as *Babesia* infection, have been completely missed by these methods. The number of fields scanned by a technologist on instrument-read smears is quite small; thus, failure to detect a light parasitemia is almost guaranteed. With both malaria and babesiosis, after diagnosis had been made on the basis of smears submitted to the parasitology division of the laboratory, all previous smears examined by the automated system were reviewed and found to be positive for parasites. Failure to make the diagnosis resulted in delayed therapy. Although these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to discriminate between uninfected RBCs and those infected with parasites may pose serious diagnostic problems in situations where the parasitemia is ≥0.5%.

Digital review of blood films. Preliminary studies are under way to develop semiautomated or automated methods for the detection and identification of *Plasmodium* species from digital stained blood film images. However, as with the automated hematology analyzers, low parasitemias may present problems with false-negative results. This may be a potential problem with travelers who present with low parasitemias, but who may be seriously ill.

Artifacts seen on blood films prepared from EDTA (time lag problems). Microscopic examination of a peripheral blood smear occasionally reveals ookinetes of *P. vivax* (or another of the *Plasmodium* species); this represents a potential "artifact" that could lead to the incorrect diagnosis of *P. falciparum* infection (Fig. 26.13). The ookinetes tend to resemble the crescent-shaped gametocytes seen in infections with *P. falciparum*. The appearance of these stages in the peripheral blood, rather than the mosquito gut, was probably due to the delay between blood collection and smear preparation. It has been documented that some gametocytes (*P. falciparum*) exflagellate at room temperature (pH 7.4). In this case, the microgametes could resemble spirochetes (8) (Fig. 26.6). These potential artifact problems usually arise when the tube of EDTA blood containing parasites is left standing at room temperature with the stopper removed. As the blood cools and becomes aerated, the *Plasmodium* parasites transition from the erythrocytic cycle in the human host to the cycle within the mosquito host. There may be other changes, including loss of parasites after 4 to 6 hours, changes in parasite shapes, changes in or loss of stippling, and overall morphology distortions. Therefore, it is important to prepare thick and thin blood films immediately after receipt of the blood (ordered, collected, processed, examined, and reported on a STAT basis) (21).

KEY POINTS—LABORATORY DIAGNOSIS

Malaria

1. Blood films should be prepared on admission of the patient (ordering, collection, processing, examination, reporting on a STAT basis). A fever pattern may not be apparent early in the course of the infection (immunologically naive patient, travelers); symptoms may be completely random and may mimic any other condition with vague complaints.
2. Both thick and thin blood films should be prepared. At least 200 to 300 oil immersion fields (×1,000) onboth thick and thin films should be examined before the specimen is considered negative.

KEY POINTS—LABORATORY DIAGNOSIS

3. Wright's, Wright-Giemsa, Giemsa, or a rapid stain can be used. The majority of the original organism descriptions were based on Giemsa stain. However, if the WBCs appear to be well stained, any blood parasites present will also be well stained. The WBCs on the patient smear serve as the quality control organism; there is no need to use a *Plasmodium*-positive slide for quality control.
4. Malarial parasites may be missed with the use of automated differential instruments. Even with technologist review of the smears, a light parasitemia is very likely to be missed.
5. The number of oil immersion fields examined may have to be increased if the patient has had any prophylactic medication during the past 48 h (the number of infected cells may be decreased on the blood films).
6. *One negative set of blood smears does not rule out malaria. Quantitate organisms from every positive blood specimen.* The same method for calculating parasitemia should be used for each subsequent positive blood specimen. Always report stages seen (rings, schizonts, gametocytes), since this information will influence therapy.
7. In spite of new technology, serial thick-film parasite counts are a simple, cheap, rapid, and reliable method for identifying patients at high risk of recrudescence due to drug resistance and treatment failure.
8. If you are using any of the alternative methods, make sure you thoroughly understand the pros and cons of each compared with the thick and thin blood film methods; see chapter 7 for additional information on diagnostic methods for blood parasites.

Report Comments

Report comments can be extremely helpful in conveying information to the physician. Depending on the results of diagnostic testing, the following information can lead to improved patient care and clinical outcomes. The report is provided with the comment following.

1. **No parasites seen:** The submission of a single blood specimen will not rule out malaria; submit additional bloods every 4 to 6 hours for 3 days if malaria remains a consideration.

Interpretation/Discussion: It is important to make sure the physician knows that examination of a single blood specimen will not rule out malaria.

2. ***Plasmodium* spp. seen:** Unable to rule out *Plasmodium falciparum* or *Plasmodium knowlesi.*

Interpretation/Discussion: Since *P. falciparum* and *P. knowlesi* cause the most serious illness, it is important to let the physician know these species have NOT been ruled out.

3. ***Plasmodium* spp., possible mixed infection:** Unable to rule out *Plasmodium falciparum* or *Plasmodium knowlesi.*

Interpretation/Discussion: Since *P. falciparum* and *P. knowlesi* cause the most serious illness, it is important to let the physician know these species have NOT been ruled out.

4. ***Plasmodium malariae*:** Unable to rule out *Plasmodium knowlesi.*

Interpretation/Discussion: If the patient has traveled to an area where *P. knowlesi* is endemic, it may be impossible to differentiate between *P. malariae* (band forms) and *P. knowlesi.*

5. ***Plasmodium falciparum*:** Unable to rule out *Plasmodium knowlesi.*

Interpretation/Discussion: If the patient has traveled to an area where *P. knowlesi* is endemic, it may be impossible to differentiate between *P. falciparum* (ring forms) and *P. knowlesi.*

6. **Negative for parasites using automated hematology analyzer:** Automated hematology analyzers will not detect low malaria parasitemias seen in immunologically naive patients (travelers).

Interpretation/Discussion: In patients who have never been exposed to malaria (immunologically naive), they will become symptomatic with very low parasitemias that will not be detected using automation (0.001 to 0.0001%).

7. **Negative for malaria using the BinaxNOW rapid test:** This result does not rule out the possibility of a malaria infection. Blood should be submitted for STAT thick and thin blood film preparation, examination, and reporting.

Interpretation/Discussion: The maximum sensitivity of this rapid test occurs at 0.1% parasitemia. Patients (immunologically naive travelers) may present to the emergency room or clinic with a parasitemia much lower than 0.1%, leading to a false-negative report. Also, this rapid test is not designed to identify P. malariae, P. ovale, *and* P. knowlesi*; the results are most clinically relevant for* P. falciparum *and* P. vivax. *The BinaxNOW is FDA approved for use within the United States.*

Treatment

Malaria has become a more common health problem during the last few years, both in residents of areas where the disease is endemic and in travelers returning to areas where

TABLE 26.10 Antimalarial drugs and their actions[a,b]

Stage affected	Antimalarial action by interference with: Folic acid synthesis	Folic acid metabolism	Nucleic acid metabolism	Iron-dependent free-radical generation	Parasite components	Unknown
Erythrocytic cycle (schizonts)	Sulfonamides Sulfones	Proguanil Pyrimethamine	Quinine[c] Amodiaquine[e]	Artemisinins	Chloroquine[d] (food vacuole function) Atovaquone (acts on mictochondria)	
Erythrocytic cycle (gametocytes)		Proguanil	Proguanil			Primaquine[f]
Exoerythrocytic cycle		Pyrimethamine	Pyrimethamine			Primaquine

[a] Format adapted from Markell EK, Voge M, *Medical Parasitology*, 5th ed., The WB Saunders Co, Philadelphia, PA, 1981; information updated from references 49, 111, and 112.

[b] Not every drug is included in this table; however, additional information can be seen in the references mentioned in footnote *a*.

[c] Affects the formation of malarial pigment; may also block ion transport to the parasite; inhibits production of tumor necrosis factor.

[d] Interferes with the normal function of the food vacuole and hence with maturation through the trophozoite stage; specific mechanisms include (i) binding to free heme to prevent its incorporation into malaria pigment, (ii) inhibiting aspartic and cysteine protease activity, and (iii) raising vacuolar pH above the pH optima of the aspartic and cysteine proteases in the food vacuole. Inhibition of DNA synthesis is no longer considered a likely mechanism for chloroqine action against the parasite.

[e] Amodiaquine binds heme and inhibits heme polymerization; this is an action similar to that seen with chloroquine.

[f] Primaquine is effective against gametocytes of all five species, unlike some of the other drugs which are partially effective; following administration of primaquine, documented swelling of mitochondria in malarial parasites.

it is not endemic. Therapy has become more complex because of the increase in resistance of *P. falciparum* to a variety of drugs and because of advances in treatment of severe disease complications (Tables 26.10 to 26.12). Antimalarial drugs are classified by the stage of malaria against which they are effective. These drugs are often referred to as tissue schizonticides (which kill tissue schizonts), blood schizonticides (which kill blood schizonts), gametocytocides (which kill gametocytes), and sporonticides (which prevent formation of sporozoites within the mosquito). To ensure that proper therapy is given, it is important for the clinician to know what species of *Plasmodium* is involved, the estimated parasitemia, and the geographic and travel history of the patient to determine the area where infection was probably acquired and the possibility of drug resistance related to that geographic area. The use of oral or parenteral therapy will be determined by the clinical status of the patient. A number of studies related to the molecular genetics of drug resistance, particularly in *P. falciparum* malaria and modeling of the development of resistance of *P. falciparum* to antimalarial drugs, are ongoing (Tables 26.13 to 26.15).

Development of resistance to the inexpensive antimalarials, such as chloroquine, has had a tremendous financial and public health impact on developing countries. In the late 1980s, chloroquine-resistant *P. falciparum* completely covered Africa.

Although chloroquine-resistant *P. falciparum* is well recognized, chloroquine has generally been effective for both chemoprophylaxis and treatment of *P. vivax*, *P. ovale*, and *P. malariae* infections. Cases of chloroquine-resistant *P. vivax* (CRPV) malaria have now been identified in Papua New Guinea, Indonesia, Malaysia, Vietnam, and Myanmar. CRPV is now endemic in Malaysia, Myanmar, and Vietnam. However, there is no evidence of CRPV from Thailand, Cambodia, Laos, China, the Korean Peninsula, or the Philippine archipelago (9). Although CRPV has been documented in a few areas within South America (Guyana, Colombia, Brazil, Peru), it is present at a very low frequency, with a risk of infection at <5%. Population-based epidemiologic studies are necessary to define the geographic range and prevalence of CRPV. It is not clear whether this development represents a newly emerging public health problem; however, clinicians need to be aware that possible therapeutic or prophylactic failures may result when chloroquine is used for *P. vivax* infections in people who have been in Indonesia or Oceania.

Suppressive Prophylaxis Therapy. Chemoprophylactic agents to prevent clinical symptoms are given to individuals who are going into areas where malaria is endemic (47). These drugs are effective only against the erythrocytic forms and do not prevent the person from getting malaria; i.e., they do not prevent sporozoites from entering the liver and beginning the pre-erythrocytic cycle of development. The most commonly used drugs for this purpose are quinine, chloroquine, hydroxychloroquine, and amodiaquine, all of which are effective when the organisms enter the RBCs from the liver and begin the erythrocytic cycle. Fansidar is recommended for prophylaxis only for travelers who are staying for a long time in high-transmission areas where choroquine-resistant malaria is endemic. This recommendation was based on revisions in response to increased

TABLE 26.11 *Plasmodium falciparum* drugs and therapeutic use[a]

Drug	Mechanisms of resistance	Clinical pharmacokinetics	Therapeutic use	Adverse effects and drug interactions
4-Aminoquinolones				
Chloroquine	Reduced cellular accumulation of drug; drug efflux mechanism; *pfcrt* major chloroquine resistance gene; resistance widespread	Rapidly absorbed after oral, intramuscular, or subcutaneous administration; half cleared by kidneys; terminal elimination half-life, 1–2 mo	*P. vivax*, *P. ovale*, *P. malariae*, *P.knowlesi*; uncomplicated *P. falciparum* in semi-immune patients; nonimmune patients require other drugs due to risks of drug failure	Well tolerated; >250 µg/ml causes dizziness, headache, diplopia, nausea, and exacerbation of epilepsy; cumulative dose of >100 g over time leads to irreversible retinopathy
Antifolate drugs[b] and combinations	Gene amplification of the first enzyme in the parasite folate synthesis pathway, GTP-cyclohydrolase, is strongly associated with resistant parasites and potentially contributes to persistence of resistant parasites.	Pharmacokinetic factors contribute to the observed high rate of treatment failure; a higher sulfadoxine-pyrimethamine dose for children under the age of 5 years is recommended; pharmacokinetics may be altered in pregnancy due to increases in oral clearance and volume of distribution	Median plasma concentrations are higher in nonpregnant versus pregnant subjects at most time points; higher doses can be given safely; differences due to physiological changes that are established in the first trimester	Severe allergic reactions to sulfa drugs well known; dapsone has concentration-related problems (allergy, problems with G6PD deficiency); pyrimethamine, proguanil, chlorproguanil have little serious toxicity other than folate deficiency
Sulfadoxine-pyrimethamine	Both long elimination half-lives, causing selective pressure for resistance; mutations in *dhfr* and *dhps* genes	Pyrimethamine well absorbed after oral or intramuscular administration; sulfa drugs given for synergistic effects with pyrimethamine or chlorproguanil	Used to treat chloroquine-resistant infections in Africa; severe skin reactions mean that it has no prophylaxis use	Skin reactions, anemia, leukopenia; single-dose therapy, but widespread resistance
Proguanil	Prophylaxis, but deteriorating clinical response; short half-life; atovaquone-proguanil-resistant *P. falciparum* rare	Atovaquone inhibits parasite mitochondrial electron transport. Proguanil inhibits the dihydrofolate reductase step in purine synthesis and lowers concentration of atovaquone necessary to kill *Plasmodium* spp.	Alone for prophylaxis; fixed-ratio combination with atovaquone (Malarone) (see below)	Nausea, vomiting, abdominal pain, hepatitis
Chlorproguanil[c] and dapsone	Converted to the active metabolite by cytochrome P450 enzymes; these metabolites inhibit the malaria parasite's dihydrofolate reductase enzyme.	Used for treatment; short half-life; low propensity to select resistant parasites	Treatment of uncomplicated *P. falciparum*; can be used during pregnancy	Associated risk of hemolytic anemia in G6PD-deficient patients; dapsone known to reduce erythrocyte lifespan
Quinine	Less potent than chloroquine, small therapeutic range; resistance rare in Africa; not major clinical problem	Oral bioavailability high; intramuscular half-life varies at 10 to 40 min; extensive hepatic biotransformation	Used in combination with antibiotics (tetracycline) in Southeast Asia; parenteral first choice for severe malaria	Tinnitus, deafness, headache, nausea, visual disturbances in the majority of patients receiving therapeutic levels; however, dose reduction not recommended; more serious sequelae can be seen

(continued)

TABLE 26.11 *Plasmodium falciparum* drugs and therapeutic use[a] *(continued)*

Drug	Mechanisms of resistance	Clinical pharmacokinetics	Therapeutic use	Adverse effects and drug interactions
Quinidine gluconate	Narrow therapeutic window; kills parasites in late stages of RBC cycle	Same mechanisms as quinine	Treatment of severe malaria	Infusion-related hypotension, QT prolongation; potential cardiotoxicity; can induce hypoglycemia (promotes insulin secretion)
Artemisinin group	Artemether, artesunate, dihydroartemisinin semisynthetic derivatives of plant extract; high-cost drugs; decreased effectiveness seen along border between Cambodia and Thailand (use of monotherapy)	Rapidly hydrolyzed *in vivo* to dihydroartemisinin; short elimination half-lives; artemether absorption slower, more variable if administered intramuscularly or intravenously	Used to treat severe malaria and as combination therapy	Generally safe and well tolerated; main concern is reproductive safety (long-bone shortening); cannot be used in first trimester (WHO)
Artemether-lumefantrine[d]	Resistance not yet detected; monitoring ongoing (*pfmdr1*-86, *pfcrt*-76, *pfmdr1*-184, 1042, 1246, *pfmdr1* gene copy number)	Take with fatty foods to increase absorption	Lumefantrine, a fluorene derivative, may interfere with heme metabolism. Artemether-lumefantrine is rapidly effective against all RBC stages.	Nausea, vomiting, dizziness, headache, possible QT prolongation

[a] Adapted from references 111–114. FDA-approved drugs include chloroquine, doxycycline (prophylaxis), mefloquine, primaquine, pyrimethamine, quinidine gluconate, quinine Coartem (artemether-lumefantrine), Fansidar (pyrimethamine-sulfadoxine), Malarone (atovaquone-proguanil). The QT interval is a measure of the time between the start of the Q wave and the end of the T wave in the heart's electrical cycle. The QT interval represents electrical depolarization and repolarization of the ventricles. A lengthened QT interval is a marker for the potential of ventricular tachyarrhythmias and a risk factor for sudden death.

TABLE 26.12 Antimalarial drugs and associated problems[a]

Drug	Associated problems[b]
Artemisinin (qinghaosu)	Recrudescence, neurotoxity; increased convulsions; short half-life
Atovaquone (Mepron)	Rash, nausea; rapid development of resistance when used alone; recrudescence common
Azithromycin	Limited use; efficacy to be determined
Chloroquine (Aralen)	Resistance worldwide except in Central America; appears to increase *P. falciparum* gametocytogenesis
Doxycycline	Phototoxicity; not used in pregnant women and children; gastrointestinal intolerance
Halofantrine (Halfan)	Cardiotoxicity, poor absorption, sporadic resistance
Mefloquine (Lariam)	Psychoses; resistance in Indochina and Africa
Primaquine	Narrow therapeutic index; not used in G6PD-deficient patients; resistance may be a problem
Proguanil (Paludrine)	Mouth ulcers, hair loss, scaling of palms and soles, urticaria; resistance worldwide
Pyrimethamine-sulfadoxine (Fansidar)	Severe allergic reactions; resistance worldwide
Quinine sulfate	Tinnitus, headache, nausea, abdominal pain, visual disturbances; resistance in Brazil and Indochina
Quinidine gluconate	Infusion-related hypotension, hypoglycemia; requires cardiac monitoring

[a] Adapted from references 115–117.

[b] G6PD, glucose-6-phosphate dehydrogenase.

TABLE 26.13 Malaria resistance[a]

Resistance definition	Comments
Sensitive	From initiation of therapy, asexual parasites are cleared by day 6; no evidence of recrudescence up to day 28 Peripheral blood films appear to go from positive to negative very quickly (can be a change from one draw to the second draw 6 h later)
Resistance type I (RI)	From initiation of therapy, asexual parasites have cleared for at least 2 consecutive days (the latest day being day 6); recrudescence follows Parasite count initially drops and blood films appear to be negative; patient should be monitored for a period of days, particularly if drug-resistant *P. falciparum* suspected
Resistance type II (RII)	Within 48 h of initiation of therapy, marked reduction of asexual parasitemia to <25% of pretreatment count; however, no subsequent disappearance of parasitemia (smear positive on day 6) Patient appears to be improving; parasite count drops, but blood films always appear positive
Resistance type III (RIII)	Modest reduction in parasitemia may be seen; no change or increase in parasitemia seen during first 48 h after treatment; no clearing of asexual parasites In some cases, parasite count continues to increase with no visible decrease at any time; blood films show overall parasite increase

[a] Adapted from references 107 and 116.

numbers of adverse reactions to Fansidar prophylaxis, including severe mucocutaneous reactions, some of which were fatal (Table 26.12). In general, chloroquine is still the choice for prophylaxis against *P. falciparum*, but it is not totally effective against *P. vivax*. Resistance to Fansidar was reported in Thailand as early as 1981. Quinine is normally used in these situations; however, quinine-resistant *P. falciparum* has been reported in Africa, with little to no information on previous chloroquine intake. A combination of quinine and tetracycline is recommended for chloroquine- and Fansidar-resistant *P. falciparum*. Areas with chloroquine-resistant *P. falciparum* are listed in Table 26.14, and drug information is presented in Tables 7.15 and 7.16; specific dosage information is given in chapter 36.

Summary of Prophylaxis. With the introduction of chloroquine, with its high potency, long half-life, and low toxicity, continued research into the chemoprophylactic potential of other antimalarial agents such as primaquine was drastically reduced. Resistance to the newer chemoprophylactic drugs such as chloroquine, sulfadoxine/pyrimethamine (Fansidar), proguanil, mefloquine, and doxycycline continues to increase, with many of these agents now becoming clinically useless. Other antimalarial agents such as quinine, halofantrine, or the artimisinine derivatives are too toxic or have too short a half-life to be used for prophylaxis. A summary of antimalarial drugs used for prophylaxis and their activity on different life cycle stages of the malaria parasite can be seen in Table 26.10.

Perhaps the most common approach to chemoprophylaxis in travelers to areas with multidrug-resistant *P. falciparum* is the use of doxycycline. However, this tetracycline derivative must be taken daily, and its use must be continued for 4 weeks after the patient has left the area. Potential side effects include diarrhea, upper gastrointestinal upset, and phototoxicity. Patients may also be predisposed to oral or vaginal candidiasis, and the drug cannot be given during pregnancy or to young children. Also, breakthrough can occur in individuals who have missed only a single dose.

Every year between 10,000 and 30,000 international travelers from nonendemic areas fall ill with malaria after returning home. Estimates indicate that around 150 returning travelers die each year from imported malaria, usually due to *P. falciparum* infection. In areas of intense malaria transmission, chemoprophylaxis remains the most important strategy for preventing malaria in travelers, but its use may be associated with adverse outcomes and even death. These potentially severe side effects often undermine compliance with chemoprophylaxis in travelers. Another problem with malaria chemoprophylaxis is that all drug regimens must be taken meticulously during and for 1 or more weeks after leaving the malaria-endemic area, a commitment that requires considerable personal discipline.

Radical Cure. The radical-cure approach to therapy eradicates all malarial organisms, both the liver and the RBC stages, from the body. Therapy is usually given to individu-

  - Venezuela (some areas)

[a] There is no malaria risk in urban areas unless otherwise indicated. This table should be used in conjunction with the text in determining appropriate prophylaxis. (From *MMWR Morb Mortal Wkly Rep* **34**[14], 1985; also see reference 118.)

[b] Malaria risk exists in most urban areas.

[c] Malaria risk exists in urban areas of Timor and Kalimantan provinces. Irian Jaya should be considered as Oceania.

[d] Malaria risk exists in all urban areas except Vientiane.

[e] Malaria risk exists in urban areas of interior Amazon River region.

[f] Malaria risk exists in urban areas of Esmeralda, Manabi, El Oro, and Guayas provinces (including the city of Guayaquil). (From Seidel JS [ed], *Pediatr Clin North Am:* **32:**1077–1096, 1985)

als who have returned from areas where malaria is endemic; it prevents relapses with *P. vivax* or *P. ovale* infection, although relapses with both *P. vivax* and *P. ovale* infections occasionally occur after treatment with primaquine (8, 48). The gametocytes are also eliminated, thus stopping the chain of transmission to the mosquito vector. The drugs used are primaquine and other 8-aminoquinolones. Treatment with primaquine is usually not necessary for malarial cases acquired by transfusion or contaminated needles or passed from mother to child as a congenital infection. More specific information can be found in chapter 36.

TABLE 26.15 Drugs available in the United States for treatment of malaria[a]

Tablets for oral use	
Atovaquone-proguanil (Malarone)	250 mg of atovaquone/100 mg of proguanil
Chloroquine phosphate (Aralen and generics)	500 mg (300-mg base), 1,000 mg (600-mg base)
Hydroxychloroquine sulfate (Plaquenil)	400 mg (310-mg base)
Mefloquine (Lariam and generics)	500 mg (456-mg base), 750 mg (684-mg base)
Primaquine phosphate	52.6 mg (30-mg base)
Pyrimethamine (Daraprim)	25 mg
Quinine	180 mg, 325 mg
Quinine sulfate	650 mg (542-mg base)
Ampoules for parenteral use	
Chloroquine hydrochloride (200-mg chloroquine base, 5-ml vial) and quinine dihydrochloride	
Quinidine gluconate, 800 mg (500 mg of quinidine) in 10 ml of sterile water	

[a] Adapted from *CDC Guidelines for Treatment of Malaria in the United States* (23 March 2005), http://www.cdc.gov/malaria/diagnosis_treatment/treatment.html. Also see Table 26.17, chapter 36, and reference 49.

Primaquine can cause hemolytic anemia, especially in patients whose RBCs are deficient in glucose-6-phosphate dehydrogenase (G6PD). This deficiency is most common in African, Asian, and Mediterranean peoples. Patients should be screened for G6PD deficiency before treatment. Limited evidence suggests that G6PD-deficient patients may be safely treated with a single weekly dose of primaquine (0.75 mg/kg) for 8 weeks. Resistance is not known to occur at a dose of 0.5 mg/kg daily for 14 days: suspected resistant strains may be treated with this daily dose for 28 days. Relapse despite adherence to a full primaquine dose may be due to a poor metabolizer phenotype. Primaquine should not be used during pregnancy. It should be taken with food to minimize nausea and abdominal pain (49).

An increase in the incidence of malaria caused by *P. falciparum* is well recognized, and delays in diagnosis and subsequent therapy may result in complicated or fatal cases, particularly in nonimmune hosts. Some of the complications of *P. falciparum* malaria that have been discussed include cerebral malaria, renal failure, respiratory problems, disseminated intravascular coagulation, blackwater fever, and hepatic dysfunction. Death is directly related to the level of parasitemia and onset of complications, with significant mortality related to >5% parasitemia in spite of appropriate parenteral therapy and supportive care. In these situations, the role of exchange blood transfusion may be appropriate for the following reasons: (i) rapid reduction of the parasitemia, (ii) decreased risk of severe intravascular hemolysis, (iii) improved blood flow, and (iv) improved oxygen-carrying capacity. Powell and Grima have published an excellent review of the use of exchange transfusion for treatment of malaria (50).

Exposure to both placental malaria and maternal HIV infection increases postnatal mortality to a greater degree than does the independent risk associated with exposure to either maternal HIV or placental malaria infection alone. Therefore, malaria chemoprophylaxis during pregnancy could decrease the impact of HIV transmission from mother to infant (Table 26.17).

New Drug Development. Past approaches used to identify potential new antimalarials involved empirical screening of many natural plant extracts, as well as synthesis of new analogs of compounds known to have activity against microbes, tumors, and/or malarial parasites. Primary studies involve *in vitro* cultures and animal models; secondary and tertiary screening is then undertaken. Very few compounds are selected for clinical evaluation due to financial, compound formulation, stability, toxicity, or efficacy problems encountered in preliminary testing. New approaches involving computerized structure-based drug design and molecular modeling represent significant improvements. Molecular biology methods have become very important and widely used in this development process.

Drug candidates are currently being identified and developed for further testing. With the continued increase in the number of multiply drug-resistant strains of *P. falciparum*, these drug development efforts have resulted from renewed commitment and have been moved up the priority list. However, the process of antimalarial drug discovery, design, and testing is very long and complex, not to mention expensive. In the United States, a national average of 12 to 15 years and an investment of $200 million to $500 million per licensed drug are expended.

There seem to be inconsistencies between malaria control initiatives and actual policy development and implementation. Current consensus seems to be that a policy change is urgent when high-level resistance occurs in 40% or more of treated patients, when parasitological response is poor, and when the costs of treatment failures are higher

TABLE 26.16 Drugs used for the prevention of malaria[a]

Drug	Usage	Adult dosage	Pediatric dosage	Comments
Atovaquone/ proguanil[b] (Malarone)	Primary prophylaxis in areas with chloroquine-resistant or mefloquine-resistant *Plasmodium falciparum*	250 mg of atovaquone/ 100 mg of proguanil hydrochloride; 1 adult tablet orally daily	62.5 mg of atovaquone/25 mg of proguanil hydrochloride 5–8 kg: 1/2 peds tablet/day 9–10 kg: 3/4 peds tablet/day 11–20 kg: 1 tablet/day 21–30 kg: 2 tablets/day 31–40 kg: 3 tablets/day >40 kg: 1 adult tablet daily	Contraindicated in persons with severe renal impairment; should be taken with food or a milky drink; not recommended for children <11 kg, pregnant women, or women breast-feeding infants weighing <11 kg
Chloroquine phosphate (Aralen and generic)[c]	Primary prophylaxis in areas where chloroquine-sensitive *P. falciparum* is endemic	300 mg of base (500 mg of salt) orally once/ wk	5 mg/kg (base), 8.3 mg/kg (salt) orally once/wk, up to maximum adult dose of 300 mg of base	Safe to take during pregnancy, including first trimester; may exacerbate psoriasis; beginning 1–2 wks before travel, continuing weekly during stay and for 4 wks after leaving malarious zone
Doxycycline (many brand names and generic)[d]	Primary prophylaxis in areas with chloroquine-resistant or mefloquine-resistant *P. falciparum*	100 mg orally once/day	>8 years of age: 2 mg/kg orally/day up to maximum adult dose of 100 mg/day	Contraindicated in children >8 years of age; teeth may become permanently stained; may cause photosensitivity; contraindicated during pregnancy
Mefloquine (Lariam and generic)[a]	Primary prophylaxis in areas with chloroquine-resistant *P. falciparum*	228 mg of base (250 mg of salt) orally once/ wk (tablet 250 mg of salt)	5–10 kg: 1/8 tablet orally once/wk 10–20 kg: ¼ tablet once/wk 20–30 kg: ½ tablet once/wk 30–45 kg: ¾ tablet once/wk >45 kg: 1 tablet once/wk The recommended dose of mefloquine is 5 mg/kg of body weight once weekly. Approximate tablet fraction is based on this dosage. Exact doses for children weighing less than 10 kg should be prepared by a pharmacist.	Contraindicated in persons allergic to mefloquine and in those with active depression or a previous history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Not recommended for persons with cardiac conduction abnormalities. As of 2013, some authorities recommend its use for prophylaxis only as a drug of last resort (CNS toxicity).[e]
Primaquine (for primary prophylaxis)	An option for primary prophylaxis in special circumstances. Call Malaria Hotline (770-488-7788) for additional information.	30 mg base (52.6 mg salt) orally daily	0.5 mg/kg base (1.0 mg/kg salt) up to adult dose orally daily	Contraindicated in persons with G6PD[f] deficiency. Also contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level. Use in consultation with malaria experts.
Primaquine (for terminal prophylaxis)	Used for terminal prophylaxis to decrease the risk of relapses of *P. vivax* and *P. ovale* infection	30 mg of base (52.6 mg of salt) orally once/ day for 14 days after departure from the malarious area **Note:** The recommended dose of primaquine for terminal prophylaxis has been increased from 15 mg to 30 mg for adults.	0.6 mg/kg base (1.0 mg/kg salt) up to adult dose orally once/day for 14 days after departure from the malarious area **Note:** The recommended dose of primaquine for terminal prophylaxis has been increased from 0.3 mg/kg to 0.5 mg/kg for children.	Indicated for persons who have had prolonged exposure to *P. vivax* and *P. ovale* or both. Contraindicated in persons with G6PD deficiency. Also contraindicated during pregnancy and lactation unless the infant being breast-fed has a documented normal G6PD level.

(continued)

TABLE 26.16 *(continued)*

Drug	Usage	Adult dosage	Pediatric dosage	Comments
Atovaquone-proguanil (Malarone); self-treatment drug	Self-treatment drug to be used if professional medical care is not available within 24 h; medical care should be sought *immediately* after treatment	4 tablets (each dose contains 1,000 mg of atovaquone and 400 mg of proguanil) orally as a single daily dose for 3 consecutive days **Seek medical care immediately after treatment.**	<5 kg: not indicated 5–8 kg: 2 peds tablet/day × 3 days 9–10 kg: 3 peds tablet/day × 3 days 11–20 kg: 1 adult tablet/day × 3 days 21–30 kg: 2 adult tablets/day × 3 days 31–40 kg: 3 adult tablets/day × 3 days >40 kg: 4 adult tablets/day × 3 days **Seek medical care immediately after treatment.**	Contraindicated in persons with severe renal impairment (creatinine clearance, <30 ml/min). Not recommended for self-treatment in persons on atovaquone-proguanil prophylaxis. Not currently recommended for children weighing <11 kg, pregnant women, or women breast-feeding infants <11 kg.

[a] From Centers for Disease Control and Prevention, Travel Information (http://www.cdc.gov/malaria/travelers/) (49). peds, Pediatric.

[b] Take the first dose 1 to 2 days before travel to malarious areas; take doses daily, at the same time each day, while in the malarious area; take doses daily for 7 days after leaving such areas. Mefloquine should be taken on a full stomach, such as after dinner; most travelers have few if any side effects. However, side effects can include abdominal pain, nausea, vomiting, and headache.

[c] Take the first dose 1 to 2 weeks prior to arrival in the malarious area; continue once a week on the same day of the week during travel to malarious areas and for 4 weeks after leaving such areas. Side effects could include gastrointestinal disturbance, headache, dizziness, blurred vision, insomnia, and pruritus, but these symptoms usually do not require discontinuation of the drug.

[d] Doxycycline should be taken on a full stomach, such as after dinner; to minimize reflux, do not lie down for 1 h; can predispose women to vaginal yeast infections; should *not* be used in pregnancy, by children younger than 8 years, or by persons allergic to tetracyclines. Doxycycline can also cause sun sensitivity, usually manifested as an exaggerated sunburn reaction. Persons taking this drug should use sunscreen that absorbs long-wave UVA radiation.

[e] Nevin RL, *Int J Parasitol Drugs Drug Resist* **4**:118–125.

[f] G6PD, glucose-6-phosphate dehydrogenase.

than those of treatments with a newer drug. Improved cooperation is needed between the private and public sectors regarding overall delivery of health care relevant to malaria control issues (51).

Counterfeit Drugs for Malaria. Counterfeiting of drugs has now emerged as one of the most critical public health problems for malaria treatment in developing countries. During the past centuries, poor quality drugs surfaced in the 1600s with fake cinchona bark and in the 1800s with fake quinine. Although the problem of modern-day counterfeit drugs was first addressed in 1985 at a conference in Nairobi, the counterfeit market continues to grow and has become worldwide during the last decade. The World Health Organization (WHO) estimates that 50% of medicines available via the Internet are fake (52).

Counterfeiting of drugs is estimated by WHO at more than US$35 billion and represents more than 15% of the pharmaceutical market worldwide; unfortunately this percentage increases to more than 60% in developing countries (35 to 90% in Southeast Asia).

The situation is even worse in sub-Saharan Africa where the burden of malaria is the greatest. In 2001, WHO recommended that malaria-endemic African countries consider changing to artemisinin-derivatives as first-line treatment for malaria. However, adopting this new policy was difficult due to the high cost and relative shortage of the raw plant material source (*Artemisia annua*). Thus, the high cost and shortage of drugs led to the spread of fake artemisinin which places many thousands of African young children at risk. A large proportion of these fake antimalarials are imported from Asia. Also, locally produced antimalarials may be substandard or fake, with a name, label, and packaging that are different from the genuine drugs. Unfortunately, there does not seem to be an easy answer to this problem; however, recognizing the scope of the problem is certainly the first step.

Overall Patient Care. It is very important to remember that patients who present to a medical clinic, office, etc., that does not have expertise in tropical medicine tend to receive suboptimal treatment. Malaria may not be recognized, and the diagnosis may be delayed until it is no longer possible to save the patient. Improvements in obtaining the patient history, symptom recognition, presumptive diagnosis development, and treatment of malaria are mandatory to prevent severe illness and death among travelers. These patients tend to be immunologically naive, have never been exposed to malaria before, and have no residual antibody. Without the benefit of immunologic protection, they present with very low parasitemias but may be seriously ill. Their illness will mimic many other conditions, adding to the lack of recognition of a possible malaria infection. Unfortunately, this situation often occurs in

TABLE 26.17 Current issues related to maternal malaria, transmission, pathogenesis, and therapy options

Issue	Comments	Reference(s)
Naturally acquired *Plasmodium knowlesi* in human (Thailand)	The occurrence of simian malaria in humans emphasizes the possible importance of wild primate populations in malaria-endemic and disease transmission areas.	119
Perinatal mother-to-child transmission (MTCT) of HIV	Placental malaria controlled at low density may cause increase in immune responses that protect against MTCT. Uncontrolled, high-density malaria may disrupt placenta structure and generate antigen stimulus to HIV replication, thus increasing the risk for MTCT.	120
Chloroquine resistance in *P. vivax*	Chloroquine has been the drug of choice for *P. vivax* since 1946. No genetic mutations have been linked to chloroquine resistance in *P. vivax* infections. Some recommend mefloquine as alternative; daily doxycycline is also an option when combined with chloroquine. Malarone plus primaquine is the only available therapy with proven efficacy (>90%).	121
Chloroquine resistance in *P. falciparum*	By 1973 in Thailand, chloroquine replaced by a combination of sulfadoxine and pyrimethamine (SP); >10 African countries also switched their first-line drug to SP. In 1985 SP was replaced by mefloquine; resistance to mefloquine led to introduction of artemisinin as combination drug in the mid-1990s. New drugs cost more, have more side effects, take longer time for cure, and have more compliance problems than chloroquine. Another option would be to combine SP (better parasitologic response than chloroquine) with chloroquine (more rapid clinical response).	122, 123
Atovaquone-proguanil resistance in nonimmune North American traveler to West Africa (*P. falciparum*)	Atovaquone-proguanil is a useful agent for treating uncomplicated *P. falciparum* malaria (oral, short course, low side effects). PCR and sequence analysis confirmed the acquisition of a point mutation in the cytochrome *b* gene of the recrudescent isolate (known to confer high-level resistance to atovaquone by reducing the binding affinity of atovaquone). Also, in this case, suboptimal therapy may have played a role in the emergence of resistance.	124
Rapid elimination of asexual forms of *P. falciparum* (most effective way to prevent development of gametocytes)	Primaquine (mefloquine-primaquine) is not effective in the eradication of gametocytes in the primary infection and in the prevention of subsequent gametocytemia compared with artesunate therapy (mefloquine-artesunate). Recrudescent infections lead to subsequent gametocytemia, which drives drug resistance.	125
Distinguishing *P. falciparum* treatment failures from reinfections: PCR genotyping	Study in Tanzania: all samples contained multiple *P. falciparum* infections; primary and recrudescent parasites analyzed by PCR; some of the recrudescing parasites originated from new infections.	126
Fake antimalarials in Southeast Asia (major impediment to malaria control)	Myanmar, Lao People's Democratic Republic, Vietnam, Cambodia, Thailand: 53% of tablet packs labeled as "artesunate" contained no artesunate; 9% of mefloquine samples contained <10% of the expected amount of active ingredient.	127
Recrudescence in artesunate-treated *P. falciparum* cases (depends on parasite burden, not on parasite factors)	Artemisinin derivatives are first-line drugs in Thailand; no documented resistance to artemisinin. Patients with admission parasitemias of >10,000/μl had a 9-fold higher likelihood of recrudescence than did patients with lower parasitemias; recrudescence not due to resistance but to admission parasitemia.	128

areas where malaria is not endemic and thus may be the last causative agent considered.

Epidemiology and Prevention

Malaria is primarily a rural disease and is transmitted by the female anopheline mosquito. There are great variations in vector susceptibility to infection with the parasite, with many variations being related to differences in parasite strain. Even when the vector is present in an area, an average number of bites per person per day must be sustained or the infection gradually dies out. This critical level can be influenced by a number of factors, including the vector preference for human blood and habitation and the duration of infection in a specific area. Once an area is clear of the infection, there may also be a drop in population immunity, a situation that may lead to a severe epidemic if the infection is reintroduced into the population (53) (Table 26.18).

Immunity. There are some genetic alterations in the RBCs that confer natural immunity to malaria. Changes in the RBC surface interfere with attachment and invasion of merozoites. Changes in hemoglobin or intracellular enzymes interfere with parasite growth and multiplication (Table 26.19).

Duffy antigen-negative RBCs lack surface receptors for *P. vivax* invasion. Many West Africans and some American blacks are Duffy antigen negative, which may explain the low incidence of *P. vivax* in West Africa. In other areas of Africa, *P. vivax* is much more prevalent.

Partial resistance is seen in individuals with the sickle cell trait and in those with sickle cell anemia. Resistance is related to the sickling of hemoglobin S (HbS)-containing RBCs. Other factors include the formation of deoxyhemoglobin aggregates within the cells, the loss of potassium from sickled cells, and the fact that the parasites actually cause HbS cells to sickle.

Resistance to *P. falciparum* is also seen in G6PD-deficient cells. Partial immunity to malarial infection is seen in areas where malaria is endemic when HbC, HbE, β-thalassemia, and pyruvate kinase deficiencies exist.

Infants are also relatively immune to malarial infections during the first year of life as a result of the presence of a large percentage of HbF, passive immunity from maternal antibodies, and diets deficient in *p*-aminobenzoic acid.

Both cellular and humoral immunities play a part in protection. However, immunity is species specific and in some cases even strain specific. It has also been noted that acute malarial infections can cause immunosuppression. Actual impairment of immune responses to vaccination after acute malaria has been documented.

Insecticide-Impregnated Bed Nets and Clothing. Insecticide-impregnated bed nets have been widely used with various degrees of success. Important factors for the success of any bed net program include insect susceptibility to the particular insecticide used (often pyrethroids), high coverage with impregnated bed nets, high malaria incidence, good community participation at an acceptable sustained level, high mosquito densities when people go to bed, and a high proportion of *P. falciparum.* Bed net impregnation appeared to be somewhat more effective than DDT spraying (Fig. 26.21) (54–56).

The use of permethrin-impregnated clothing has also been evaluated and has been found to reduce the incidence of both malaria and leishmaniasis by a large percentage in the absence of any other interventions. In addition to use by the military (57), permethrin-impregnated clothing for travelers has a number of advantages. First, this insecticide is not a repellent but actually kills mosquitoes, flies, and ticks on contact. Also, impregnated clothing fibers remain effective even after 3 months of repeated machine washing. Apparently, this approach, in which the clothing is soaked with the appropriate solutions, works better than use of an aerosol spray. It is recommended that travelers treat two sets of clothing to wear in high-risk situations. Permethrin liquid is available in the United States as Permanone.

Vaccines. The development of techniques for *in vitro* culture of *P. falciparum* has enhanced the ability to study parasite metabolism and mechanisms of attachment and invasion. Other studies involving genetic engineering techniques and serologic immunofluorescence tests have led to the development of genetic manipulation of *Escherichia coli* to produce proteins that are identical to the receptor protein on the parasite necessary for RBC attachment. With the use of these and other, newer techniques, progress toward vaccine production may lead to effective protection against malarial infections. Increased funding through private and public partnerships has led the industrial sector to become more involved in vaccine research.

The Perfect Vaccine. A perfect malaria vaccine will induce immune responses to every stage of the complicated life cycle of *Plasmodium*. Different and distinct immune mechanisms operate against these different stages in the life cycle. Therefore, a multistage vaccine must be a multi-immune response vaccine. Development of these types of vaccines is required to reduce significantly the increasing numbers of malaria infections and deaths seen each year (58).

Pre-erythrocytic stage as vaccine target. A pre-erythrocytic stage vaccine would prevent sporozoites from invading the liver or prevent liver-stage parasites from developing to maturity and releasing infective merozoites, or both. This type of vaccine would prevent disease (absence of RBC cycle and clinical symptoms) and the transmission of malaria (no gametocyte formation).

Erythrocytic stage as vaccine target. The asexual RBC stage vaccine would prevent or reduce morbidity or mortality by parasite load reduction. Neutralizing antibodies to parasite products (released during schizont rupture) or inhibiting cytoadherence of infected RBCs in severe forms of malaria would thus reduce morbidity and mortality.

Sexual stage as vaccine target. A vaccine designed to induce immune responses to the sexual-stage antigens would provide no protection to the infected patient but would dramatically limit or eliminate transmission of the parasite within the community (it would destroy gametocytes, prevent fertilization, and prevent development of the parasite within the mosquito).

Multistage, multivalent, multi-immune response vaccine. One of the main advantages of the multistage vaccine is its ability to combat parasite variation. Organism variants that evade the immune mechanisms operating at one of the early stages in the life cycle would most probably be susceptible to one of the later-stage immune mechanisms. Antigenic characteristics of the parasite vary with the life cycle stages, and most antigens are not expressed during all stages but may be present only during a single stage. This mandates either total removal of the parasite in one form within the

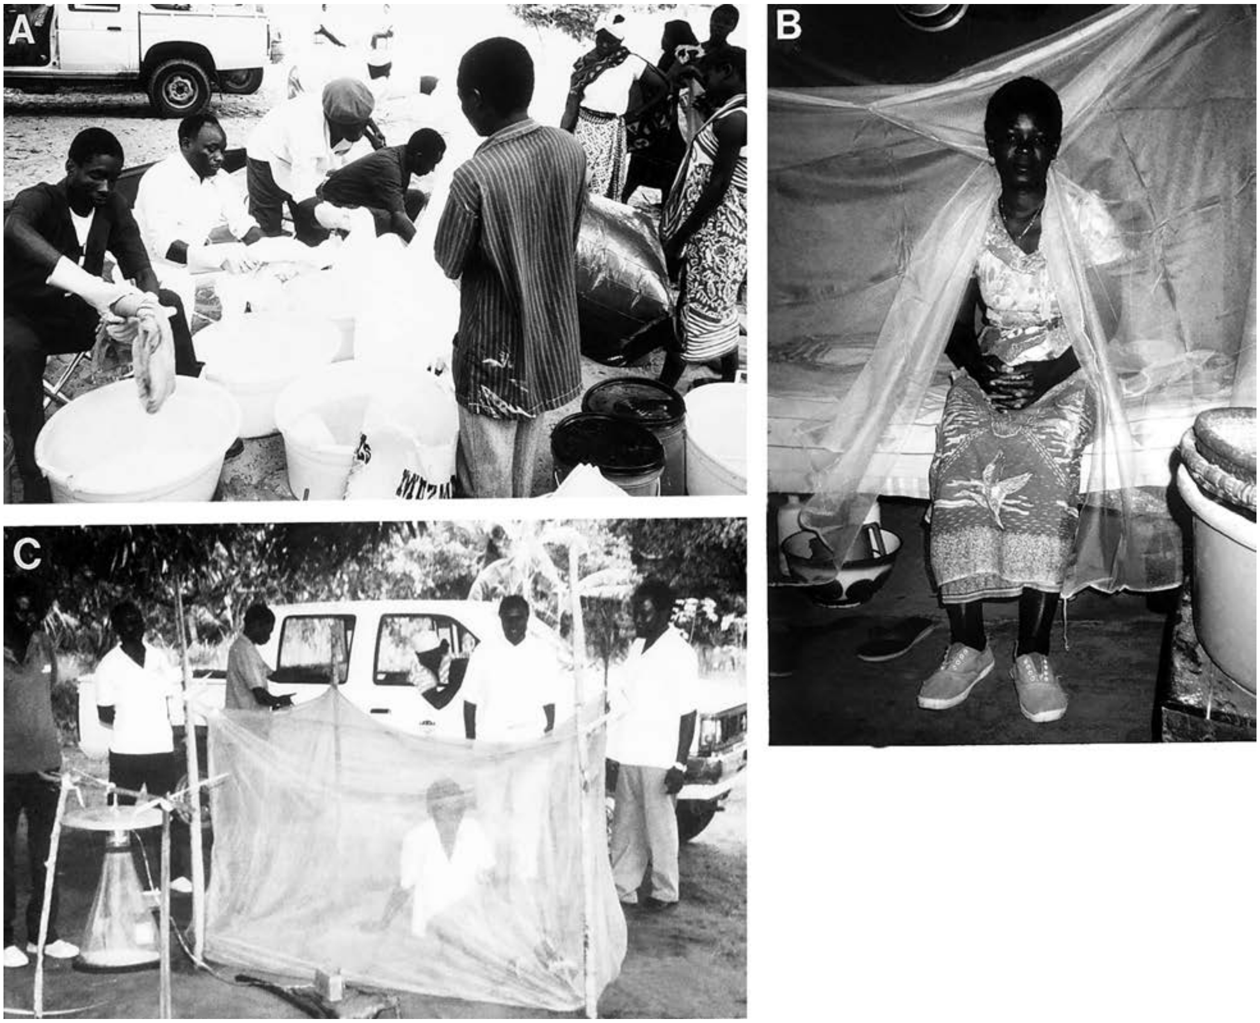

Figure 26.21 Bed nets used in malaria prevention. (A) Nets being dipped in a suspension of insecticide following purchase. For people to appreciate the value of the insecticide treatment, it is important for them to see the process. The nets are wrung out, placed in a plastic bag, and returned to the owner. Later, in the house, the net is laid directly on the bed and allowed to dry out. This must be done indoors to avoid direct exposure to the sun, which degrades the insecticide. (B) Net in place in the home. The occupant of the house in the Bagamoyo BedNet Project, Tanzania, is preparing for rest. The net is a rectangular design, which provides a better ventilating effect than the conical variety. (C) Rectangular bed net being set up outdoors to enable the collection of mosquitoes by the Centers for Disease Control and Prevention Light Trap suspended on the left. Nets for this use are not treated with insecticide. Mosquitoes attracted to the person sleeping under the net are attracted to the light and enter the trap. In the morning, the trap is removed and the collection will indicate which mosquito species are hunting outdoors for blood meals. Similar collections can be made indoors. (Courtesy of Clive Shiff, Johns Hopkins University, with permission.) doi:10.1128/9781555819002.ch26.f21

life cycle or partial removal of various stages, with the overall result being parasite elimination (59).

For a malaria vaccine to induce optimal and sustainable protection, both cellular and humoral responses will have to be elicited against multiple targets from the different life cycle stages. It appears that global malaria vaccine development will move forward on several fronts, hopefully leading to effective products available for clinical use (58, 59).

Overall Control of Malaria. The major determinants related to malaria transmission include (i) the parasite, with its many biological options and genetic diversity; (ii) the vector, with tremendous differences in behavior and transmission capability; (iii) the human host, with biological, behavioral, political, and social ramifications; and (iv) the environment, with tremendous changes such as altitude, temperature, rainfall, and global climate change (Table 26.20). Relevant concepts for the control of mosquito transmission of human

TABLE 26.18 Malaria epidemics in recent years: climatic change, population displacement, control policy failures, drug resistance[a]

Geographic area	Comments
Central America	Agricultural development, irrigation changes, colonization, insecticide resistance have led to overall increase in malaria
South America	
Amazon rain forest	New settlement and mining have led to >500,000 cases/year in Brazil (>50% of malaria cases in the Americas) and 6,000–10,000 deaths
Peru	Prolonged rains, abnormally high temperatures, and long, humid summers have led to an increase in malaria
Africa	
Savanna and forest	Increasing chloroquine resistance; >50% of population is infected; malaria is main cause of death in children, killing 1 in 20 younger than 5 yr
Dry savanna and desert fringe	Increased rains and population movements have led to epidemics
Cities	Severe increased drug resistance, inadequate sanitation, overextended services, and increasing deaths in young adults are all factors
Burundi, Rwanda, neighboring countries	Mass refugee problem has led to worsening overall malaria situation
Botswana, Namibia, Swaziland, Zimbabwe	Exceptional rains and population movements have led to an overall increase in malaria
East African highlands and Madagascar	Cyclical epidemics related to meteorological changes, complicated by agriculture changes, deforestation, and population movements
Ethiopia	Repeated epidemics in highlands due to degradation of environment, drought and famine, and large-scale resettlement approaches
Azerbaijan, Iraq, Tajikistan, Turkey	Civil disturbances, population displacement, and intensified agricultural activities have led to an epidemic resurgence of malaria
Afghanistan	Interruption of control and displacement of populations due to war are responsible for 2 million to 3 million cases annually
South Asia: middle	Increased epidemics in tribal, forest, and hill areas; periodic epidemics in dry lands of northwestern India and Sri Lanka (pooling of river sources, environment conducive to vector breeding); over 2.5 million cases/yr
Cambodia, Lao People's Democratic Republic, Myanmar, Thailand, Vietnam	500,000 cases/yr; rapidly increasing risk in frontier areas of economic activity, often including illicit mining and civil unrest; most severe drug resistance in the world
Papua New Guinea, Philippines, Solomon Islands, Vanuatu	300,000 cases/yr, released to colonization of new areas

[a] Adapted from the WHO/CTD Health Map, 1997, and reference 53.

malaria parasites are listed in Table 26.21; examination of this aspect of malarial transmission control provides an excellent example of the complexities that exist.

Another critical aspect of control involves the safety of the blood supply. A number of factors impact the blood supply worldwide, including government policies and regulations, professional society standards, the donor pool (voluntary and/or paid), the ability of health care personnel to order blood when necessary, infectious-disease screening, posttransfusion adverse effects monitoring, and product-related side effects (60). A number of constraints will continue to affect the development of a global strategy for the control of malaria (Table 26.22).

Babesiosis

When blood parasites are discussed, malaria is usually considered the most important and well-known infection. However, there is another organism that also causes human infection. Recognition of the spectrum of disease caused by organisms of the genus *Babesia* has recently resulted in an increase in the number of cases reported. Increased interest has also been generated because the infection can be transmitted via transfusion, can cause serious illness, particularly in compromised patients, and is difficult to treat (61).

The *Babesia* blood parasite was first discovered in cattle in 1888, and in 1893 it was recognized as the cause of Texas cattle fever transmitted by ticks (48). Cases of babesiosis have been documented worldwide, and several outbreaks in humans have occurred in the northeastern United States, particularly in Long Island, Cape Cod, and the islands off the East Coast (61). Although there are many species of *Babesia*, *Babesia microti* is the cause of most human infections in the United States.

A case reported from California occurred in a 24-year-old man who had been splenectomized in 1985 for an immune system-mediated thrombocytopenia and who was a U.S. Army officer stationed at Fort Ord in Monterey County. This is the third reported case of presumed indige-

TABLE 26.19 Host genetic factors in resistance to malaria[a]

Factor[b]	Comments
Hemoglobin disorders	
Sickling disorders	Includes sickle cell disease (SS), heterozygous states for sickle cell gene and those for hemoglobin C (SC) or β-thalassemia (S-thal); carrier state for sickle cell gene is AS; widely distributed throughout tropical Africa, parts of the Mediterranean, the Middle East, and central India; hemoglobin S confers protection against *P. falciparum* malaria (the parasite cannot complete life cycle due to cell sickling and destruction; reduced oxygen levels result in diminished parasite growth; reduced rosetting of RBCs in sickle carriers; protection also related to hemoglobin structure and parasite inability to metabolize)
Hemoglobins C and E	Data relating to selective advantage against malaria less convincing than for hemoglobin S; reduced parasite invasion and impaired growth have been documented; data for hemoglobin E have shown inconsistent results
Hemoglobin F	Growth of *P. falciparum* reduced in presence of hemoglobin F, thought to be due to hemoglobin itself rather than RBC properties; higher levels of hemoglobin F during first year of life might offer protection (newborn infants and adults with persistent fetal hemoglobin production)
Thalassemia (α and β)	Distribution of β-thalassemia coincides with that of malaria; 70% reduction in clinical malaria and 50% reduction in risk; although not seen in all geographic areas, in Papua New Guinea high protective effect of homozygous state for β-thalassemia against complications of *P. falciparum* malaria; babies under 2 yr (homozygous for α^+-thalassemia) had higher frequency of both *P. vivax* and *P. falciparum* but were resistant from 2 yr of age
Erythrocyte polymorphisms	
Glucose-6-phosphate dehydrogenase deficiency	Both female heterozygotes and male hemizygotes have reduced risk (around 50%) of developing severe malaria
Duffy-negative RBCs	Resistant to invasion by *P. vivax*
Ovalocytosis	Patients subject to severe malarial infection with high parasitemias; however, there is strong protection against cerebral malaria; structural change in RBC membrane interferes with binding of infected RBCs to vascular endothelium
Immunogenetic variants	
HLA genes	Each protective HLA type associated with 40–50% decrease in risk; these HLA types are common
HLA class I	HLA-A, -B, -C determine specificities of $CD8^+$ T cells (cytotoxic, major role in defense against intracellular pathogens); HLA-B35 frequency reduced in children with cerebral malaria and those with severe malarial anemia
HLA class II	HLA-DR, -DQ, -DP determine specificities of $CD4^+$ T cells that secrete cytokines and provide T-cell help for antibody production and action of other T cells; HLA-DRB1*1302–HLA-DQB1*1501 frequently reduced in children with severe malarial anemia
Cytokine, other immune response genes	
TNF	Major mediator of malaria fever; TNF is increased in children with cerebral malaria and markedly so in children with fatal cerebral malaria
MBL	Deficiency may be associated with increased susceptibility to infectious diseases; effect on malaria may be small to none
CD35	Also called complement receptor 1 (CR1); plays a role in rosetting; African variant of CR1 may protect against severe malaria

[a]Adapted from reference 129.

[b]HLA, human leukocyte antigen; TNF, tumor necrosis factor; MBL, mannose-binding lectin.

nous transmission of babesiosis in patients in California, all of whom had been previously splenectomized.

Over the past few years, one patient from Washington and four from California were identified as being infected with a similar protozoal parasite, very similar in morphology to *Babesia* species; the Washington isolate was designated WA1. All four patients had undergone splenectomy, two as a result of trauma and two for medical reasons. Two of the four patients had complications, and one died. Piroplasm-specific nuclear small-subunit ribosomal DNA was recovered from the blood of the four patients by PCR amplification. Genetic sequence analysis showed that the organisms were almost identical. Phylogenic analysis showed that this strain is more closely related to a known canine pathogen (*B. gibsoni*) and to *Theileria* species than to most members of the genus *Babesia*. Serum from three of the patients was reactive to WA1 but not to *B. microti* antigen. It now appears that there is a newly identified *Babesia*-like organ-

TABLE 26.20 Epidemiology of malaria[a]

Characteristic	Stable malaria	Unstable malaria
Transmission pattern	Occurs throughout the year; uniform intensity; pattern repeated yearly	Seasonal transmission intensity variable; dramatic epidemics likely
Community immunity	Strong resistance due to intense transmission	Reduced resistance due to low-level and variable transmission intensity
Age group affected	Mainly young children	All age groups
Control	Difficult	Easier
Major determinants relevant to malarial transmission	Parasite—different biology, genetic diversity Vector—air temperature, relative humidity, breeding sites, density, feeding times, resting places, life cycle Human host—genetic factors, acquired immunity, general health status, behavior patterns, political/social factors Environment—altitude, temperature, rainfall, flow rate of rivers and streams, global climate change, colonization, group migrations, agricultural and building projects, deforestation	

[a] Adapted from reference 107.

ism which causes clinical infections in the western United States. The spectrum of illness ranges from asymptomatic infection to fulminant, fatal disease (61). The first case of transfusion-transmitted babesiosis with the WA1 type has been reported from Washington State.

Studies in New York State indicate evidence of exposure to five tick-borne pathogens, including *B. microti*, in a high-risk population in the northeastern United States. There was also evidence of possible dual infection in some patients (62). In the same area, a cluster of transfusion-associated babesiosis cases was traced to a single asymptomatic donor; six patients were exposed, and three of these developed parasitemia (63). Environmental conditions necessary for the transmission of *B. microti* now appear to be present in areas of New Jersey, and physicians in central New Jersey should be aware of this potential threat.

A total of 10 cases of babesiosis have been reviewed, most of which were probably acquired in northwestern Wisconsin. Of 10 cases, 3 were fatal and occurred in elderly patients, who died after experiencing complications (64). These cases also serve to emphasize the importance of this potentially fatal zoonosis, which is not limited to the northeastern United States. In another case from western Wisconsin, a woman who had not traveled outside of Wisconsin was hospitalized and found to be infected with both *B. microti* and *Borrelia burgdorferi* (65).

Babesia spp. are grouped into the small *Babesia* spp. (1.0 to 2.5 µm), which include *B. gibsoni*, *B. microti*, and *B. rodhaini*, and the large *Babesia* spp. (2.5 to 5.0 µm), which include *B. bovis*, *B. caballi*, and *B. canis*. These phenotypic classifications are, for the most part, consistent with genetic characterization based on nuclear small-subunit ribosomal DNA sequences. The small *Babesia* spp. are more closely related to *Theileria* spp. than are the larger organisms. The one exception is *B. divergens*, which appears small on blood smears but is genetically related to the large *Babesia* spp. The two primary pathogens of humans are *B. microti* and *B. divergens*, along with the unnamed species WA1 (Washington), CA1 (California), and MO1 (Missouri) (66).

Life Cycle and Morphology

These organisms have at least three stages of reproduction within the life cycle: (i) gamogony (formation and fusion of gametes inside the tick gut), (ii) sporogony (asexual reproduction in salivary glands), and (iii) merogony (asexual reproduction in the vertebrate host). Infection is transmitted by several species of ticks in which the sexual multiplication cycle occurs. Several thousand sporozoites can be found in the dermis surrounding the tick's mouth during the final hours of attachment and subsequent feeding. In addition to tick bites, transmission can also occur via blood transfusion or vertical transmission from mother to child, confirmed by detection of *Babesia* DNA in placenta tissue (67).

When a tick takes a blood meal, the infective forms are introduced into the human host (Fig. 26.22). The organisms infect the RBCs, in which they appear as pleomorphic, ring-like structures (Fig. 26.23). They tend to be somewhat pear-shaped within the RBCs (piroplasms). They resemble the early trophozoite (ring) forms of malarial parasites, particularly *P. falciparum*. The organisms measure 1.0 to 5.0 µm, the RBCs are not enlarged or pale, and the cells do not contain stippling. Malarial pigment is never seen. The early form contains very little cytoplasm and has a very small nucleus. In mature forms, two or more chromatin dots may be seen. Occasionally, a tetrad formation, referred to as a Maltese cross, is seen (Fig. 26.23). While ring forms may be seen outside the RBCs in *Babesia* infections, ring forms outside of the RBCs are rare in *Plasmodium* infections.

TABLE 26.21 Relevant concepts for the control of mosquito transmission of human malaria parasites[a]

Concept	Discussion	Control relevance
Only mosquitoes in the genus *Anopheles* support the sporogonic development of human malaria parasites.	A high degree of specificity exists between mosquito species and malaria parasites. Approximately 50 of the 500 *Anopheles* species mosquitoes are competent vectors of human malaria.	It is important to correctly identify vector species in nature and to target vector control to coincide with blood-feeding and resting behaviors of the vector species.
Infected humans carrying gametocyte-stage parasites are the "reservoir of infection."	The probability that mosquitoes will become infected depends on the number and quality of gametocytes present and ingested during blood-feeding.	Most antimalarials have no direct effects on gametocytes; thus, treated individuals may remain infectious for the mosquito vectors.
The rate of *Plasmodium* development in the mosquito depends primarily on temperature.	The rate of development from ingested gametocytes to sporozoites in the salivary glands depends on temperature. Temperature also determines mosquito survival and the probability of mosquito infection.	These relationships play a large role in parasite survival and parasite growth, affecting both the probability and intensity of transmission.
A female mosquito can remain infective for life.	The female anopheline mosquito is capable of transmitting sporozoites during each consecutive blood-feeding instance, occasionally to multiple individuals during each feeding cycle.	Mosquito control has multiple parameters for consideration.
Epidemiology of human infection associated with vector populations	Worldwide patterns of epidemics are associated with environmental and climatic factors that influence vector distribution, abundance, and blood-feeding behavior.	Personnel knowledgeable about environmental issues and the relationship between the environment and vector control are vital.
Parasite transmission intensity depends on both the numbers of biting vectors and the proportion of vectors carrying sporozoites in the salivary glands.	Intensity of transmission depends on the entomological inoculation rate (EIR), which is the product of the biting rate and the proportion of mosquitoes with sporozoites. EIRs are expressed in terms of average numbers of infective bites per person per unit of time.	EIRs in Africa range from 1 to >1,000 infective bites/yr. EIRs of >5 bites/yr are associated with malaria prevalence rates of >70% in human populations.
Both the frequency of sporozoite inoculation and dose per infectious bite are important determinants of human infection.	Sporozoites inoculated by only a single mosquito can cause human malaria and serious illness, even death.	In areas of Africa where residents are exposed to <5 bites/yr, some of the highest incidences of severe disease can be seen.
Marked reduction in transmission intensity is required to lower the prevalence of human malarial infection.	An infection acquired by a single individual can be transmitted via mosquitoes to many uninfected individuals in a short time.	In some areas, EIR reductions of >95% are required before the malaria prevalence drops.
From a public health point of view, there are no acceptable levels of malaria transmission.	Multiple factors are required for control efforts to be successful, including an integrated approach: drug therapy, vector control, and public health education at the community level.	Future efforts will include vaccines, new antimalarial drugs, and better vector control means. Public health will emphasize "control" rather than "eradication."

Clinical Disease

The majority of babesiosis cases in the United States are caused by *B. microti* and occur in the Northeast and upper Midwest. A small number of infections caused by *B. duncani* and *B. duncani*-like organisms have been reported on the West Coast from California to Washington State. Also, *B. divergens*-like organisms have been reported in Kentucky, Missouri, and Washington State. In Europe, almost all reported cases have been due to *B. divergens*, and a few have been caused by the EU1 species, now called *B. venatorum* (68). Sporadic cases of babesiosis have also been reported in Asia, Africa, Australia, and South America. The symptoms in human babesiosis are quite variable, ranging from asymptomatic to intense malaria-like episodes resulting occasionally in death. Most often, symptoms are nonspecific (fever, headache, and myalgia).

It is suspected that the frequency of babesiosis in the United States is greater than the number of cases reported. Between 1970 and 1991, 136 cases were reported in New York State, while between 1969 and 1998, 160 cases were reported in Nantucket. Babesiosis is usually a self-limiting disease; there are probably also asymptomatic and undiag-

TABLE 26.22 Global strategy for malaria control: constraints[a]

Problem	Comments
Misleading assumptions: Malaria control is a vertical program Existing tools will not allow impact on morbidity and mortality Malarial control is sole responsibility of health sector Malaria in Africa is uniform and can be controlled by "magic bullet"	Misconceptions have led to reduced political and financial commitment at local, national, and international levels. Accelerated control programs have not been achieved due to lack of funding.
Shortage of people with appropriate knowledge	Little knowledge and understanding of malaria epidemiology and planning/management of control efforts. Peripheral health services are not equipped for correct and adequate diagnosis and treatment. Very few countries have operational training programs in place.
Drug resistance; shortage of antimalarial drugs	Complicates the development of national antimalarial drug policies and provision of adequate disease management. Poor-quality antimalarial drugs; no mechanisms to ensure quality, availability, and rational use of affordable and effective drugs.
Poor collaboration	Inter- and intracollaborative efforts within and among countries are poor. Surveillance systems and information exchange mechanisms are limited; improvement is required for successful implementation.
Limited commitment from private sector	New links between research and development and malaria control needs are minimal; limited commitment to development of new tools for control. However, various initiatives aiming to develop malaria clinical research have recently been launched. Donors are public or international (Global Fund, Roll Back Malaria Initiative, National Institutes of Health [NIH], European Developing Countries Clinical Trial Partnership [EDCTP] program), as well as private (Bill & Melinda Gates Foundation). These substantial funds should enhance the research of new antimalarial drugs and large-scale, adequately designed trials.

[a] Adapted from reference 53.

nosed carriers. The mortality rate has been reported at about 5% (61).

However, infections caused by *B. divergens* in Europe are far more serious, with a mortality rate of 42%. Fatal cases of *B. divergens* have been reported in France, Britain, Ireland, Spain, Sweden, Switzerland, the former Yugoslavia, and the former USSR (Table 26.23). In two patients from Austria and Italy, the DNA sequences were identical; however, in phylogenetic analysis, the organism clusters with *B. odocoilei*, a parasite of white-tailed deer that is related to *B. divergens* (69). Although human babesiosis is relatively new to Japan, it appears that a new type of *B. microti*-like parasite, the Hobetsu type, is the major type among Japanese wild rodents.

***Babesia microti*.** Most cases have been reported from seven states (Connecticut, Massachusetts, Minnesota, New Jersey, New York, Rhode Island, and Wisconsin). The incubation period may last from 1 to 9 weeks and clinical features are similar to those of malaria. The severity is variable depending on the immune status of the host, ranging from an asymptomatic infection to a severe life-threatening disease. Severe disease generally occurs in patients over the age of 50 years or with splenectomy, malignancy, HIV, or immunosuppressive medication. Although headache and lethargy are common, babesiosis is rarely associated with specific neurological problems in humans. Diminished consciousness and/or coma are rare complications that are associated with severe and often fatal disease. Most patients with *B. microti* infections develop mild to moderate flu-like illnesses characterized by malaise and fatigue that include the following symptoms: rash, fever, chills, sweats, headache, arthralgia, myalgia, anorexia, cough, or nausea. Rarely, mild splenomegaly or hepatomegaly may be seen. Clinical symptoms may last for weeks to months, but rarely for more than a year.

In the first four human cases (before 1969) within the United States, the patients had been splenectomized and three died as a result of the infection. Since then, other cases have been found in patients with intact spleens. In the patients from Nantucket Island, Massachusetts, who were not splenectomized, symptoms began 10 to 20 days after a tick bite and continued for several weeks. The symptoms started with general malaise, which was followed by fever, shaking chills, profuse sweating, arthralgias, myalgias, fatigue, and weakness. Hepatosplenomegaly was present, and five patients had slightly elevated serum bilirubin and transaminase levels as a result of hemolytic anemia.

During the summer of 1980, six patients from Shelter Island and eastern Long Island were diagnosed as having babesiosis caused by *B. microti*. Symptoms lasted for 19 to 24 days in five patients and included fever, shaking chills,

TABLE 26.23 Similarities and differences in *Babesia* spp.[a]

Species[b]	Geographic location	Vector	Incubation period	Disease	Comments
Babesia divergens	Europe; relatively rare, but 42% mortality	*Ixodes ricinus*	1–3 wk	Sudden appearance, hemoglobinuria followed by jaundice; shock-like picture	Most patients splenectomized (frequent contact with cattle); bovine pathogen; same vector for Lyme disease
EU1 (*B. divergens*-like) *B. venatorum*	Italy, Austria	Not known, but probably *I. ricinus*	One patient had possible tick exposure 2 wks prior to symptoms	Fever, chills, confusion, jaundice	Both patients splenectomized; organism most closely related to *B. odocoilei* (infects white-tailed deer)
Babesia divergens-like	Washington	Not known	Not known	Asplenic 82-year-old male with high parasitemia (41.4%) and multiorgan dysfunction including renal failure; survived	Patient's serum reacted to *B. divergens* but not to *B. microti* or WA1
Babesia microti	United States: northeastern and Great Lakes regions; range probably expanding to include as far south as New Jersey, parts of Europe, and Japan; mortality rate for clinically apparent infections, 5%	*Ixodes scapularis* (*I. dammini*)	1–6 wk; up to 3 mo	Most cases are mild and resolve on their own; most severe cases have fulminating malaria-like infection; malaise, chills, myalgia, anemia, fatigue, fever; hepatomegaly and splenomegaly may be present; hemolytic anemia several days to few months (more common in elderly or asplenic individuals)	Age range 3 wk to 86 yr; most within 50–60 yr; most are normosplenic; Japanese strains appear to be *B. microti*-like
Babesia duncani WA1	California, Washington	Not known, but *Dermacentor variabilis*, *Ornithodoros coriaceus*, and *Ixodes pacificus* found in areas where WA1 found	Not known	Splenectomized patients	Related to canine pathogen, *B. gibsoni*, but WA1 does not seem to infect dogs; highly virulent in hamsters
Babesia sp. CA1	California	Not known	Not known	Splenectomized patient; 2 patients had complicated courses, and 1 died	This strain is more closely related to *B. gibsoni* and to *Theileria* species
Babesia sp. MOI	Missouri	*Ixodes dentatus*	Not known	Parasitemia in 3–4%; systemic lupus erythematosus, diagnosed in 1979, taking prednisone; splenectomy in 1979	*B. divergens*-like; 72-year-old asplenic male
PB-1	Baboon colonies	Not known	Not known	Potential problems with organ xenotransplantation to human recipients	Most closely related to *B. microti*; may be organism previously described as *Entopolypoides*; issues include prevention of potential zoonotic transmission

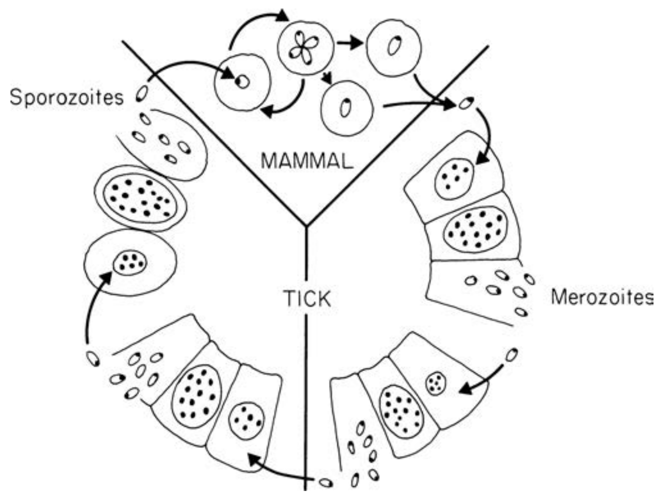

Figure 26.22 Life cycle of *Babesia* spp. (Illustration by Gwen Gloege.) doi:10.1128/9781555819002.ch26.f22

dark urine, and headache, as well as anorexia, malaise, and lethargy. The one patient in the group who had been splenectomized also had the most severe illness. The parasitemia could not be detected in one patient, was 5% in four of the six, and was 80 to 90% in the splenectomized patient. Hamster inoculation produced a patent parasitemia in all cases.

By the end of 1991, 13 cases of babesiosis had been reported in Connecticut, this being the largest number of human cases reported on the mainland United States. Information from the patients indicated that 12 infections were probably acquired via tick bites and 1 was acquired from a blood transfusion. The ages of the patients ranged from 61 to 95 years for those with tick-acquired infections. Two patients died of active infections, and one died of chronic obstructive pulmonary disease. Indirect fluorescent-antibody titers ranged from 11,024 to 14,096, and five of eight patients had significant IgG or IgM titers (1,640 to 15,120) to *B. burgdorferi*. *B. microti* from the blood of 7 of 12 patients tested was isolated in Syrian hamsters. It is now clear that babesiosis is endemic in New Jersey, as well as other areas of the northeast (70).

Cases of congenital babesiosis share similarities, including asymptomatic maternal infection and development of fever, hemolytic anemia, and thrombocytopenia in the infant detected between 19 and 41 days after birth. All of the infants responded to antimicrobial drug therapy; three were treated with azithromycin plus atovaquone, the preferred treatment regimen for mild babesiosis. All infants required a blood transfusion because of severe anemia. The clinical signs and symptoms for these cases of congenital babesiosis are similar to those of congenital malaria in nondisease endemic areas (67).

***Babesia duncani* (WA1).** *Babesia* infections described in California are quite different from those seen in the northeastern United States with *B. microti*, where the infection is most often subclinical. Infections in California and Washington tend to present as a fulminant, febrile, hemolytic disease affecting splenectomized or immunosuppressed individuals. *B. duncani* n.sp. is a distinct species from other known *Babesia* spp. for which morphologic and sequence information is available (71). All reported cases of WA1 babesiosis have occurred in the Pacific coast region of the United States, suggesting that WA1 is limited to this geographic area. However, WA1 IgG was found in 27% of clinical sera sent to a large reference laboratory for WA1 IgG testing from across the United States over a 2-year period, implying that exposure to WA1 or a closely related organism occurs outside Pacific coast states (72).

The serum of an 82-year-old splenectomized man from Washington reacted to *B. divergens* but not to *B. microti* or WA1 antigens. This case emphasizes the point that unusual parasites may be detectable by blood film examination but not by serologic or molecular testing for *B. microti* or WA1-type parasites (66). This is important to remember, since new organisms similar but not identical to a number of the well-known *Babesia* spp. may be identified in patients in different parts of the world. Without the manual examination of blood films, these organisms may be missed.

***Babesia* sp. CA-type.** Four severe to fatal human cases with *Babesia* sp. CA-type have been reported in splenectomized patients from California. Although this organism is morphologically indistinguishable from *B. duncani*, it can be distinguished by genetic sequencing.

***Babesia* sp. MO1.** *Babesia* sp. MO1 is a rare cause of babesiosis in the United States. In 1992, this novel *Babesia* species was detected in a splenectomized patient in Missouri. Despite treatment, the patient died 13 days after diagnosis. Two additional cases of *Babesia* sp. MO1 in splenectomized patients, both nonfatal, have been reported in Kentucky and Washington. Initial phylogenetic analyses indicated that the *Babesia* sp. (MO1) was closely related to *B. divergens*, suggesting that this European parasite had been introduced into the United States; however, additional research proved that *Babesia* sp. MO1 is distinct from *B. divergens*.

***Babesia divergens*.** The most common cause of human babesiosis in Europe is *B. divergens*, but other zoonotic species include a *B. divergens*-like species from the Canary Islands, *Babesia* sp. EU1 (also called *B. venatorum*), and a *B. microti*-like species. Infection with *B. divergens* is associated with a high death rate in splenectomized or immunocompromised patients. In Europe, sporadic cases of babesiosis have also been reported in immunocompetent persons.

The incubation period is usually 1 to 3 weeks during which the patients complain of malaise and discomfort.

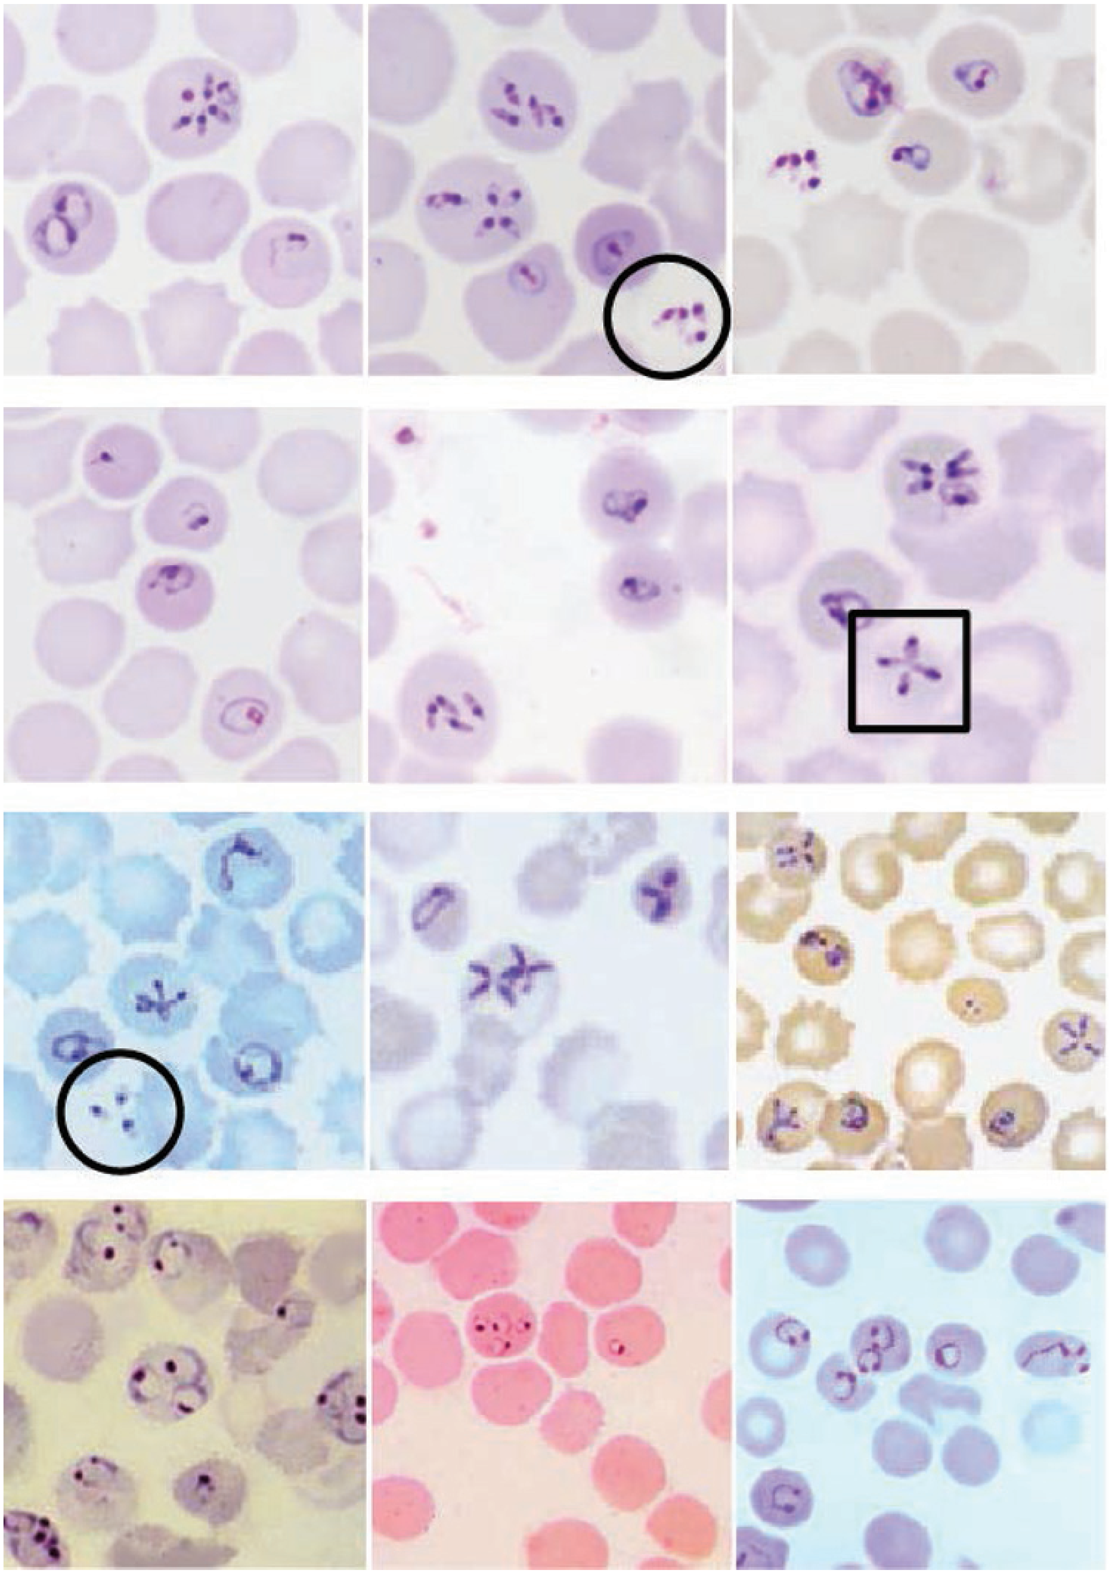

Figure 26.23 (Top three rows) Nine examples of blood films containing the ring-like forms of *Babesia* spp. Shown are various ring forms, multiple rings per cell, some rings present outside of the red blood cells (circles), and the typical image of the Maltese cross configuration of the four rings (square). (Bottom) *Plasmodium falciparum* rings for comparison. Note: it is rare to see *Plasmodium* rings outside of the RBC.
doi:10.1128/9781555819002.ch26.f23

Onset of serious illness is sudden, with hemoglobinuria as the most common sign. Clinical signs of *B. divergens* infection are easily confused with those of malaria including jaundice, nonperiodic fever, sweats, shaking, headache, vomiting, and diarrhea. Most cases of *B. divergens* infection result in major organ failure and death within 4 to 7 days after the onset of hemoglobinuria. However, prompt therapy with blood transfusion and respiratory support has reduced the mortality rate.

Diagnosis

Babesiosis needs to be diagnosed for various reasons: (i) without treatment, babesiosis can lead to severe illness; (ii) the disease can persist for a long period as an asymptomatic infection, which could lead to posttransfusion cases; and (iii) effective specific treatments are available. Most documented human patients have had a low parasitemia; thus, both thick and thin blood films stained with one of the blood stains must be examined. Although this strategy is rarely used, when the organisms cannot be demonstrated in a suspected patient, blood can be inoculated intraperitoneally into a hamster or gerbil. The organisms can usually be demonstrated within a few days, with the same morphology as that seen in humans.

Conventional Microscopy. Often, when the diagnosis of babesiosis is considered, only a single blood specimen is submitted to the laboratory for examination; however, single films or specimens cannot be relied on to exclude the diagnosis, especially with a low parasitemia.

It is recommended that both thick and thin blood films be prepared on admission of the patient, and at least 200 to 300 oil immersion fields should be examined on both films before a negative report is issued (20, 21). Since one set of negative films will not rule out babesiosis, additional blood specimens should be examined over a 36-h time frame. Although Giemsa stain has been used for all parasitic blood work, the organisms can also be seen if other blood stains, such as Wright's stain or one of the rapid stains, are used. If the WBC morphology is acceptable, then any parasites present will also exhibit typical morphology. Blood collected with the use of EDTA anticoagulant is acceptable; however, it is important to remember that the proper ratio between blood and anticoagulant is necessary for good organism morphology. Heparin can also be used, but EDTA is preferred. Finger stick blood is also acceptable. The blood should be free flowing when taken for smear preparation and should not be contaminated with alcohol used to clean the finger prior to the stick.

Automated Hematology Analyzer. Potential diagnostic problems with the use of automated differential instruments have been reported. Cases of babesiosis and malaria have been missed when blood smears were examined by these methods. The number of fields scanned by a technologist on instrument-read smears is quite small; therefore, a light parasitemia will almost surely be missed. Failure to make the diagnosis results in a delay of a number of days before therapy is instituted. Although the majority of these instruments are not designed to detect intracellular blood parasites, routine use of the automated systems may pose serious diagnostic problems, particularly if the suspected diagnosis is not conveyed to the laboratory.

Alternative Methods. Stained thick and thin blood films have been used to diagnose babesiosis for years and have always been considered the "gold standard." However, a number of alternative methods have been developed, including different approaches to microscopy, flow cytometry, biochemical methods, immunoassay, and molecular methods.

Microhematocrit centrifugation. Microhematocrit centrifugation, using the QBC tube (glass capillary tube and closely fitting plastic insert [QBC malaria blood tubes; Becton Dickinson, Sparks, MD]), has been used for the detection of blood parasites. At the end of centrifugation of 50 to 110 µl of capillary or venous blood (5 min in a QBC centrifuge [14,387 × *g*]), parasites or RBCs containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain that induces fluorescence in the parasites. This method automatically prepares a concentrated smear that represents the distance between the float and the walls of the tube. The tube is placed into a plastic holder, a drop of oil is applied to the top of the hematocrit tube, a coverslip is added, and the tube is examined with a 40× to 60× oil immersion objective (the objective must have a working distance of 0.3 mm or greater).

Note Although a *Babesia* sp. infection can be detected by the microhematocrit centrifugation method (which is more sensitive than use of the thick or thin blood smear), *appropriate thick and thin blood films must be examined to accurately confirm babesiosis compared with malaria.*

Molecular methods. Certainly PCR has been found to be more sensitive than blood film examination that often results in false-negative results due to low blood parasitemias. One real-time PCR assay was shown to be 100% specific when tested against a panel of 24 organisms consisting of *Babesia microti*, other *Babesia* species, *Plasmodium* species, tick-borne and other pathogenic bacteria, and other blood-borne parasites. The results using clinical specimens demonstrate that the assay can detect infections of lower parasitemia than can be detected by microscopic examination (73).

Serologic methods. Serologic studies have been reported; however, cross-reactivity has been seen among different species of *Babesia* and several species of *Plasmodium*. False-positive results have been seen in patients with connective tissue disorders such as systemic lupus erythematosus and rheumatoid arthritis. Titers of 1:128 to 1:256 rarely represent false positives; however, blood donor screening at a 1:64 titer may result in occasional false positives. False-negative results can be seen in immunosuppressed patients or in patients from whom blood specimens are drawn early in the course of the infection. Use of the indirect fluorescent-antibody test is helpful in the diagnosis of *B. microti* infections, particularly chronic infections. This test is specific and sensitive and is the currently recommended serologic method. Antibody can usually be detected when patients are first diagnosed; titers can remain elevated for 13 months to 6 years.

B. microti, the most common cause of transfusion-transmitted babesiosis, is widely endemic in the northeastern and upper midwestern United States. High seroprevalence in endemic areas limits antibody-based donor screening. A high-performance molecular test is needed to identify donors in the preseroconversion window phase as well as to discriminate past serologic exposure with parasite clearance from continued parasitemia. A highly sensitive and specific, quantitative real-time PCR-based assay for detection of *B. microti* has been developed that could have a useful role in blood screening (74).

KEY POINTS—LABORATORY DIAGNOSIS

Babesiosis

1. Blood films should be prepared on admission of the patient. Travel history and/or possible exposure to tick-infested areas, recent blood transfusion, or splenectomy information is very important.
2. Both thick and thin blood films should be prepared. At least 200 to 300 oil immersion fields should be examined before the smears are considered negative.
3. Wright's, Wright-Giemsa, Giemsa, or rapid stain can be used; if the WBC morphology is acceptable, any parasites would also exhibit typical morphology. Color variation is not critical.
4. *Babesia* parasites may be missed by automated differential instruments. Even with technologist review of the smears, a light parasitemia is very likely to be missed.
5. There does not have to be any significant history of travel outside the United States. If organisms are seen, they tend to mimic *P. falciparum* rings.
6. No morphological stages other than ring forms will be seen. The classic arrangement of the four rings (Maltese cross) is not always seen.
7. *One negative set of blood smears does not rule out a* Babesia *infection.*
8. The quantitative buffy coat system can also be used and has shown 100% correlation with Giemsa-stained peripheral blood smears for the detection of parasitemia in patients with babesiosis. However, confirmation of morphologic differences between *Babesia* and malarial rings might require examination of Giemsa-stained blood films.
9. The indirect fluorescent-antibody test and possibly PCR are recommended. Hamster inoculation is helpful but is neither realistic nor practical for most diagnostic laboratories.

Treatment

Often, babesiosis can be effectively managed with supportive care. Currently, the combination of atovaquone plus azithromycin has been recommended as the standard regimen for human babesial infection. Clindamycin plus quinine is recommended for severe symptoms with *B. microti* infection and for all *B. divergens* infections. Clindamycin plus quinine is also the treatment of choice for infections caused by *B. duncani*, *B. divergens*-like organisms, or *B. venatorum*. Exchange transfusion should be considered for severely ill patients and those with high (>10%) parasitemia or pulmonary, renal, or hepatic compromise when infection is caused by *B. microti*, and is recommended for cases of *B. divergens* infection. Highly immunosuppressed patients should be treated for a minimum of 6 weeks and at least 2 weeks past the last positive smear. High doses of azithromycin (600 to 1,000 mg) have been used in combination with atovaquone for the treatment of immunocompromised patients. Resistance to atovaquone plus azithromycin has been reported in immunocompromised patients treated with a single subcurative course of this regimen.

Any person with babesiosis acquired in Europe should be treated on an emergency basis. Such patients should receive prompt specific therapy to reduce parasitemia and to prevent the extensive hemolysis and renal failure that may follow. The element of time becomes critical; with the onset of hemoglobinuria, rapidly increasing intravascular hemolysis leads to renal failure. Treatment for these seriously ill patients can include exchange transfusion, intravenous clindamycin, and oral quinine.

Epidemiology and Prevention

The public health notice that was distributed to the Nantucket Board of Health indicated that *Babesia* parasites are transmitted from mice to humans primarily by the bite of the deer tick *Ixodes scapularis* and that individuals with the infection may be asymptomatic. The notice indicated that prevention still relies on the avoidance of ticks or their prompt removal once detected, since there are apparently no fully effective tick repellents. If symptoms appear 1 to 2 weeks after a tick bite, a physician should be consulted. In a study of Block Island, RI, from 1991 through 2000, the incidence of babesial infection appeared to be at least 10-fold greater than previously recognized elsewhere.

Another problem is related to blood donors. The duration of parasitemia following asymptomatic or symptomatic infection is not known. In areas where the infection is endemic, exclusion of blood donors who are febrile, who are known to have had babesiosis, or who have an anti-*Babesia* titer of 116 or higher may reduce the risk. However, until a practical, effective, and sensitive screening method is developed, cases of transfusion-induced babesiosis will probably continue to occur.

It is now well established that under blood-banking conditions (4°C for 30 days), *B. microti* can remain infective and that transfusion-acquired infection with this parasite could occur during the normal storage time for blood.

There is no vaccine for human babesiosis. The most common and accepted approach used to protect humans from infection involves methods to reduce the tick density (Fig. 26.24 and 26.25). A number of methods have been used, including spraying acaricidal emulsions on vegetation. Repellents are useful for personal protection; however, daily examination of the body surface of a person who may have come in contact with ticks is critical. If ticks are found, they should be removed immediately to take advantage of the time lag between attachment to the human and transmission of infection (usually 50 to 60 h).

Leishmaniasis

Cutaneous Leishmaniasis: General Comments

Old World (Eastern) Leishmaniasis: Cutaneous Leishmaniasis

New World (Western) Leishmaniasis: Cutaneous Leishmaniasis

Visceral Leishmaniasis: General Comments

Old World (Eastern) Leishmaniasis: Visceral Leishmaniasis

New World (Western) Leishmaniasis: Visceral Leishmaniasis

Leishmania spp. are protozoa belonging to the family *Trypanosomatidae* (Table 27.1). They are obligate intracellular parasites that are transmitted to the mammalian host by the bites of infected sand flies. On the basis of development in sand flies, the genus *Leishmania* has been divided into two subgenera. In the subgenus *Leishmania*, the development of organisms is restricted to the anterior portion of the alimentary tract of the sand fly, while in the subgenus *Viannia*, the parasites develop in the midgut and hindgut of the sand fly.

Leishmaniasis is mainly a zoonosis, although in certain areas of the world there is primarily human-vector-human transmission. The World Health Organization estimates that 1.5 million cases of cutaneous leishmaniasis (CL) and 500,000 cases of visceral leishmaniasis (VL) occur every year in 88 countries. Estimates indicate that there are approximately 350 million people at risk for acquiring leishmaniasis, with 12 million currently infected (1–3).

Leishmaniasis refers to a diverse group of diseases, with the spectrum of disease depending on the infecting species. Disease syndromes range from self-healing cutaneous lesions to debilitating mucocutaneous infections, subclinical viscerotropic dissemination, and fatal visceral involvement. Since disease presentations vary considerably, a well-defined classification system based on clinical findings is difficult and sometimes confusing (4–13). With recent outbreaks in many areas of the world, including Brazil, India, Italy, Spain, Sudan, and Kenya, leishmaniasis has become more widely recognized as an important emerging infectious disease in many developed as well as underdeveloped countries.

Cutaneous Leishmaniasis. The most common presentation is localized CL, most frequently caused by *Leishmania major* and *Leishmania tropica* in the Old World and *Leishmania braziliensis*, *Leishmania mexicana*, and related species in the New World. Spontaneous healing is the rule, but requires months to years and varies by species.

Mucosal/Mucocutaneous Leishmaniasis. Mucosal leishmaniasis (ML) usually occurs months or years after healing of primary CL, most commonly due to *L. braziliensis*, and can cause destruction of the nasal septum, palate, and other

doi:10.1128/9781555819002.ch27

TABLE 27.1 Taxonomic classification of *Leishmania* parasites pathogenic for humans[a]

Taxon	Old World[b]				New World[c]			
Family	*Trypanosomatidae*							
Genus	*Leishmania*							
Subgenus	*Leishmania*				*Leishmania*		*Viannia*	
Complex	*L. major*	*L. tropica*	*L. aethiopica*	*L. donovani*	*L. donovani*	*L. mexicana*	*L. braziliensis*	*L. guyanensis*
Species	*L. major*	*L. tropica*	*L. aethiopica*	*L. donovani* *L. infantum*	*L. chagasi*	*L. mexicana* *L. venezuelensis* *L. garnhami* *L. amazonensis* *L. pifanoi*	*L. braziliensis* *L. peruviana* *L. colombiensis* *L. lainsoni* *L. shawi* *L. naiffi*	*L. guyanensis* *L. panamensis*
Hybrid species[d]							*L. braziliensis/L. panamensis* *L. braziliensis/L. guyanensis*	

[a] The classification scheme is based on biochemical and molecular characteristics.

[b] Animal parasites of the Old World (*L. arabica*, *L. turanica*, and *L. gerbilli*) are not listed.

[c] Animal parasites of the New World (*L. aristedesi*, *L. enrietti*, *L. forattinii*, *L. deanei*, *L. equatorensis*, and *L. bertigi*) are not shown; although human infection with these species has not yet been identified, there is often a time lag between the discovery of new animal genera and confirmation of human infection. In many cases, the relevant vectors have been found to bite humans as well as the normal animal hosts.

[d] Strains with phenotypic and genotypic characters of two species have been recorded in different geographic areas of Latin America; either they represent strains that originated from a common ancestor or they are the result of genetic exchange.

mucosal structures, leading to devastating facial mutilation and, rarely, death from airway involvement. Other forms include disseminated cutaneous leishmaniasis (DCL), which is a diffuse, nodular, nonulcerating disease, and leishmaniasis recidivans, which produces localized, slowly progressive, nonhealing lesions. Both are rare and difficult to treat and can be severe.

Visceral Leishmaniasis. VL (kala azar) is usually caused by *Leishmania donovani* and *Leishmania infantum* and is characterized by progressive fever, weight loss, splenomegaly, hepatomegaly, hypergammaglobulinemia, and pancytopenia. Kala azar is lethal in nearly all untreated cases, and in treated patients, case-fatality rates are often 10% or higher.

Post-Kala Azar Dermal Leishmaniasis. Post-kala azar dermal leishmaniasis (PKDL) is a chronic rash seen in apparently cured kala azar patients in South Asia and the Horn of Africa. PKDL patients present with erythematous or hypopigmented macules, sometimes progressing to plaques or nodules. In Sudan, PKDL is reported to resolve without treatment in most mild cases, while the condition is said to require universal treatment in South Asia. A high percentage of patients with kala azar develop PKDL in Sudan, with lower percentages in South Asia.

Leishmaniasis in the United States. Cases of leishmaniasis are diagnosed each year in the United States and can be attributed to immigrants from countries with endemic infection, military personnel, and American travelers. Another concern is the potential for more infections occurring in areas of endemic infection in Texas and Arizona (14–19). Organisms can remain latent for years, and even when the potential exposure history is in the past, leishmaniasis should be considered, particularly in immunocompromised patients such as those infected with HIV (20–25).

The taxonomy of the *Leishmania* spp. is controversial and reflects the development of multiple parameters on which classification is based. Previously, organisms were classified based on the clinical disease picture and geographic locations; with the development of criteria based on biochemical and genetic data, the taxonomic groupings no longer coincide with recognized disease entities.

Cutaneous Leishmaniasis: General Comments

There are multiple clinical presentations associated with cutaneous leishmaniasis; however, five different syndromes are currently recognized: (i) localized ulcerative or nodular cutaneous leishmaniasis (CL), (ii) mucosal leishmaniasis (ML), (iii) leishmaniasis recidivans (LR); (iv) diffuse or disseminated cutaneous leishmaniasis (DCL); and (v) post-kala azar dermal leishmaniasis (PKDL). Immunocompromised patients may have atypical presentations (1).

Old World (Eastern). LR is most common in the Middle East. PKDL is seen in India and East Africa (Kenya and the Sudan) following treatment of kala azar with pentavalent antimony.

New World (Western). CL is found in the Americas from southern Texas to northern Argentina. ML is most common in the jungles of Amazonia (especially in southern Brazil), but cases have been reported throughout the Americas. Most DCL infections are seen in Brazil, the Dominican Republic, Ethiopia and Venezuela, but there are sporadic infections in Bolivia, Colombia, Honduras, Mexico, Peru, and the southern United States.

Old World (Eastern) Leishmaniasis: Cutaneous Leishmaniasis

Leishmania major, *L. tropica*, *L. aethiopica*, and, rarely, *L. infantum* cause cutaneous disease in the Old World; disease manifestations include nodular and ulcerative skin lesions (Table 27.2; Fig. 27.1). Local geographic names for CL include Oriental sore, Baghdad boil, Delhi boil, Biskra button, and Aleppo evil. Although Wright was credited with the first detailed description of the cutaneous form of the disease, it had already been described by Borovsky in 1898 in an obscure military medical journal.

Life Cycle and Morphology

The life cycle can be seen in Fig. 27.2. The parasite is found in two morphologic forms in the life cycle, the amastigotes and the promastigotes. The amastigotes are small (3 to 5 μm in diameter), ovoid, nonmotile intracellular forms, while the promastigotes are elongated, motile, extracellular stages (1.5 to 3.5 by 15 to 20 μm with a single free flagellum 15 to 28 μm long) (Fig. 27.3 and 27.4). The form introduced into the skin of the mammalian host by the sand fly is the promastigote. The organism is engulfed by reticuloendothelial (RE) cells of the mammalian host, where the parasite transforms into the intracellular amastigote form (Leishman-Donovan body). Apparently, this process takes approximately 12 to 24 h. The large nucleus and small kinetoplast in the amastigotes can be seen in tissue after staining with Giemsa, Wright's, or other blood stains. The short intracytoplasmic portion of the flagellum can also be seen within some of the amastigotes. The amastigotes multiply by binary fission within the macrophage until the cell is destroyed, and the released parasites are phagocytized by other RE cells or ingested by sand flies. This phase is chronic and can last from months to years, even a lifetime, depending on the species involved. In CL, the amastigotes remain confined to the skin, usually as skin lesions such as raised papules or ulcers. Lesions usually occur on exposed parts of the body such as the face, hands, feet, arms, and legs; uncommon sites include the ears, tongue, and eyelids.

During a blood meal taken by the sand fly (genus *Phlebotomus*), amastigotes are ingested and transform into the promastigote stage. Promastigotes multiply by longitudinal fission in the insect gut. Stages found in the sand fly vary from rounded or stumpy forms to elongated, highly motile

TABLE 27.2 Old World cutaneous leishmaniasis, subgenus *Leishmania*

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
L. major: *Phlebotomus papatasi*, *P. duboscqi*, *P. salehi*	Cutaneous leishmaniasis (Oriental sore; rural, zoonotic); lesions may number >100; wet lesion with crusting; necrotic and exudative	North Africa, sub-Saharan Africa, Central and West Asia	Great gerbil (*Rhombomys opimus*), fat sand rat (*Psammomys obesus*)	Primarily an infection of desert rodents; gerbil infection rate may reach 30%; village inhabitants near gerbil burrows may have infection prevalence rates of 100%; major problem for rural settlers in Israel, military personnel in the Sinai Desert, Israel, Iraq, and Iran
L. tropica: *Phlebotomus sergenti*, *P. papatasi*, *P. chaudaudi*	Cutaneous leishmaniasis (Oriental sore; urban, anthroponotic); lesions usually ~2; lesions more swollen, less necrotic; less exudate than with *L. major*; leishmaniasis recidivans also seen (chronic lesions on face or other exposed areas, persist for years)	Middle East, Mediterranean littoral, India, Pakistan, Central Asia, Iran, Iraq	Dogs and humans	Major epidemic of anthroponotic CL has occurred in war-ravaged Kabul, Afghanistan, with thousands of cases identified; responsible for viscerotropic syndrome in a small group of American military personnel infected in the Persian Gulf War; extensive scarring can lead to disfigurement; can last for up to 40 years
L. aethiopica: *Phlebotomus longipes*, *P. pedifer*	Cutaneous leishmaniasis, diffuse cutaneous leishmaniasis; lesions more swollen, less necrotic; barely exudative	Ethiopia, Kenya, bordering countries	Rock hyraxes (*Heterohyrax brucei*, *Procavia* spp.)	Human disease usually self-healing, small number develop nonhealing disseminated CL

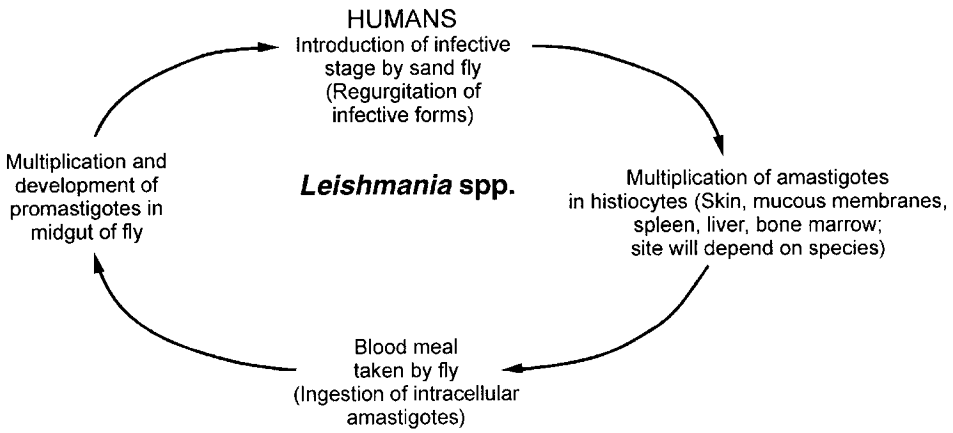
metacyclic promastigotes. The metacyclic promastigotes migrate to the hypostome of the sand fly, where they are inoculated into humans when the sand fly takes its next blood meal. Various surface molecules on the promastigote, such as gp63 and lipophosphoglycans, help bind the parasite to the host macrophage receptors, thus allowing it to be phagocytized. Depending on the species, the duration of the life cycle in the sand fly varies from 4 to 18 days.

Sand flies are pool feeders and possess cutting mouthparts that slice into the skin, allowing a small pool of blood to form. Thus, although they are small flies (2 to 3 mm), the bite can be painful. In most foci of endemicity, the vast majority of sand flies are uninfected; however, those that are infected are very efficient vectors. Infected flies probably remain so for life, although this is just a matter of weeks. Under optimal conditions, transformation of the amastigotes to promastigotes generally takes 5 to 7 days; by that time, the female phlebotomine fly is ready to take her next blood meal.

Leishmaniavirus is a double-stranded RNA virus that persistently infects some strains of *Leishmania*. There is a great deal of interest in the possibility that the presence of



HUMANS
Introduction of infective stage by sand fly (Regurgitation of infective forms)
Multiplication of amastigotes in histiocytes (Skin, mucous membranes, spleen, liver, bone marrow; site will depend on species)
Blood meal taken by fly (Ingestion of intracellular amastigotes)
Multiplication and development of promastigotes in midgut of fly
Leishmania spp.

Figure 27.2 *Leishmania* life cycle. doi:10.1128/9781555819002.ch27.f2

doi:10.1128/9781555819002.ch27.f3

this virus may be able to alter the parasite phenotype and may affect disease pathogenesis. The virus has been detected in cultured parasites and has also been detected in human biopsy samples prior to manipulation in culture (26).

Clinical Disease

The incubation period of CL is usually 2 to 8 weeks but can be as long as several years. The first sign of cutaneous disease is a lesion (generally a firm, painless papule) at the bite site. Although a single lesion may appear insignificant, multiple lesions of *L. major* or disfiguring facial lesions of *L. tropica* may be psychologically or physically devastating. In general, all lesions on a patient have a similar appearance and progress at the same speed.

The original lesion may remain as a flattened plaque or may progress, with the surface becoming covered with fine, papery scales. These scales are dry at first but later become moist and adherent, covering a shallow ulcer. As the ulcer enlarges, it produces exudate and may develop a crust. The edge of the lesion is usually raised. Depending on the species, satellite lesions are common and merge with the original lesion (Fig. 27.5).

doi:10.1128/9781555819002.ch27.f5

***L. major* (Rural Disease).** *L. major* causes rural disease, a variety of CL. Multiple lesions are present and are accompanied by marked inflammation and crusting. The center of the lesion tends to be necrotic and exudative, forming a loose crust. The lesions tend to mature and heal relatively quickly, often lasting only a few months. Lymphatic spread may occur in *L. major* infections, with subcutaneous nodules in a linear distribution and regional lymphadenopathy; if the initial lesion is on the hand, this clinical presentation may resemble sporotrichosis. *L. major* infections may result in severe scarring.

From August 2002 to February 2004, over 500 cases of parasitologically confirmed cases of CL were found in U.S. military personnel serving in Afghanistan, Iraq, and Kuwait. Currently, the number of cases may be 1,500 or more; many feel this number may be underestimated due to cases that have been misdiagnosed. The majority of these cases were probably acquired in Iraq, with *L. major* being confirmed for most of the cases through isoenzyme electrophoresis of cultured parasites (6, 27). Based on the data from Fort Campbell, KY, approximately 1% of troops returning from Iraq were diagnosed with CL, most by laboratory confirmation, including PCR.

***L. tropica* (Urban Disease).** The lesions of urban disease (a type of CL) caused by *L. tropica* occur singly or two at a time, develop more slowly than those caused by *L. major*, and can take a year or more to heal. They tend to be more swollen and less necrotic, with less exudate and a thicker crust.

***L. tropica* (Leishmaniasis Recidivans).** LR is generally associated with *L. tropica*. Small, nonulcerating lesions begin to appear, mainly on the margins of healed lesions, and continue to expand the limits of the original scar (Fig. 27.6). Disfigurement due to extensive scarring can develop. This condition is thought to be associated with a strong cell-mediated immune response and tends to occur primarily in Iran and Iraq. Although there is a strong immune response on the part of the host, not all amastigotes are eliminated, and the infection can last for up to 40 years. The patient's physical appearance, as well as histologic sections, resemble those of cutaneous tuberculosis; therefore, the name "lupoid leishmaniasis" has also been used. Parasites may be very difficult to demonstrate; however, culture or animal inoculation has been successful. The leishmanin skin test (LST) (Montenegro test) is strongly positive in these patients.

***L. aethiopica* (Cutaneous Leishmaniasis).** Lesions of CL caused by *L. aethiopica* are the least inflamed but are more swollen. There may be very little exudate, but scaling and exfoliation of the dermis occur. These lesions tend to remain for years prior to complete healing.

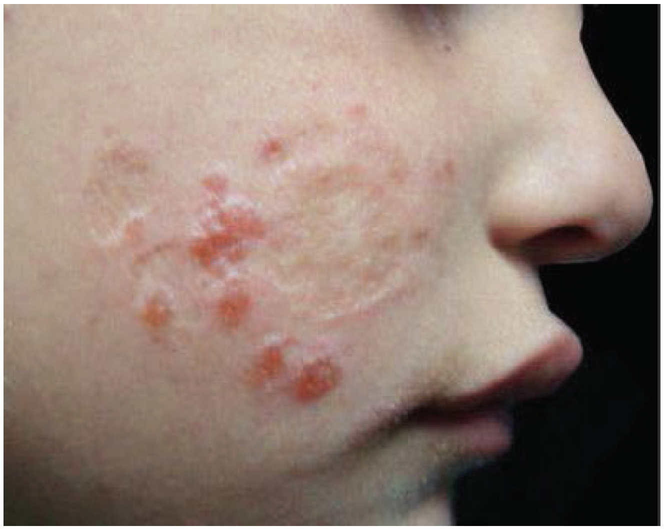

Figure 27.6 Leishmaniasis recidivans (LR) is a rare complicating form of cutaneous leishmaniasis caused by *L. tropica*. After healing of the initial lesion, a few soft red papules may appear at or around the scar of the previously healed lesion that spread peripherally with no tendency for spontaneous healing. Few parasites are found in the skin smear or biopsy. (Courtesy of the Global Skin Atlas, submitted by Nameer Al-Sudany; http://www.globalskinatlas.com/imagedetail.cfm?TopLevelid=2268&ImageID=5064&did=458.)
doi:10.1128/9781555819002.ch27.f6

***L. aethiopica* (Diffuse Cutaneous Leishmaniasis).** Diffuse or disseminated CL (DCL) is an anergic form of CL in which neither humoral nor cell-mediated immune responses are functional; however, delayed hypersensitivity to tuberculin appears to be normal. DCL is caused by *L. aethiopica* and is seen in Ethiopia and Kenya; approximately 100 cases have been reported. The parasites are found in the skin, and the disease is characterized by the formation of thickened skin in plaques, papules, or multiple nodules. This condition is similar to that associated with the specific anergy in lepromatous leprosy, and DCL was originally confused with and thought to be leprosy. Although lesions are usually seen on the face, nose, limbs, and buttocks, they can occur over the entire body (Fig. 27.7). The nodules are often described as soft and fleshy, while those of leprosy are generally more indurated. Although organisms have rarely been recovered from blood or bone marrow, there are no visceral lesions associated with this form of leishmaniasis. Treatment is difficult, and the infection may last for the life of the patient. The LST remains negative unless treatment is effective and recovery occurs.

Diagnosis

In areas of the world where physicians are very familiar with leishmaniasis, the diagnosis may be made on clinical

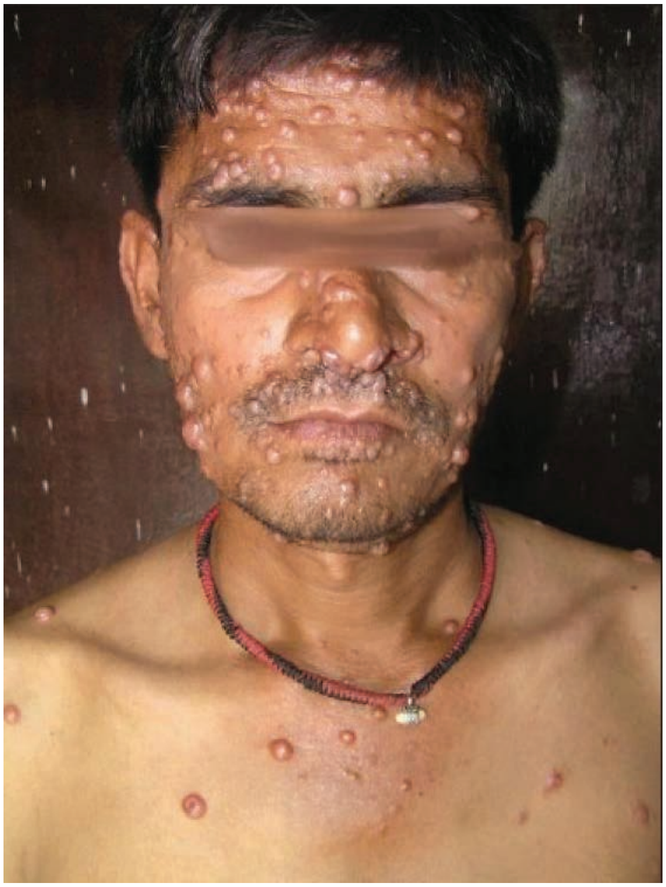

Figure 27.7 Diffuse cutaneous leishmaniasis seen in an HIV-positive patient (courtesy of Purohit HM et al, *Indian J Sex Transm Dis* **33:**62–64, 2012).
doi:10.1128/9781555819002.ch27.f7

grounds. However, in other areas of the world, where the disease is rare, the condition may not be recognized. Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture (Table 27.3). CL may have to be differentiated from a number of other lesions and diseases, including basal cell carcinoma, tuberculosis, various mycoses, keloid scarring, and lepromatous leprosy.

Specimen Collection. CL normally presents with no visceral involvement or systemic disease. The ability to detect parasites in aspirates, scrapings, or biopsy specimens depends on the number of amastigotes present, the level of the host immune response, the absence or presence of bacterial and/or fungal contamination within the lesion, and whether the specimen is collected from an active or healing lesion. If the patient has multiple lesions, specimens should be collected from the more recent or active lesions. These lesions should be thoroughly cleaned with 70% alcohol, and necrotic debris should be removed to prevent the risk of bacterial and/or fungal contamination of the specimen. This is mandatory if cultures are to be used for isolation and growth of the parasites; excess bacterial or fungal contamination prevents development of the promastigote forms. Also, the specimen should be taken from the advancing margin of the lesion; the central portion of the ulcer contains nothing but necrotic debris.

If specimens are collected by aspiration, scraping, or biopsy, local anesthesia may be used to reduce patient discomfort. The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion areas. Biopsy specimens can be divided and used for cultures and touch preparations; some material should always be saved and submitted for routine histology. If biopsy specimens need to be divided, material for culture should be obtained by using sterile techniques and instruments. The biopsy specimen can be used to make impression smears (touch preparations); these smears should be prepared after portions of the specimen have been placed in culture media by using a sterile technique. After any excess blood is cleaned off, a horizontal cut is made through the biopsy core and the cut surface is gently touched to glass slides; multiple slides should be prepared. Once material has been set up for culture and touch preparations have been made, the remainder of the tissue can be sent to the pathology laboratory for routine processing. It is important to remember that the amastigotes are more difficult to identify in tissue sections than in touch preparations; they appear smaller and may be cut at different angles.

Another option involving sterile techniques is to make a perpendicular slit in the margin of the lesion. After blood is removed with sterile gauze, the blade can be used to scrape the inner walls of the slit. Material can be inoculated into culture media and can be smeared onto several glass slides; the use of multiple slides is recommended to increase the chances of seeing the parasites. Fine-needle aspiration can also be performed with a sterile syringe containing sterile saline (0.1 ml) and a 26-gauge needle. The needle is inserted into the outer border of the lesion and rotated several times, after which saline is injected and tissue fluid is aspirated back into the needle. Material can be submitted for culture, and/or smears can then be prepared for staining. Additional techniques and specific methods can be found in chapters 6 to 8.

Specimen Staining. All smears to be Giemsa stained should be air dried and fixed with 100% methanol prior to staining. Any of the other blood stains can also be used. The amastigotes are found within the macrophages or close to disrupted cells (Fig. 27.8). Although this intracellular form may mimic other intracellular parasites (*Histoplasma capsulatum* and some of the microsporidia), the presence of the

TABLE 27.3 Features of Old World human leishmanial infections related to demonstration of the parasite[a]

Organism	Disease type[b]	Humoral antibodies	Delayed hypersensitivity to leishmanin	Parasite present in clinical specimen	Self-cure	Recommended biopsy specimen
Old World CL

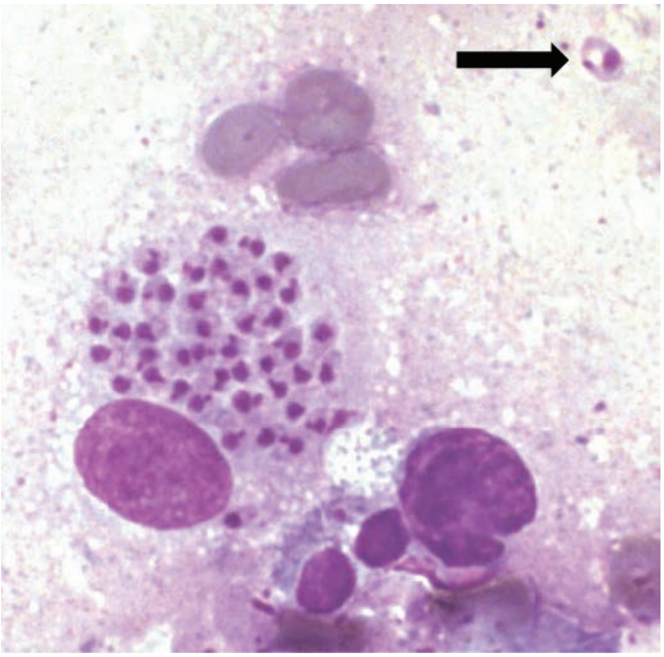
L. infantum	VL	Abundant	Absent	Present	Variable	Bone marrow, spleen

[a] For culture, specimens must be collected aseptically, and in older lesions the parasites may be scant and difficult to recover. Animal isolation involves hamsters and culture media (Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium with 30% fetal bovine serum). Serologic testing is most suitable for VL, has little value for CL, and has limited value for MCL. The Montenegro test (LST) is a delayed hypersensitivity reaction to intradermal injection of cultured parasites.

[b] Additional information on relevant diagnostic methods can be found in chapters 7 and 8.

Figure 27.8 Cutaneous leishmaniasis. Smear of skin lesion with amastigotes with the macrophage; Giemsa stain. In these types of preparations, often some of the amastigotes will appear outside of the cells (arrow). (Courtesy of the Armed Forces Institute of Pathology.) doi:10.1128/9781555819002.ch27.f8



intracytoplasmic kinetoplast confirms the identification. After staining, the cytoplasm appears light blue and the nucleus and kinetoplast appear red to purple. In very early and older lesions, very few organisms may be present, so that prolonged examination of the slide may be required.

Culture Media. Media used for the growth of *Leishmania* spp. will also support the growth of bacteria and fungi, hence the need for aseptic techniques in collecting the clinical specimen. If cultures become overgrown with contaminating organisms, the parasites will not survive. It is also important to release the organisms from tissue prior to culture; mincing is recommended. However, tissue grinders are not recommended because of possible damage to the organisms. Culture media that have been used for the recovery and growth of leishmaniae include Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium supplemented with 30% fetal bovine serum (see chapter 8). A number of other medium formulations have also been developed and may prove very useful. These include a completely defined medium without serum and macromolecules (28), a semisynthetic fetal calf serum-free liquid medium (29), a new liquid medium with less expensive chemicals (30), and a sensitive new microculture method involving microcapillary tubes (31). Patient cultures should not be set unless the laboratory maintains specific organism strains for quality control checks. Both the control and patient cultures should be examined twice a week for the first 2 weeks and once a week thereafter for up to 4 weeks before they are reported as negative. Promastigote stages

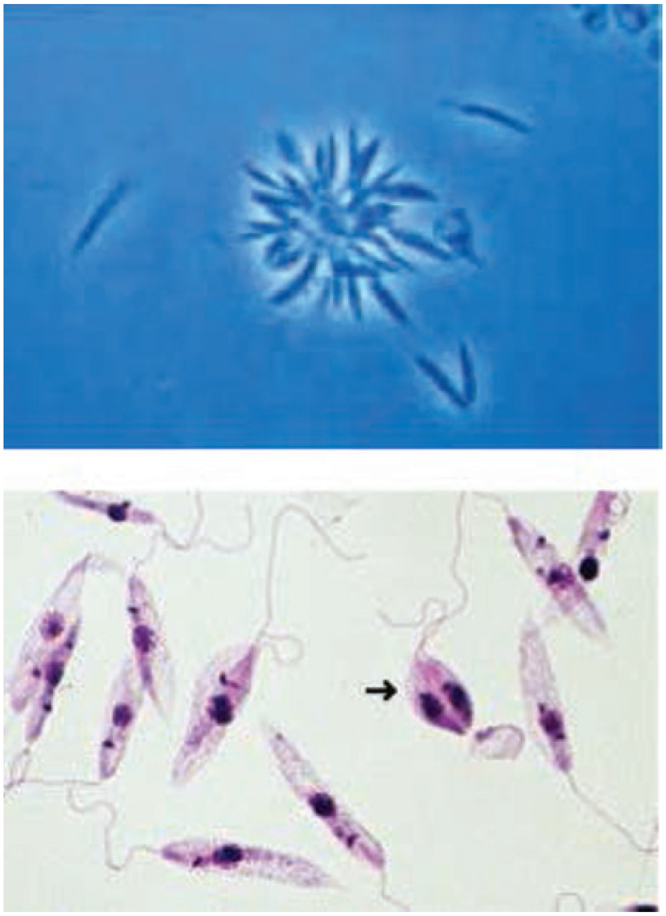


Figure 27.9 *Leishmania* sp. promastigotes in culture. (Upper) Wet mount. (Lower) Stained organisms; note promastigotes dividing by longitudinal binary fission (arrow). (Courtesy of WHO, images from Jorge Alvar.) doi:10.1128/9781555819002.ch27.f9

can be detected microscopically in wet mounts taken from centrifuged culture fluid (Fig. 27.9). This material can also be stained with Giemsa stain to facilitate observation at a higher magnification. A number of molecular methods have been developed for species identification of the promastigotes, including the use of DNA probes, isoenzyme analysis, PCR, and monoclonal antibodies (32–37).

Animal Inoculation. Animal inoculation can be helpful when only a small number of organisms are present; however, most laboratories no longer consider this approach practical. Golden hamsters are inoculated intranasally, and the major argument against this approach is that it may take several months before the animal gives positive responses. A combination of tissue smears, culture, animal inoculation, and histopathology may be required for optimal diagnosis.

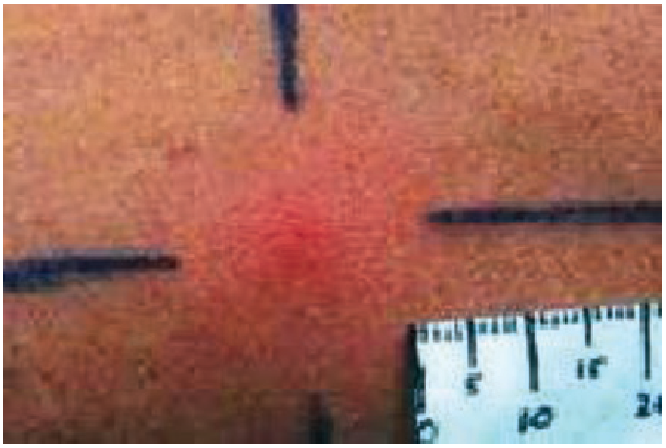

Figure 27.10 LST (Montenegro skin test); positive test result (courtesy of *Dermatology Online Journal*, University of California, Davis, eScholarship http://escholarship.org/uc/item/9ct3h710). doi:10.1128/9781555819002.ch27.f10

Skin Test. The LST (Montenegro test) is useful for epidemiologic population surveys to detect groups at risk for infection. However, the test is not species specific and must be interpreted with caution, particularly since some patients may have more than one type of leishmaniasis. Apparently, cross-reactions do not occur with African or American trypanosomiasis. The LST involves a delayed hypersensitivity reaction to a suspension of killed promastigotes. The reaction is read at 48 and 72 h after injection. Positive reactions are generally seen in patients with cutaneous lesions; however, those with DCL give negative reactions (Fig. 27.10).

Serologic Tests. Although available for epidemiology and/or research studies, serologic tests are not very useful for the diagnosis of CL. Reagent availability is usually limited to areas of endemic infection. Antibody detection is variable in patients with CL; if antibody is present, titers are usually low, and cross-reactions have been seen in patients with leprosy. Patients infected with the viscerotropic form of *L. tropica* seen during Operation Desert Storm have had low or undetectable antibody titers (38).

KEY POINTS—LABORATORY DIAGNOSIS

Old World (Eastern) Leishmaniasis: Cutaneous Leishmaniasis

1. For a complete laboratory diagnosis, microscopic examination of Giemsa-stained touch preparations and cultures is recommended. Other blood stains are also acceptable.
2. Aspirates or biopsy specimens should be taken from the margin or base of the most active lesion (papule or ulcer). The lesion should be cleaned before the sample is collected, to reduce the chances of culture

KEY POINTS—LABORATORY DIAGNOSIS

contamination with fungi or bacteria. Punch biopsies are recommended: one for routine pathology, two for microbiology (squash preps/sterile for culture).

3. Multiple slides should be prepared for examination.
4. Tissue imprints or smears should be stained with Giemsa stain (or one of the stains commonly used for blood smears) (see chapter 7).
5. Amastigote stages should be found within macrophages or close to disrupted cells.
6. If cultures are to be performed, specimens must be taken aseptically and control organism cultures should be set up at the same time (see chapter 8).
7. Cultures should be checked weekly for 4 weeks before they are declared negative.

Treatment

Most Old World CL lesions are self-healing over a period of a few months to several years. This healing process confers immunity to individuals living within the immediate area of endemic infection; therefore, treatment is not recommended unless disfiguring scarring is a possibility. Chemotherapy should be given to patients with lesions on the face, particularly if the lesions are multiple or large. Pentavalent antimonials (sodium stibogluconate [Pentostam] and meglumine antimoniate [Glucantime]) are usually effective but must be given in adequate doses for the complete recommended time frame, often weeks or months (see chapter 36). Miltefosine is another option, with paromomycin or pentamidine being alternatives. Toxicity does not usually present a problem. Specific chemotherapy, including systemic administration, is used much less frequently for Old World leishmaniasis than for the New World disease presentations. The lesions of LR respond to Pentostam at doses used for treatment of VL, and local heat therapy and intralesional injections are commonly used in the Middle East. In treating DCL, pentamidine, given as a single weekly injection for at least 4 months longer than it takes to eliminate parasites from slit skin smears, seems to be a good compromise between efficacy and toxicity. Cutaneous lesions, whether treated or not, should always be cleaned and covered to prevent secondary infections and vector access to the lesion.

In addition to chemotherapy, other more local treatment options have included cryotherapy, heat, and surgical excision of lesions (27). Organisms within the *L. tropica* group do not survive in temperatures above 37°C, and local heat therapy has proven to be effective. The temperature within the lesion should reach 40 to 42°C for 12 h at a time; this can be accomplished by using an infrared heat lamp. The use of hot water in baths or saunas has been helpful in cases of DCL, particularly since the response to chemotherapy is poor.

The administration of Pentostam as direct injections into the lesion has also been used. The dose is divided into four parts and injected into four different quadrants of the lesion (10). Another approach involves the application of a topical formulation of 15% paromomycin–12% methylbenzethonium chloride in soft white paraffin (Pointment or the “El-On” preparation), which decreases the healing time by half. Since this preparation causes multiple local reactions, a number of other preparations have been tried, some effective and some no better than the placebo.

Epidemiology and Prevention

L. major, the cause of rural Oriental sore, is a zoonotic parasite and is found primarily in desert rodents such as gerbils that live in the dry desert areas of central Asia, in southern Russia, throughout Iran and Pakistan, in parts of Iraq, and in northwestern India and China. In areas of Libya, Saudi Arabia, and Israel, the rat is an important host. The infection is maintained in the reservoir population by sand flies that frequent rodent burrows. Human disease is maintained through the vectors *Phlebotomus papatasi* in Sudan and *Phlebotomus duboscqi* elsewhere.

L. tropica, the cause of urban CL, has been isolated from dogs and rats; however, humans are considered to be the primary reservoir and source of infection. Various phlebotomine sand flies (*Phlebotomus sergenti* and *P. papatasi*) transmit the infection, depending on the specific geographic area; areas of endemic infection include southern France, Italy, some Mediterranean islands, the Middle East, Greece, Pakistan, and northwestern India. In the first half of the 20th century, 40 to 70% of Europeans living in Delhi became infected. A major epidemic of CL due to *L. tropica* has occurred in war-ravaged Kabul, Afghanistan, with thousands of cases identified in the displaced population.

L. aethiopica is also a zoonotic parasite, primarily involving the rock hyrax (*Procavia habessinica*) and the tree hyrax (*Heterohyrax brucei*). The organism is found in the Rift Valley in Ethiopia and Kenya. As human habitation moves into deforested mountain areas, exposure to the hyrax becomes much greater and coincides with the vector, *Phlebotomus longipes*, while *Phlebotomus pedifer* is implicated in Kenya.

Preventive measures involve vector control; residual spraying with DDT as a means of malaria control was very helpful. However, with the decline and total cessation of spraying in many areas, the leishmaniasis has returned. The infection can also be transmitted by direct contact with infected lesions and mechanically through bites by the stable or dog fly (*Stomoxys* spp.); lesions should be kept covered to prevent this type of transmission by primary or secondary vectors. Application of insect repellents to the skin has also been effective. Although reservoir control has been unsuccessful in most areas, disease incidence has been reduced by poisoning or deep plowing gerbil burrows.

In areas of Iran, Iraq, Israel, Jordan, and Russia where CL is endemic, vaccination has been used for many years. Exudate from a naturally acquired lesion can be inoculated onto an inconspicuous area of the body of a nonimmune person. Another approach is to use live, attenuated *L. major* promastigotes, which are inoculated intracutaneously. The infection is allowed to develop and is usually limited to a single lesion; self-cure proceeds as in a natural infection. The immunized individual will become a carrier and source of infection until the lesion heals; a very small percentage of those vaccinated will develop lesions requiring treatment. Lifelong immunity to the homologous species develops and is comparable to that following a natural infection.

New World (Western) Leishmaniasis: Cutaneous Leishmaniasis

New World CL extends from southern Texas and Arizona to Latin and South America and the Caribbean islands (18). As seen in Old World leishmaniasis, there is a wide range of disease presentation, and separation based on clinical signs and symptoms is not possible (Fig. 27.11 and 27.12). Organisms in this group belong to the subgenera *Leishmania* and *Viannia* (Table 27.1). Within the subgenus *Leishmania* is the *L. mexicana* complex (Table 27.4), and within the subgenus *Viannia* are the *L. braziliensis* complex (Table 27.5) and the *Leishmania guyanensis* complex (Table 27.6). It is very likely that taxonomy will continue to change as molecular methods reveal genetic differences and similarities among the various genera and species. Common names for New World CL include uta (Peru), dicera de Baurid (Brazil), chiclero ulcer or bay sore (Mexico), and pian bois or forest yaws (Guyana). Collectively, this group has also been called American CL. This disease is quite old and has even been depicted on pottery from Peru and Ecuador that has been dated ca. AD 400 to 900.

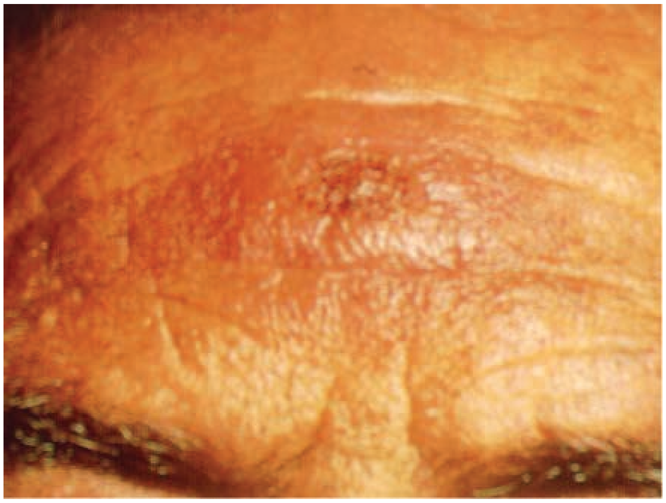

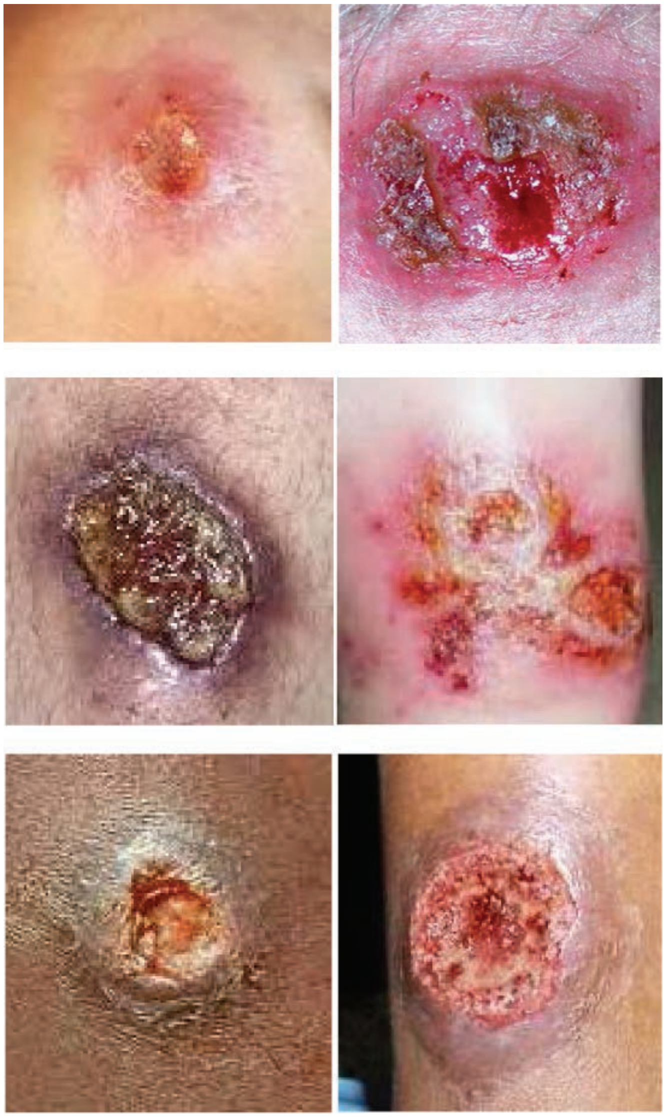

Figure 27.12 New World cutaneous leishmaniasis: six examples of cutaneous lesions. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch27.f12

TABLE 27.4 New World cutaneous leishmaniasis subgenus *Leishmania*, complex *Leishmania mexicana*

Species and sandfly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
L. mexicana: *Lutzomyia olmeca*, *L. anthophora* (Texas and Arizona)	Cutaneous leishmaniasis, chiclero ulcer	Belize, Guatemala, Honduras, Costa Rica, Mexico, Texas, Arizona (Panama, South America questionable); Southern Plains of Texas (wood rat [*Neotoma micropus*]); Arizona (white-throated wood rat [*Neotoma albigula*])	Forest rodents	Prolonged exposure of "chicleros," who live in forest collecting chewing gum latex from chicle trees (30% infected during first year); timber cutters, road builders, agricultural workers
L. venezuelensis: *Lutzomyia olmecabicolor*	Cutaneous leishmaniasis	Venezuela (humans only)	Humans	Poor long-term growth in blood agar medium; wild mammalian host not yet discovered; found in horses and the domestic cat
L. garnhami: *Lutzomyia youngi* (not confirmed)	Cutaneous leishmaniasis	Venezuelan Andes	Humans, marsupial (*Didelphis marsupialis*)	Identical to *L. amazonensis* by isoenzyme profiles, but clear differences between nontranscribed rDNA intergenic spacer sequences; still difference of opinion regarding validity of species designation
L. amazonensis: *Lutzomyia flaviscutellata*	Cutaneous leishmaniasis, diffuse cutaneous leishmaniasis	Amazon region of Brazil, Bolivia, Colombia, French Guyana, Paraguay	Forest rodents (primary); marsupials, foxes (secondary)	Human disease uncommon; vector nocturnal and not very anthropophilic, lives in swampy areas with few inhabitants; DCL similar to that seen in Ethiopia (Old World); specific anergy to leishmanin (Montenegro) skin test
L. pifanoi *Lutzomyia flaviscutellata*	Diffuse cutaneous leishmaniasis	Venezuela (states of Yaracuy, Lara, and Miranda)	Humans	Some confusion regarding actual taxonomy; wild mammalian host not yet discovered; DCL similar to that seen in Ethiopia (Old World); specific anergy to leishmanin (Montenegro) skin test

Life Cycle and Morphology

The life cycle and organism morphology are essentially the same as for Old World CL (Fig. 27.2). However, in some cases, destructive oral, nasal, or pharyngeal lesions may develop, causing mucocutaneous disease. In New World leishmaniasis, the sand fly vector is in the genus *Lutzomyia* or *Psychodopygus* rather than *Phlebotomus*. The genus *Leishmania* is divided into its two subgenera, *Leishmania* and *Viannia*, depending on the location of the development of the promastigote within the sand fly. Promastigotes from the subgenus *Viannia* develop in the midgut and hindgut of sand flies, while promastigotes from the subgenus *Leishmania* develop in the anterior portion of the sand fly alimentary tract (39).

Clinical Disease

Cutaneous Leishmaniasis. The lesions of New World CL are very similar to those seen with Old World cutaneous disease. Weeks to months after infection, an erythematous, often pruritic papule develops at the bite site. This papule may become scaly and enlarge, developing a central ulcer surrounded by a raised margin. Disease progression at this point will vary depending on the species involved. Lesions may be single or multiple and usually occur on exposed areas of the body. Many lesions may self-heal over a period of approximately 6 months (Fig. 27.11); however, lesions on the ear occur in 40% of the patients and are chronic, lasting many years. Ulcerations on the ears may be quite destructive but cause the patient few problems. *L. mexicana* lesions are usually single, self-limiting cutaneous papules, nodules, or ulcers that are painless and are found on the face and ears (Fig. 27.12 and 27.13). Other infections that are usually associated with single cutaneous lesions include those due to *Leishmania colombiensis*, *Leishmania amazonensis*, *Leishmania garnhami*, *Leishmania lainsoni*, *Leishmania peruviana*, and *Leishmania venezuelensis*. Multiple lesions caused by spread along lymphatics are common with *L. guyanensis* infections, and subcutaneous

TABLE 27.5 New World cutaneous leishmaniasis, subgenus *Viannia*, complex *L. braziliensis*

Species and sandfly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
L. braziliensis: *Lutzomyia wellcomei*, *L. intermedius*, *L. pessoai*	Cutaneous leishmaniasis, mucocutaneous leishmaniasis	Brazil, Guatemala, Belize, Honduras, Nicaragua, Peru, Ecuador, Bolivia, Costa Rica, Panama, Colombia, Venezuela, Paraguay, Argentina	Forest rodents, humans	Vector feeds primarily during daylight hours; common in farming communities in newly cleared forest areas and in road construction and mining workers; also known as nariz de anta (tapir nose) and espundia
L. peruviana: *Lutzomyia peruensis*, *L. verrucarum*	Cutaneous leishmaniasis	Peru, western slopes of the Andes, inter-Andean valleys; 900–3,000 m above sea level	Humans, dogs	Frequent in school children, commonly resulting in extensive facial scars; ulcers self-healing; known as uta; in some villages 90% of people are infected or scarred
L. colombiensis: *Lutzomyia hartmanni*, *L. gomezi*, *Psychodopygus panamensis*	Cutaneous leishmaniasis	Colombia, Panama, Venezuela, probably into Brazil, Peruvian lowlands	Humans, single isolate from the sloth (*Choloepus hoffmanni*)	Single to multiple ulcerating skin lesions; ML has not been seen
L. lainsoni: *Lutzomyia ubiquitalis*	Cutaneous leishmaniasis	Amazon region of northern Brazil, probably elsewhere	Humans, rodent (*Agouti paca*)	Multiple lesions have also been seen; ML has not been seen
L. shawi: *Lutzomyia whitmani*	Cutaneous leishmaniasis	Amazon region of northern Brazil, south of the Amazon River	Humans, monkeys, sloths, coatimundi	Multiple lesions have also been seen; ML has not been seen
L. naiffi: *Psychodopygus ayrozai*	Cutaneous leishmaniasis	Brazilian states of Pará and Amazonas	Humans, nine-banded armadillo (*Dasypus novemcinctus*)	Multiple lesions have also been seen; ML has not been seen

lymphatic nodules can be seen with *Leishmania panamensis*; the lesions can mimic those seen in sporotrichosis. The differential diagnosis of New World CL includes sporotrichosis, blastomycosis, yaws, syphilis, cutaneous tuberculosis, *Mycobacterium marinum* infection, and dermatologic cancers.

Mucocutaneous Leishmaniasis. ML is most common in the jungles of Amazonia (especially in southern Brazil), but cases have been reported throughout the Americas. Cutaneous lesions caused by *L. braziliensis* usually require a longer period for self-cure, taking up to 18 months or longer, and they can begin with lymphadenopathy. Approximately 1 to 3% of patients infected with *L. braziliensis* develop metastatic spread of the organisms to the nasal, pharyngeal, and buccal mucosa (ML). ML, also known as espundia, may occur months to years after the initial cutaneous lesion has healed partially or completely.

TABLE 27.6 New World cutaneous leishmaniasis, subgenus *Viannia*, complex *Leishmania guyanensis*

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
L. guyanensis: *Lutzomyia umbratilis* (high infection rate, up to 7%)	Cutaneous leishmaniasis	Brazil north of Amazon River, Guyanas; range extends into Ecuador, Venezuela, lowland forests of Peru	Humans, two-toed sloth, lesser anteater, rodents, opossums	Reservoir infections inapparent, organisms in normal skin and viscera; vector lives in forest canopy and tree trunks; timing right for deforestation (early-morning biting); Brazil nut and fruit collectors, topographers, visiting botanists, zoologists, tourists affected; also known as pian bois or forest yaws
L. panamensis: *Lutzomyia trapidoi*, *L. ylephiletor*, *L. gomezi*, *Psychodopygus panamensis*	Cutaneous leishmaniasis	Panama and the Canal Zone, western and central Colombia, Ecuador, Venezuela, Costa Rica, Honduras, Nicaragua	Humans, sloths (two-toed and three-toed), occasionally other animals	Frequent in American military personnel; rare cases of ML

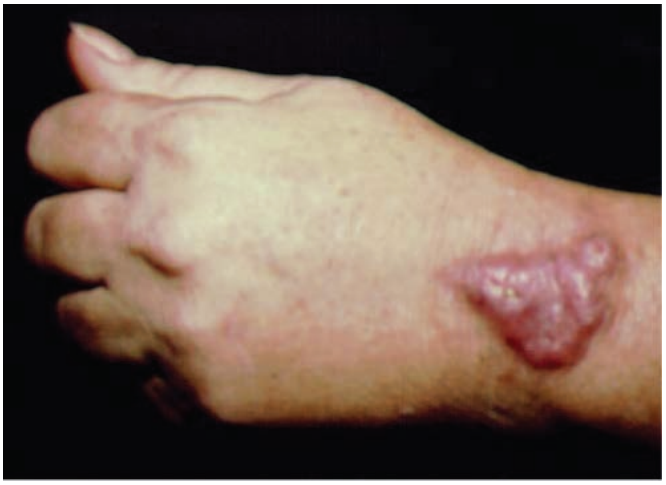

Figure 27.13 Large erythematous nodule with early ulceration on the left wrist, due to *Leishmania mexicana*. (Courtesy of Bonnie B. Furner.) doi:10.1128/9781555819002.ch27.f13

However, in many cases, mild mucosal lesions are present concomitantly with active cutaneous lesions. Mucosal disease tends to occur more frequently in males than females, and the patients are usually 10 to 30 years of age.

ML may begin with erythema and edema of the involved mucosal tissues, along with nasal inflammation, stuffiness, difficulty in breathing through the nose, and occasional bleeding. Following the early symptoms, ulcerations covered with a mucopurulent exudate may develop (Fig. 27.14). There is often severe erosion and destruction of the soft tissues and cartilage, leading to loss of the lips, soft parts of the nose, and soft palate. The lesions are chronic and progressive and can lead to death due to secondary infection or aspiration pneumonia. In the nonulcerative form, there may be hypertrophy of the tissues of the upper lip and nose, leading to the development of the "tapir nose." Unfortunately for diagnosis, parasites are few and difficult to find in tissues involved in ML. Although this disease can be extremely disfiguring, the mortality rate is low. New World ML mimics paracoccidioidomycosis, histoplasmosis, tuberculosis, syphilis, malignant tumors, and lethal midline granuloma.

Diffuse or Disseminated Cutaneous Leishmaniasis. DCL is an anergic form of CL in which neither humoral nor cell-mediated immune responses are functional but in which delayed hypersensitivity to tuberculin appears to be normal. DCL is seen most frequently in Venezuela, Brazil, Mexico, and the Dominican Republic. Individuals infected with *Lesihmania pifanoi* and 30% of those infected with *L. amazonensis* are likely to develop DCL (Fig. 27.15).

The parasites are found in the skin, and the disease is characterized by the formation of thickened skin in plaques, papules, or multiple nodules. Although lesions are usually seen on the face, nose, limbs, and buttocks, they can occur over the entire body (Fig. 27.16). The nodules are often described as soft and fleshy, while those of leprosy are generally more indurated. Although organisms have rarely been recovered from blood or bone marrow, there

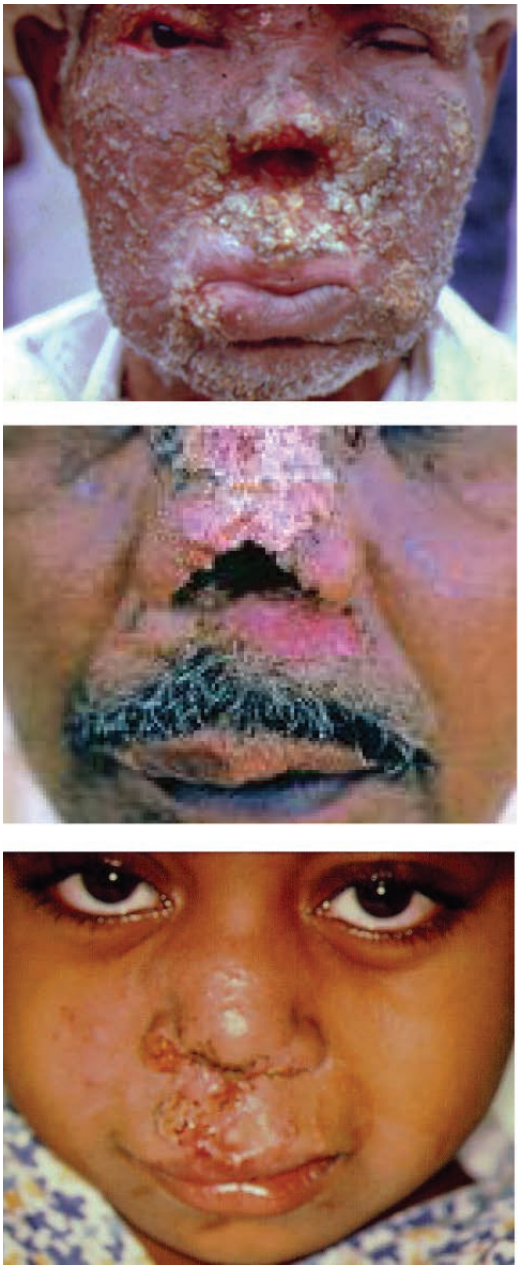

Figure 27.14 Mucocutaneous leishmaniasis, several examples of typical lesions (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). (Bottom image courtesy of Yoshihisa Hashiguchi.) doi:10.1128/9781555819002.ch27.f14

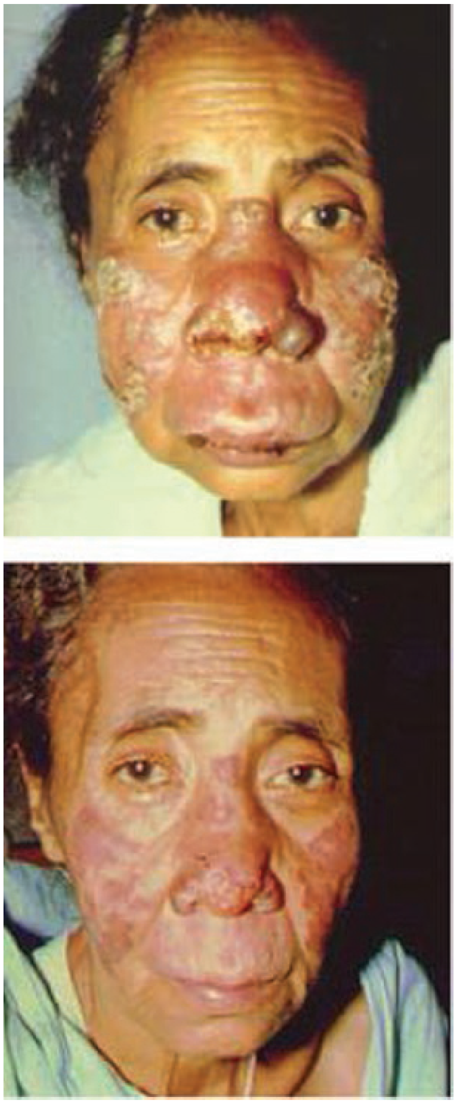

Figure 27.15 Mucocutaneous leishmaniasis. (Upper) Patient prior to therapy; (lower) patient after therapy (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). doi:10.1128/9781555819002.ch27.f15

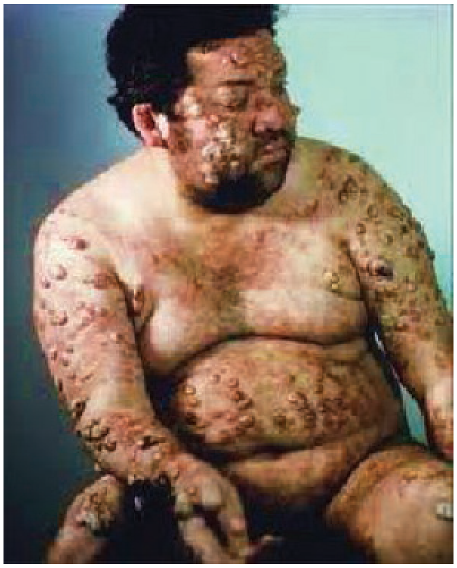

Figure 27.16 Diffuse anergic cutaneous leishmaniasis due to *Leishmania mexicana* in a patient of Dr. Convit (Venezuela). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch27.f16

are no visceral lesions associated with this form of leishmaniasis. Treatment is difficult, and the infection may last for the life of the patient. The LST remains negative unless treatment is effective and recovery occurs. Nodular DCL will have to be differentiated from lepromatous leprosy.

Diagnosis

In areas of the world where physicians are very familiar with leishmaniasis, the diagnosis may be made on clinical grounds. However, in locations where the disease is rare, the condition may not be recognized as leishmaniasis. Definitive diagnosis depends on demonstrating the amastigotes in tissue specimens or the promastigotes in culture (Table 27.7). More recent results suggest that PCR is a valuable tool for the diagnosis of leishmaniasis on a routine basis and can provide valuable epidemiologic information in areas of endemic infection. CL may have to be differentiated from a number of other lesions and diseases, including basal cell carcinoma, tuberculosis, various mycoses, keloid scarring, and lepromatous leprosy.

Specimen Collection

CL normally presents with no visceral involvement or systemic disease. The ability to detect parasites in aspirates, scrapings, or biopsy specimens depends on the number of amastigotes present, the level of the host immune response, the absence or presence of bacterial and/or fungal contamination within the lesion, and whether the specimen is collected from an active or healing lesion. If the patient has multiple lesions, specimens should be collected from the more recent or active lesions. These lesions should be thoroughly cleaned with 70% alcohol, and necrotic debris should be removed to prevent the risk of bacterial and/or fungal contamination of the specimen. Also, the specimen should be taken from the advancing margin of the lesion; the central portion of the ulcer contains nothing but necrotic debris unless portions of the lesion are taken below the crater area.

The specimen of choice would be a collection of several punch biopsy specimens taken from the most active lesion

TABLE 27.7 Features of New World human leishmanial infections related to demonstration of the parasite[a]

Organism	Disease type[b]	Humoral antibodies	Delayed hypersensitivity to leishmanin	Parasite present in clinical specimen	Self-cure	Recommended biopsy specimen
New World CL						
L. mexicana complex	CL	Present	Present	Present	Yes	Skin

L. braziliensis complex	CL	Present	Present	Present	Yes	Skin
	ML	Variable	Present	Few	No	Skin, mucous membranes
L. guyanensis complex	CL	Present	Present	Present	Slow	Skin
New World VL						
L. chagasi	VL	Abundant	Absent	Present	Possible	Bone marrow, spleen

[a] For culture, specimens must be collected aseptically, and in older lesions the parasites may be scant and difficult to recover. Animal isolation involves hamsters and culture media (Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium with 30% fetal bovine serum). Serologic testing is most suitable for VL, has little value for CL, and has limited value for MCL. The Montenegro test (LST) is a delayed hypersensitivity reaction to intradermal injection of cultured parasites.

[b] Additional information on relevant diagnostic methods can be found in chapters 7 and 8.

areas. Biopsy specimens can be divided and used for cultures and touch preparations; some material should always be saved and submitted for routine histologic testing. The biopsy specimen can be used to make impression smears (touch preparations); these smears should be prepared after portions of the specimen have been placed in culture media by using a sterile technique. After any excess blood is cleaned off, a horizontal cut is made through the biopsy specimen core and the cut surface is gently touched to glass slides; multiple slides should be prepared. Once material has been set up for culture and touch preparations have been made, the remainder of the tissue can be sent to the pathology laboratory for routine processing.

Another option involving sterile techniques is to make a perpendicular slit in the margin of the lesion. After blood is removed using sterile gauze, the blade can be used to scrape the inner walls of the slit. Material can be inoculated into culture media and can be smeared onto several glass slides; multiple slides are recommended to increase the chances of seeing the parasites. Fine-needle aspiration can also be performed with a sterile syringe containing sterile saline (0.1 ml) and a 26-gauge needle. The needle is inserted into the outer border of the lesion and rotated several times, after which saline is injected and tissue fluid is aspirated back into the needle. Material can be submitted for culture, and/or smears can be prepared for staining. Additional techniques and specific methods can be found in chapters 6 to 8.

Specimen Staining. All smears to be Giemsa stained should be air dried and fixed with 100% methanol prior to staining. The amastigotes will be found within the macrophages or close to disrupted cells. In very early and older lesions, very few organisms may be present, so that prolonged examination of the slide may be required. Other blood stains can also be used with good morphologic results.

Culture Media. It is important to release the organisms from tissue prior to culture; mincing is recommended. However, tissue grinders are not recommended because of possible damage to the organisms. Culture media that have been used for the recovery and growth of the leishmaniae include Novy-MacNeal-Nicolle medium and Schneider's *Drosophila* medium supplemented with 30% fetal bovine serum (see chapter 8). Patient cultures should not be set unless the laboratory maintains specific organism strains for quality control checks. Both the control and patient cultures should be examined twice a week for the first 2 weeks and once a week thereafter for up to 4 weeks before they are reported as negative. Promastigote stages can be detected microscopically in wet mounts taken from centrifuged culture fluid. This material can also be stained with Giemsa stain to facilitate observation at a higher magnification.

Animal Inoculation. Animal inoculation can be helpful when only a small number of organisms are present; however, most laboratories no longer consider this approach practical. Golden hamsters are inoculated intranasally, and the major argument against this approach is that it may take several months before the animals give positive responses. A combination of tissue smears, culture, animal inoculation, and histopathology may be required for optimal diagnosis.

Skin Test. The LST (Montenegro test) is not species specific and must be interpreted with caution, particularly since some patients may have more than one type of leishmaniasis (Fig. 27.10). Positive reactions are generally seen in patients with cutaneous lesions; however, those with DCL give negative reactions.

Serologic Tests. Standard serologic tests are not particularly useful for the diagnosis of New World CL or ML. Low titers are seen, tests are likely to be negative in early disease, and overall interpretation is difficult at best. However, if a patient is positive, serial measurement of antibody titers may be helpful in tracking the outcome of therapy. The development and use of recombinant antigens for specific and sensitive serodiagnosis of CL have led to improved diagnostic results (40).

Treatment

In contrast to Old World CL, systemic chemotherapy is recommended for New World CL. Differences between the two types of CL tend to justify this recommendation and include cases with multiple lesions; the long-term, chronic nature of some infections; and the tendency for disease progression and mucosal involvement in the absence of chemotherapy. Time to healing has been improved in studies in which recombinant human granulocyte-macrophage colony-stimulating factor coupled with stibogluconate has been used (41). Studies also show that the combination of allopurinol and stibogluconate is superior to stibogluconate alone and can be used as an adjunct to stibogluconate or other oral agents in the treatment of CL (41). However, a combination of allopurinol and stibogluconate used for the treatment of ML provided no clinical benefit. It also appears that low-dose CL therapy using an antimony regimen (5 mg/kg/day for 30 days) may work just as well as the larger recommended dose (20 mg/kg/day for 3 to 4 weeks), particularly for children and the elderly (42).

The most promising drug found so far is an anticancer compound, miltefosine, which has undergone experimental and clinical trials and is 94 to 97% effective. However, the drug is contraindicated during pregnancy and may cause severe gastrointestinal side effects. Also, the cost is another limiting factor. Other drugs such as paromomycin, allopurinol, and sitamaquine have been reported to have variable cure rates. Because of these limitations, a combination therapy, preferably coupled with specific parasite enzyme inhibitors, may be the most effective approach (43).

In Mexico, CL occurs in 17 of 32 states and is considered a serious public health problem. Treatment with a localized current field radiofrequency device to generate precisely controlled heat as an alternative to expensive drug treatment appears to be effective and convenient for use in primary health care facilities. Lesions were first anesthetized with 1% lidocaine hydrochloride and moistened with normal saline solution. Treatment consisted of a single application of heat that produced 50°C for 30 s. After 4 weeks, 95% of 122 patients were totally cured (including those with infected ear cartilage), and at 8 weeks, 90% of 191 patients were cured (44).

ML is the most serious clinical form of CL and, once diagnosed, requires prolonged and close supervision of therapy; incomplete treatment can lead to severe sequelae and even death. For many years, mucosal involvement of leishmaniasis in America was attributed to *L. braziliensis* only. However, dissemination via blood or lymph or extension to mucosal tissue has been documented for *L. panamensis*, *L. guyanensis*, *L. mexicana*, and *L. amazonensis*. It is now accepted that most of the New World *Leishmania* species are capable of causing a wide spectrum of disease, depending on the immune status of the host, parasite strain, and anatomic exposure. The simultaneous presentation of both mucosal and active cutaneous lesions contrasts with the classical descriptions of ML caused by *L. braziliensis*, thus emphasizing the importance of early diagnosis of mucosal disease by examination of the mucosa in all patients with CL. In some cases, treatment with both conventional and experimental regimens may not be effective against ML (45).

Epidemiology and Prevention

***L. mexicana* Complex.** *L. mexicana* (Table 27.4) causes chiclero ulcer and is common throughout Mexico, Belize, Guatemala, and the southern United States. It is transmitted among forest rodents by vectors that are not particularly attracted to humans. However, prolonged exposure of many forest workers leads to a high infection rate in these groups. The range of endemic infection has now been expanded within the United States to include areas in Arizona that are farther north than the southern Texas site previously identified. Apparently, wood rats serve as the primary wild reservoir hosts in these two states.

L. venezuelensis is found in the Lara and Yaracuy States, Venezuela, and has been recovered from humans, horses, and domestic cats; no wild reservoir hosts have been identified. Although it develops rapidly in hamsters (animal inoculation), it does not grow well in the blood-based media routinely used for culture.

Recovery of *Leishmania garnhami* is limited to the Venezuelan Andes. Although the human is a known host, a single infection has also been recorded in the opossum, *Didelphis marsupialis*.

L. amazonensis has been found in Bolivia, Brazil, Colombia, French Guyana, and Paraguay and is likely to be found in other South American geographic locations where the appropriate vector is located. It is primarily an infection of forest rodents; however, marsupials and foxes can also be reservoir hosts. The vector tends to be nocturnal; this is probably the reason why human disease is not as common as with other species.

L. pifanoi is limited to the states of Yaracuy, Lara, and Miranda within Venezeula, and humans are the only known mammalian host. The wild mammalian host has not yet been identified.

***L. (Viannia) braziliensis* Complex.** Unfortunately, the geographic distribution of *L. braziliensis* (Table 27.5) is not well defined, but infections have been reported from most Latin American countries including Argentina, Belize, Bolivia, Brazil, Colombia, Costa Rica, Ecuador, French Guyana, Guatemala, Honduras, Nicaragua, Panama, Paraguay, Peru, Suriname, and Venezeula. Many researchers think that it is unlikely that this broad a geographic range is accurate. The situation is even more confusing when ecologic and epidemiologic features of CL and ML differ in different regions. Humans are the main hosts, and wild hosts include sylvatic mammals such as rodents and marsupials. Infections have also been seen in dogs, mules, horses, and, rarely, cats. Extensive deforestation has been implicated in areas with suspected domestic animal transmission. Because there are questions regarding the reports of geographic range, it is difficult to accurately define vectors with proven transmission related to *L. braziliensis*. Human infections tend to be common in farming communities that develop along with deforestation, road construction, and mining.

L. peruviana is found in Peru on the western slopes of the Andes, including the inter-Andean valleys, generally at 900 to 3,000 m above sea level. It probably has a wider geographic range than reported. Transmission occurs in mountainous areas with little vegetation, and wild reservoir hosts probably include rodents and marsupials. Suspect vectors have been identified, but confirmation is often difficult. Human infection is usually contracted in and around the dwelling, and in some villages, the combined rate of present and past infection reaches 90%.

L. colombiensis has been found in Colombia, Panama, and Venezuela but probably has a wider geographic range, extending into Brazil and Peru, where appropriate wild reservoir hosts and vectors are found. Humans are the main host; however, a single isolate has been found from a sloth in Panama.

L. lainsoni occurs in the Amazon region of northern Brazil; however, the geographic range probably extends beyond these limits, as does the wild reservoir, *Agouti paca*, and the sand fly vectors. Evidence indicates that the vector, *Lutzomyia ubiquitalis*, does not like human blood, probably accounting for the low infection rate with *L. lainsoni*.

Leishmania shawi is also found in the Amazon region of northern Brazil, south of the Amazon river. Humans are recognized hosts, and wild reservoir hosts include monkeys, sloths, and coatimundi, as well as probably a few others.

Leishmania naiffi infections have been recorded from the Brazilian states of Pará and Amazonas. Like many of the other species where the wild reservoir hosts and appropriate vectors are found beyond these recorded boundaries, it is strongly suspected that the infection also has a broader range into other areas of Brazil and surrounding countries. The only recorded wild reservoir host is the nine-banded armadillo, in which there is a high infection rate in what appears to be normal skin and viscera. Like *L. lainsoni*, the vector of *L. naiffi* does not prefer human blood, hence the low human infection rate. However, other vectors may be implicated and do prefer human blood.

***L. (Viannia) guyanensis* Complex.** *L. guyanensis* (Table 27.6) is a very common cause of CL in Brazil, north of the Amazon river, and the Guyanas. Infections have also been recorded from Ecuador, Venezuela, and the lowland forests of Peru. Humans are known hosts, as are wild mammalian reservoir hosts such as the sloth and lesser anteater; other rodents and opossums have also been implicated. Like the wild reservoir hosts of *L. naiffi*, large numbers of parasites are located in what appears to be normal skin and viscera. The vector thrives in primary forest land, rather than in secondary forests or plantings of nonindigenous trees, and there may be a high human infection rate in such areas. Disease tends to be common in forest workers.

L. panamensis is found in Panama and the Canal Zone and has been reported as causing frequent infection in American military personnel stationed in these areas, as well as in agricultural workers. It has also been found in western and central Colombia, Ecuador, Venezuela, Costa Rica, Honduras, and Nicaragua. Humans are known hosts, and the epidemiology is similar to that seen with *L. guyanensis*. The major wild reservoir host is the two-toed sloth; fewer infections have been found in two genera of the three-toed sloths that live in the forest canopy, as do the vectors.

Vaccines. Current control of leishmaniasis is based on chemotherapeutic treatments which are expensive, toxic, and associated with high relapse and resistance rates. Vaccination remains the best hope for control of all forms of the disease. The development of a safe, effective, and affordable antileishmanial vaccine is a critical public health priority. Extensive evidence from studies in animal models indicates that solid protection can be achieved by immunization with defined subunit vaccines or live-attenuated strains of *Leishmania*. However, to date, no vaccine is available despite substantial efforts by many laboratories (46). Although not currently available, research and potential trials continue to be undertaken for vaccine development.

Visceral Leishmaniasis: General Comments

VL is widely distributed and endemic in 82 countries (Fig. 27.17). The estimated incidence of VL worldwide is a minimum of 100,000 per year, with close to 200 million people at risk of infection globally. Over 90% of these patients come from three regions: (Eastern/Old World) the Ganges River basin in India, Bangladesh, and Nepal, and the East African countries of Ethiopia, Sudan, and Kenya; and (Western/New World) northeastern Brazil. Since the 1990s, southern Sudan and the state of Bihar in India have been epidemic centers. These areas typically have high infection rates and a high mortality.

Old World (Eastern) Leishmaniasis: Visceral Leishmaniasis

VL (kala azar or dumdum fever) is caused by *L. donovani* and *L. infantum* in the Old World (Fig. 27.17). *L. tropica* also causes classical kala azar in India and causes viscerotropic leishmaniasis in the Middle East. The two main species tend to cause similar diseases, although *L. infantum* mainly affects young children and has a greater tendency to cause lymph node enlargement. The course of the disease and outcome depend on the general health status of the patient at the time of infection; apparently malnutrition exacerbates *L. infantum* infection (47). Dermotropic strains of *L. infantum* are known to cause visceral infection in immunocompromised patients with AIDS. VL is very prevalent among AIDS patients in certain geographic areas (e.g., southern Spain), with a high proportion of cases being subclinical. Like other opportunistic infections, subclinical VL can be found at any stage of HIV-1 infection, but symptomatic cases appear mainly when severe immunosuppression is present. HIV-*Leishmania* coinfection is being seen more and more frequently in the Mediterranean basin, especially in Spain, France, and Italy.

Life Cycle and Morphology

The life cycle and morphology of the organisms are essentially the same as for those causing Old World CL (Fig. 27.2). However, amastigotes can be found throughout the body and are not confined to the macrophages of the skin. Organisms inoculated into the bite site by the sand fly are engulfed by tissue macrophages, which then enter the bloodstream and are carried to RE centers such as the bone marrow, spleen, and liver (Fig. 27.18).

Clinical Disease

Visceral Leishmaniasis. Once the organisms have been carried to the bone marrow, spleen, and liver, a granulomatous cell-mediated immune response occurs that can result in subclinical disease and self-cure or in the clinical syndrome of VL (Table 27.8). The incubation period usually ranges from 2 to 6 months; however, it can take a few days or weeks to several years. When giving a history, many patients do not remember having a primary skin lesion. In areas of endemic infection, the onset may be gradual, with vague symptoms and a general feeling of ill health. The onset in naive patients (migrants, soldiers, or travelers to areas of endemic infection) may be acute, with high fever, chills, anorexia, malaise, weight loss, and, frequently, diarrhea. This syndrome can easily be confused with typhoid fever, malaria, or other febrile illnesses caused by bacteria or viruses. Death may occur after a few weeks or several years. Generally, untreated VL leads to death; secondary bacterial and viral infections are also common in these patients.

In areas where VL is endemic, many people develop a positive LST (Montenegro test) with no history of actual clinical disease; these individuals appear to be resistant to infection with *L. donovani*. The difference between an asymptomatic infection and subclinical disease is difficult to establish, particularly since many of these patients do not seek medical care. However, "viscerotropic" leishmaniasis may be more common than was previously thought and should be considered in individuals with unexplained mild symptoms (cough, malaise, chronic fatigue, abdominal pain, intermittent fevers, and diarrhea) in areas of endemic infection or in travelers with a history of exposure.

Immunology. With parasitization of RE cells, there is a hyperplasia of RE cells from the liver, spleen, bone marrow, lymph nodes, mucosa of the small intestine, and other lymphoid tissues. Hematopoiesis is initially normal and then becomes depressed, with a reduction in the life span of erythrocytes and leukocytes, causing anemia and granulocytopenia. RE cell proliferation may lead to massive hypertrophy of the liver and spleen, both of which may return to normal size after successful treatment (Fig. 27.19). In response to infection, there are decreases in T-cell blastogenesis production of interleukin-1 and -2, gamma interferon, and tumor necrosis factor. With successful therapy, these responses return to normal. Infection results in suppression of cell-mediated immunity, leading to uncontrolled reproduction of the parasite and dissemination. There is increased production of globulins, with high levels of IgG and IgM. The major target for the humoral immune response is heat shock proteins; Hsp70 was recognized in 92% of persons with VL (10). Circulating immune complexes involving IgA, IgG, and IgM can be found in the

TABLE 27.8 Old World visceral leishmaniasis

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
L. donovani: *P. argentipes*, *P. orientalis*, *P. martini*	Visceral leishmaniasis, kala azar, post-kala azar dermal leishmaniasis	Indian subcontinent, East Africa	Humans	Characterized by irregular fever, splenomegaly, hepatomegaly, weight loss, pancytopenia, and hypergammaglobulinemia; statistically significant differences between number of organisms in peripheral blood taken during the evening and during the day (66 and 46%, respectively), which coincides with biting habit of sand fly vector (night biting) (45)
L. infantum: *P. ariasi*, *P. perniciosus*	Infantile visceral leishmaniasis, cutaneous leishmaniasis (rare)	Mediterranean basin, central and western Asia	Domestic dogs	Mainly affects young children and tends to cause lymph node enlargement; poor nutrition exacerbates infection

serum. Delayed hypersensitivity responses to skin test antigens are suppressed or absent. With resolution of infection, the delayed hypersensitivity reaction returns, and patients recovering from infection are considered immune to reinfection.

Clinical signs. Fever may occur at irregular intervals and, once established, may be seen as a double (dromedary) or triple fever peak each day. The patient is often weak and appears emaciated (Fig. 27.20). Common clinical signs include a nontender enlarged liver with Kupffer cells containing many amastigotes and little or no cellular reaction, a markedly enlarged spleen, femoral and inguinal lymphadenopathy, and occasional acute abdominal pain or vague abdominal discomfort. In progressive disease, splenic infarcts are common; in acute cases, the spleen is smooth and friable, while in more chronic cases, the spleen is firm. Hair changes (thinning, dryness, hypopigmentation, and loss of curl) may be seen. Edema of the legs, jaundice, petechiae, and purpura have also occasionally been seen.

Skin. Skin changes are often seen on the face, hands, feet, and abdomen, particularly in India, where patients acquire an earth-gray color; this darkening of the skin apparently gave rise to the name kala azar (black sickness). In Africa, skin lesions often accompany VL and may appear very different from one patient to another. Some lesions are diffuse, warty, and nonulcerated and contain variable numbers of amastigotes.

Mouth and nasopharynx. Patients with VL in the Sudan and sometimes in East Africa and India have mucosal lesions in the mouth and nasopharynx. The lesions may appear as nodules or ulcers; the gums, palate, tongue, or lips can be involved. Lesions in the nasal mucosa can result in perforation of the septum, while nasopharyngeal and laryngeal lesions are characterized by mucosal swelling and subsequent hoarseness. Parasites tend to be more numerous in oral than in nasopharyngeal lesions; however, they can be demonstrated in nasal and pharyngeal fluids.

Laboratory findings. Patients generally have anemia (normocytic and normochromic, assuming that there is no underlying iron deficiency), neutropenia, relative lymphocytosis, an almost complete absence of eosinophils, thrombocytopenia, and hypergammaglobulinemia (polyclonal B-cell activation). Liver enzyme levels may be mildly elevated, but elevations of bilirubin levels are uncommon. Malabsorption may be a severe problem in children with VL and can lead to complications or death.

Infections in immunocompromised individuals. During the last decade, leishmaniasis has emerged as one of the first and most important opportunistic infections in HIV-infected patients. Over 1,600 coinfection cases have been recorded, the majority from Europe, where 7 to 17% of HIV-positive individuals with fever have amastigotes. This finding strongly suggests that individuals infected with *Leishmania* spp. without symptoms will express symptoms of leishmaniasis if they become immunosuppressed. Based on the patient's general health status and prior exposure to the infection, leishmaniasis may be seen as an early opportunistic infection or as a complication late in the course of AIDS. In HIV-infected patients, VL occurs in late stages of HIV disease and often has a relapsing course (24). Secondary prophylaxis reduces the risk of relapse. VL in the HIV-infected population should be included in the Centers for Disease Control and Prevention clinical category C for the definition of AIDS in the same way that other geographically specific opportunistic infections are included. The majority of AIDS patients present with the classical picture of VL, but asymptomatic CL, mucocutaneous leishmaniasis, DCL, and PKDL can be seen (these are usually caused by *L. infantum*). Cutaneous lesions of VL are being found increasingly frequently in patients with

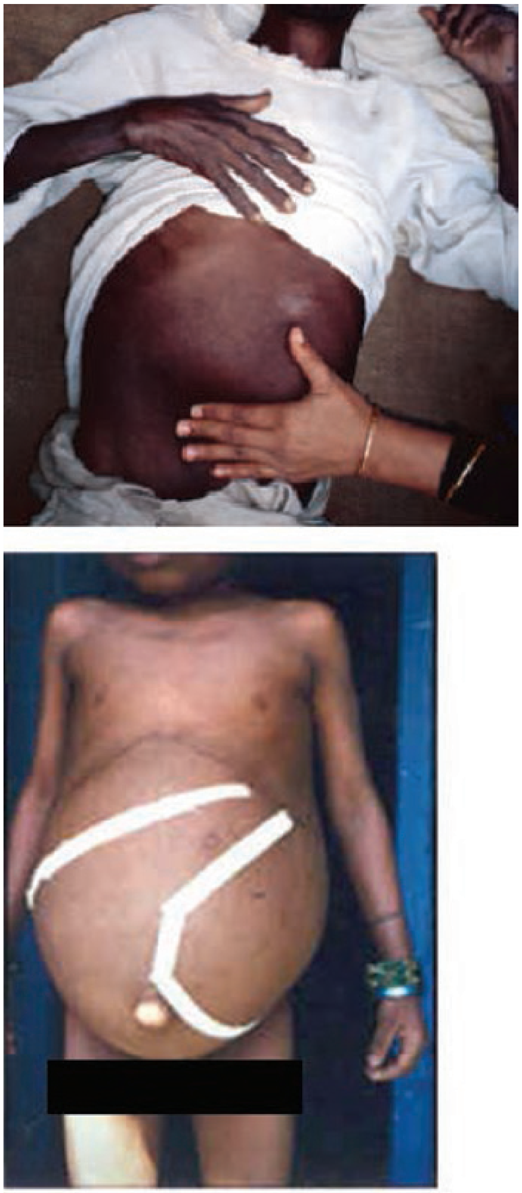

Figure 27.19 (Upper) Marked splenomegaly in a patient in lowland Nepal who has visceral leishmaniasis (VL) (courtesy of the CDC Public Health Image Library, C. Bern). (Lower) Marked splenomegaly and hepatomegaly in a patient with VL (courtesy of WHO, image from Philippe Desjeux).
doi:10.1128/9781555819002.ch27.f19

HIV infection, and their significance is still somewhat unclear. Lesions often do not present a uniform or specific appearance and have been seen as erythematous papules and hypopigmented macules on the dorsa of the hands, feet, and elbows; small subcutaneous nodules on the thighs; and erythematoviolaceous, scaly plaques on the face. Also, the digestive and respiratory tracts are often parasitized (21), as well as the pleura and peritoneum. Lesions can also be coinfected with other organisms, as evidenced by a case in which VL and *Mycobacterium avium-intracellulare* were seen in the same specimens from bone marrow and duodenal mucosa.

CD4 T-lymphocyte counts are usually <50/mm^3 and are almost always <200/mm^3. However, many physicians think that VL does not cause severe symptoms in these patients but is just one of several opportunistic infections that may coinfect AIDS patients. However, VL can manifest atypical aspects in HIV-positive patients depending on the degree of immunosuppression and should therefore be listed among AIDS-defining conditions. The most common symptoms are fever, splenomegaly, hepatomegaly, and pancytopenia.

Data from Spain provide some interesting outcome figures regarding coinfection compared with leishmanial infections in non-HIV-infected persons. In spite of a good initial response to treatment for VL, 60.6% of the HIV-coinfected patients had relapsed by the end of 1 year. Mortality from the first episode was 18.5%, and 24% died in the first month after diagnosis of any VL episode. The mean survival of the 29 patients who died was 10.27 months. Survival in patients with and without AIDS at the time of the first episode of VL was compared at 30 months and found to be 53.7 and 30.5%, respectively. A diagnosis of AIDS at the time of the first episode of VL and thrombocytopenia were the only risk factors found to be related to survival. Certainly in AIDS patients, VL is a recurrent disease that is highly prevalent and whose clinical course is modified by HIV (48). VL is very prevalent among HIV-1-infected patients in southern Spain, with a high proportion of cases being subclinical. Symptomatic cases appear mainly when severe immunosuppression is present. There is also an association between VL, the male sex, and intravenous drug use.

In HIV-1-infected patients with active VL, the sensitivity of a peripheral blood smear is about 50%, due to a high parasitemia in these patients. However, in patients with HIV-1 and subclinical VL, the sensitivity of a routine blood smear is <10% (49). Unfortunately, in these patients serology and *Leishmania* skin tests have low sensitivities and are not very helpful. Cultures have proven to be effective in diagnosing VL in patients who are coinfected with HIV-1 (50).

Post-Kala Azar Dermal Leishmaniasis. PKDL generally develops after apparent successful cure from visceral leishmaniasis and is confined to two geographically distinct zones, namely South Asia (India, Nepal, and Bangladesh) and East Africa, mainly Sudan. PKDL was first detected in patients with VL in India, occurs in up to 20% of these patients, has been called dermal leishmanoid, and is associated with *L. donovani* only. PKDL has also been

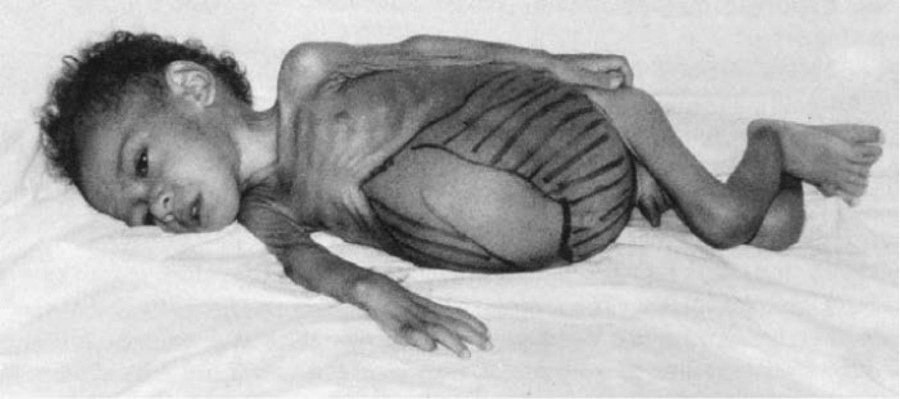

Figure 27.20 Cachexia (wasting) seen in severe visceral leishmaniasis (courtesy of Richard D. Pearson).
doi:10.1128/9781555819002.ch27.f20

seen in >50% of Sudanese VL patients treated in the current epidemic. In India, skin lesions may appear 2 to 10 years after successful therapy for VL; in East Africa, lesions appear within a few months; and in the Sudan, onset also occurs in about 2 months. Macules and papules usually appear first around the mouth and spread to the face and then to the extensor surfaces of the arms, the trunk, and sometimes the legs. In the beginning they look like small hypopigmented patches; these then enlarge and may progress to nodules that often resemble leprosy. The lesions are somewhat delicate but do not tend to ulcerate unless traumatized. In some cases, PKDL is seen in patients with no history of visceral disease (Fig. 27.21). Some patients with past or concomitant PKDL also have ocular lesions including conjunctivitis, blepharitis, and anterior uveitis; these conditions all respond to antimonial therapy, including steroid and atropine eyedrops.

The exact immune mechanisms of PKDL are still somewhat undefined, and the immunobiology of the Sudanese and South Asian PKDL differs. In Sudanese PKDL, because of the shorter time lag between cure from VL and development of PKDL, the disease-associated immune involvement mimics immune reactivation after cure from VL. Peripheral blood mononuclear cells from Sudanese PKDL patients react and proliferate following induction by *Leishmania* antigens and secrete more IFN-γ, whereas inteleukin-10 was produced primarily from CD4$^+$ T cells. In contrast, South Asian PKDL is more chronic due to the longer gap between cure from VL and disease onset. Here, CD8$^+$ T cells predominate in lesions and circulation. Also, in Sudanese PKDL, the lesions regress spontaneously, whereas in South Asia, prolonged treatment is essential (51).

Treatment of PKDL with antimonials usually brings improvement; however, the skin changes persist indefinitely. The course of therapy is generally longer than that required for VL and may require 120 days. In Africa, patients with PKDL may self-cure. It is important to remember that these patients may serve as reservoirs of infection during interendemic cycles, since some patients with PKDL tend to have large numbers of parasites in the skin. Persistent lesions currently require daily injections of sodium stibogluconate for 2 to 4 months, and even then the treatment may not be successful. Treatment with liposomal amphotericin B (AmBisome) has been found effective and is considered less nephrotoxic than nonliposomal amphotericin B because it specifically targets the macrophages in which the *Leishmania* parasites develop. Apparently, there are also intrinsic differences in the antibodies generated in the sera from patients with PKDL and VL (52). Diagnostic methods would be identical to those used for the isolation and identification of amastigotes found in CL.

Diagnosis

A clinical diagnosis of Old World VL is often made based on clinical findings and local epidemiologic factors. However, confirmation of the diagnosis requires demonstration of the amastigotes in tissues or clinical specimens or the promastigotes in culture (Algorithm 27.1). Detection of parasite genetic material or antigen detection also suffices for confirmation. Leishmaniasis should be suspected in individuals who have resided in or traveled to areas where the disease is endemic. The diagnosis would be supported by findings of remittent fevers, hypergammaglobulinemia with anemia, circulating immune complexes, rheumatoid factors, weight loss, leukemia, and splenomegaly. The differential diagnosis of late-stage VL is limited to hematologic and lymphatic malignancies. The diagnosis of early disease is more difficult, and the differential would include malaria, African trypanosomiasis, brucellosis, enteric fevers, bacterial endocarditis, generalized histoplasmosis, chronic myelocytic leukemia, Hodgkin's disease and other lymphomas, sarcoidosis, hepatic cirrhosis, and tuberculosis. Also, patients with multiple myeloma and Waldenström's macroglobulinemia have monoclonal hypergammaglobulinemia. Mixed cryoglobulinemia secondary to VL has also been documented.

Blood. Examination of buffy coat smears shows that there is a significant difference in recovery between samples col-

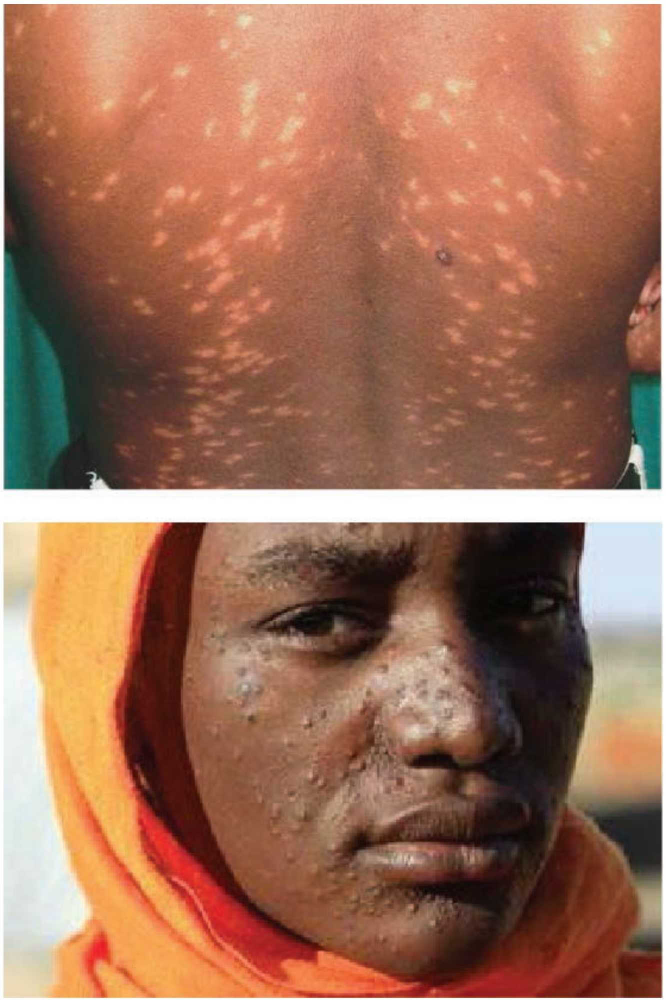

Figure 27.21 Post-kala azar dermal leishmaniasis (PKDL). (Upper) Notice the depigmented macules on the skin of a patient from India. This patient was treated for visceral leishmaniasis with miltefosine 7 years prior. He developed hypopigmented lesions about 3 years ago, which gradually became depigmented. With therapy the lesions disappeared. (Courtesy Koley S et al, *Indian J Dermatol* **58:**241, http://www.e-ijd.org/text.asp?2013/58/3/241/110848.) lected during the day (46%) and those collected during the night (66%) (53). Prior to an invasive procedure, blood specimens should be collected, keeping in mind the amastigote diurnal periodicity.

Tissue Aspirates. Although splenic puncture yields the highest rate of organism detection (98%), it carries a high degree of risk for the patient. Certainly deaths have occurred after this procedure, probably due to splenic laceration. Patients with coagulation disorders should not undergo splenic puncture. Other specimens include lymph node aspirates, liver biopsy specimens, sternal or iliac crest bone marrow, and buffy coat preparations of venous blood. Bone marrow aspirate is generally used in lieu of splenic puncture; however, smears from bone marrow usually contain fewer organisms, with a positivity rate of 80 to 85%. As discussed earlier in this chapter, it is important to prepare multiple smears for examination. Although amastigotes can be seen in buffy coat smears in Indian and Kenyan patients with VL, it is unusual to make the diagnosis by this method.

Culture and Animal Inoculation. Culture and animal inoculation studies are also helpful. Culture requirements, including specimen collection by an aseptic technique and the use of quality control strains, were discussed earlier in this chapter and are also addressed in chapter 8. A method for rapidly isolating promastigotes from the culture fluid has been developed using the stain acridine orange. This type of vital staining combines the advantages of direct microscopic examination with more accurate morphological imaging of the stained parasites. If available, hamsters should be inoculated intraperitoneally and killed after 2 to 3 months, and the liver and spleen should be checked for parasites (microscopic examination and/or cultures).

PCR and Other Antigen Detection Methods. PCR methods have excellent sensitivity and specificity for direct detection, for identification of causative species, and for assessment of treatment efficacy (34, 35, 54–59). A rapid immunochromatographic dipstick test using the recombinant RK39 antigen has become available for the qualitative detection of total anti-*Leishmania* immunoglobulins. The test uses antigen-impregnated nitrocellulose paper strips. Results from one study were very promising, with 100% sensitivity and 98% specificity (60). The RK39 strip test is ideal for rapid reliable field diagnosis of visceral leishmaniasis (61). The test has high sensitivity and specificity; however, it remains positive long after treatment (up to 3 years). For this reason, PCR is recommended as the more effective diagnostic approach (62).

Formol-Gel Test (Hypergammaglobulinemia). In patients with kala azar, there is a characteristic hypergammaglobulinemia, including both IgG and IgM. This fact has been used as the basis for a diagnostic procedure called the formol-gel test, which is used in areas of endemic infection. The test can be used as a screen; most patients with active disease are positive. A drop of formaldehyde is added to a test tube containing 1 ml of patient serum, which is observed for opacity and a stiff jelly consistency within 3 min to 24 h. Results also indicate that a specific IgE response is useful in the diagnosis of active VL and may be used to evaluate the response to treatment (63).

Skin Test. The Montenegro (LST) skin test is described above. In patients with active VL, this delayed hypersensitivity test is negative. However, within several months to a year after recovery, the skin test reverts to positive. It is of limited value because it becomes positive late in the course of disease, and false-positive results are common.

Serologic Tests. A number of serologic diagnostic methods have been developed worldwide, although they are not widely available. In general, sensitivities are >90% but specificities are lower. False-positive results can be seen in patients with other infectious diseases, in patients treated for VL (in whom antibodies persist for months), and in some asymptomatic VL patients. There are currently four tests in use, the direct agglutination test (DAT), the indirect fluorescent-antibody test, counterimmunoelectrophoresis, and enzyme-linked immunosorbent assay (ELISA). DAT appears to be the best choice as a diagnostic tool since it is very specific and does not require expensive equipment or reagents (64). However, patients may still have positive sera 1.5 to 5 years after treatment (65). DAT has also been adapted to filter paper sampling, and the filter paper eluates compared well with their homologous sera and correlated strongly with respect to antibody titers (66). DAT based on axenic amastigote antigen provided 100% sensitivity and specificity, making it particularly useful for diagnosis of macular PKDL cases, which are often missed by the RK39 strip test. Thus, DAT provides a simple, reliable, and inexpensive test for PKDL diagnosis with potential applicability under field conditions (67). However, newer studies using ELISA formats indicate excellent sensitivity and specificity and may be very helpful in diagnosis of early infections (68).

KEY POINTS—LABORATORY DIAGNOSIS

Old World (Eastern) Leishmaniasis: Visceral Leishmaniasis

1. For a complete laboratory diagnosis, microscopic examination of Giemsa-stained touch preparations and cultures is recommended, as well as PCR and animal inoculation if available. Other blood stains are also acceptable.
2. Due to potential problems with splenic puncture, bone marrow specimens may be recommended. Although not that productive, examination of buffy coat preparations is recommended prior to a more invasive procedure. When collecting blood specimens, remember the diurnal periodicity.
3. Multiple slides should be prepared for examination from aspirates and/or biopsy specimens.
4. Tissue imprints or smears should be stained with Giemsa stain (or one of the stains commonly used for blood smears) (see chapter 7).
5. Amastigote stages should be found within RE cells or close to disrupted cells.
6. If cultures are to be performed, specimens must be collected aseptically and control organism cultures should be set up at the same time (see chapter 8).
7. Cultures should be checked weekly for 4 weeks before they are declared negative.
8. Patients with kala azar have hypergammaglobulinemia; the formol-gel procedure may be helpful.
9. Serologic tests are helpful, and newer procedures demonstrate increased sensitivity and specificity; this should be considered if parasites cannot be detected in clinical specimens.

Treatment

Patients should receive supportive care, especially if they are malnourished or have other infections such as pneumonia, tuberculosis, or other chronic conditions. Since the mid-1930s, pentavalent antimony compounds have been the drugs of choice for the treatment of VL. However, with the first reports of primary treatment failures in the mid-1990s, additional drugs have been used and include lipid-associated amphotericin B for Mediterranean and Indian VL (52). VL in renal transplant recipients has been successfully treated with liposomal amphotericin B (AmBisome). The disadvantages of using Pentostam and Glucantime include the need for intravenous administration and hospitalization, cardiotoxicity, pancreatitis, treatment failures, and increasing resistance (69). The dosing regimen for treating VL is also associated with a high rate of serious side effects in HIV-infected patients (70). Therapy combining either paromomycin or allupurinol with pentavalent antimonials has also been used with some success.

There is no effective orally administered medication for any *Leishmania* infection. However, studies with miltefosine appear very promising. This drug is a phosphocholine analogue that affects cell-signaling pathways and membrane synthesis. When 100 mg of miltefosine was given per day (approximately 2.5 mg/kg of body weight/day) for 4 weeks, 29 (97%) of 30 patients with at least moderate *Leishmania* in their splenic aspirates were cured (71). Gastrointestinal side effects were frequent but were only mild to moderate in severity, and no patient discontinued therapy. Oral miltefosine and safe AmBisome along with better use of amphotericin B have been rapidly implemented in the last decade. A combination therapy will substantially reduce the required dose and duration of drug administration and reduce the chance of the development of resistance (41, 72).

Epidemiology and Prevention

The epidemiology of VL depends on a number of factors including the interaction between sand flies, reservoir hosts, and susceptible humans. In the two main areas of endemicity, the Ganges river basin and southern Sudan, high infection rates and many deaths have been documented during the last 20 years. Factors which affect the number of infections and the transmission include population movements often related to forced migration, poor general health, and poverty, all of which are seen in both geographic areas. The disease is a zoonosis, with the exception of India, where humans serve as the major reservoir host and the relevant vector is *P. argentipes*. Dogs serve as the main reservoir host around the Mediterranean, and the infection is transmitted through bites of infected sand flies such as *Phlebotomus perniciosus*, *Phlebotomus major*, *Phlebotomus simici*, and *Phlebotomus longicuspis*. Disease in this area is usually found in infants and children; young dogs are very susceptible to *L. infantum* and often die of the disease. Dogs are also important reservoirs in certain parts of China. In southern France and central Italy, infected foxes appear to be the reservoir, with *Phlebotomus ariasi* and *Phlebotomus perfiliewi* serving as vectors. Jackals also probably serve as reservoir hosts in the Middle East and central Asia. The epidemiology of VL in Africa is somewhat confusing, since the presence of epidemics suggests a human reservoir but dogs have also been found to be infected. The main vector in Kenya appears to be *Phlebotomus martini*, and in the Sudan the vector is *Phlebotomus orientalis*.

L. donovani occurs in Africa and Asia, and in areas where transmission is somewhat sporadic, wild canids and various rodents are natural reservoirs of the disease. *L. infantum* is seen in Africa, Europe, the Mediterranean area, and southwest Asia. Humans are accidental hosts, with dogs and other members of the *Canidae* acting as natural reservoirs (73).

Although the usual route of transmission is through the bite of infected sand flies, parasites can be transmitted in other ways including blood transfusion, sexual contact, congenital transmission, and occupational exposure. However, for the most part, transmission is through the normal vector cycle. Apparently, *L. infantum* can circulate intermittently and at low density in the blood of healthy seropositive individuals, who appear to be asymptomatic carriers; this certainly has implications for the safety of the blood supply in certain areas of the world, including southern France.

In areas where humans serve as the main reservoir host, treatment of active cases is likely to interrupt the cycle of transmission. Reservoir control has proven to be somewhat sporadic, and there is little indication that it has any impact on overall infection rates. Residual insecticide spraying, primarily for malaria vector control, was relatively successful; however, when spraying of DDT was discontinued, the incidence of VL began to increase again. Vaccines hold a great deal of promise, but currently no commercial products are available (74).

New World (Western) Leishmaniasis: Visceral Leishmaniasis

New World VL (sometimes called American VL [AVL]) is caused by *Leishmania chagasi* and has many similarities to Old World VL caused by *L. infantum*, including the fact that the infection is seen primarily in children and that both infections cause visceral and cutaneous disease.

Life Cycle and Morphology

The life cycle and morphology of *L. chagasi* are essentially the same as those of the species causing Old World VL (Fig. 27.2). Amastigotes can be found throughout the body and are not confined to the macrophages of the skin. Organisms inoculated into the bite site by the sand fly are engulfed by tissue macrophages, which then enter the bloodstream and are carried to RE cell centers such as the bone marrow, spleen, and liver.

Clinical Disease

L. chagasi causes subclinical infections and AVL, which is potentially fatal if not treated, and it has recently been

TABLE 27.9 New World (American) visceral leishmaniasis

Species and sand fly vector	Human disease and lesion	Geographic distribution	Important hosts	Comments
L. chagasi: Lutzomyia longipalpis	Visceral leishmaniasis, kala azar, post-kala azar dermal leishmaniasis, atypical cutaneous leishmaniasis	Most of Latin America (Argentina, Bolivia, Brazil, Colombia, Ecuador, Paraguay, Suriname, Venezuela, Guatemala, Guadeloupe, Honduras, Martinique, Mexico, El Salvador, Costa Rica)	Humans, dogs, foxes	Closely resemble *L. infantum* infections in Old World; fatal outcome unless treated; the term American visceral leishmaniasis (AVL) is preferred to kala azar (reserved for Indian VL)[a]

[a] Although there is some controversy about whether *L. chagasi* is indigenous to the Americas or whether AVL is due to *L. infantum* which was introduced into the New World by immigrants in post-Columbian times via infected dogs, there appears to be strong evidence for the former hypothesis.

associated with atypical cutaneous leishmaniasis (ACL) in Central America, particularly in Honduras (Table 27.9). Typically, AVL is associated primarily with malnourished children younger than 5 years, whereas the ACL presentations are seen mainly in children older than 5 years and young adults. Data indicate that this atypical disease presentation may be more common than was previously thought and may affect up to 10% of a local population (75). The fact that the same organism can cause AVL and ACL suggests that the host immune response may play a role in the outcome. The disease presentation includes nonulcerated cutaneous nodules.

Diagnosis

Confirmatory diagnosis depends on the demonstration of parasites, either amastigotes in stained smears of spleen, bone marrow, or lymph node aspirates or promastigotes in culture (Algorithm 27.1). Although tissue aspirates should contain many parasites, this is not always the case. If only a few are present, culture may not be successful. Intraperitoneal inoculation of aspirate material into hamsters is by far the most reliable means of isolating *L. chagasi*; however, there may be long delays before parasites are detected in the animals. PCR will probably become the test of choice, as with other types of leishmaniasis, but the practicality and cost issues mean that routine methods will continue to be the most likely approach, particularly since the majority of cases are seen in more remote rural areas.

Treatment

Although the treatment regimens are similar to those used for Old World VL, some patients are unresponsive to the recommended antimonial dosages; this has been seen in Bahia, Brazil. Alternatives would include increased dosages and/or the use of second-line drugs such as pentamidine. Unfortunately, serious side effects also increase when increased dosages are used. A review of available therapy for both Old World and New World VL is given in Table 27.10 and chapter 36.

Epidemiology and Prevention

The public health implications of widespread *L. chagasi* infections in Central and South America may be quite broad. Parasites that cause American CL (ACL) appear to be genetically very similar to those that cause AVL. This suggests that with diminished immune capacity, cutaneous infection may cause visceral disease, particularly since it is well known that this occurs in AIDS patients. ACL cases may also serve as reservoirs for vector transmission, leading to additional cases of visceral disease. Certainly treatment of these ACL patients would be recommended as a preventive measure for reduction of the number of potential future cases. Subcutaneous nodules are often misdiagnosed and treated inappropriately. Also, ACL may serve as a marker for the possible occurrence of AVL in a particular area and could be used as an indicator to more closely monitor for the presence of AVL.

In areas where humans serve as the main reservoir host, treatment of active cases is likely to interrupt the cycle of transmission. Reservoir control has proven to be somewhat sporadic, and there is little indication that it has any impact on overall infection rates. Residual insecticide spraying, primarily for malaria vector control, was relatively successful; however, when spraying of DDT was discontinued, the incidence of AVL began to increase again. Vaccines hold a great deal of promise, but currently no commercial products are available. As the incidence of disease continues to increase, particularly in Brazil, the importance of reviewing procedures for acceptance of blood donors and subsequent transfusions is becoming more relevant and important. Currently, blood is not routinely monitored for antibodies; however, serologic studies would serve as a first approach to the study of transmission of leishmanial organisms through blood transfusion. A seroreactivity of 9% has been found, increasing to 25% in a periurban focus of AVL infection (76). In another study from the midwest region of Brazil, 15.6% of samples tested were positive for antibodies to *Leishmania* sp. (77).

TABLE 27.10 Specific drugs for the treatment of visceral leishmaniasis (see also chapter 36)[a]

Drug	Dosage	Side effects	Comments[a]
Amphotericin B deoxycholate Lipid-associated amphotericin B Liposomal amphotericin B (AmBisome) Cholesterol dispersion (Amphotec) Amphoterican B lipid complex (Abelcet) **Liposomal amphotericin B is the drug of choice. The total dose administered seems to be more important than the number of infusions or duration of therapy.**	Slow i.v. over 4–6 h, starting at 0.1 mg/kg daily, increasing to 1 mg/kg every 2 days until total dose of 20 mg/kg has been given; AmBisome regimen is 3 mg/kg daily on days 1–5, sixth dose on day 14, seventh dose on day 21 (total dose is 21 mg/kg); regimen for immunosuppressed patients is 4 mg/kg daily on days 1–5, 10, 17, 24, 31, and 38 (total dose of 40 mg/kg); in this group relapse is common	Fever, chills, thrombophlebitis, renal insufficiency, anemia, hypokalemia, anorexia, nausea; caution when used on patients previously receiving SbV, who may be predisposed to cardiac events; for treatment of patients with VL within the United States, AmBisome is recommended and should be used unless contraindicated	Used in cases of VL resistant to SbV compounds; cure rates in VL clinically resistant to SbV and pentamidine approach 100%; all drugs available in the U.S. have been approved for other conditions; AmBisome now also approved for VL; AmBisome effective and safe for VL (Brazil, India, Kenya, Mediterranean); lipid-associated amphotericin B preparations probably not more effective than amphotericin B deoxycholate but can be given at higher doses with less toxicity; also more expensive
Pentavalent antimonials (SbV) Sodium stibogluconate (SSG) (Pentostam) Sodium antimony gluconate Meglumine antimoniate (Glucantime)	Pentostam for VL (India, Kenya): 20 mg/kg/day (28 days Kenya,40 days India); upper limit of safe, daily dose not as relevant, with the exception of AIDS patients	i.m. injections painful; recommend slow injection with 23- to 26-gauge needle, dilution of daily dose 1:10 with 5% DW. Nausea, anorexia, abdominal pain, malaise, headache, arthralgias, myalgias, lethargy (beginning 7–10 days into therapy); VL patients tolerate SbV better than do CL or ML patients; symptoms resolve after therapy; serum amylase and lipase levels rise (peak at 7–14 days); may need to interrupt therapy for 5-fold increase in amylase and 15-fold increase in lipase levels; ECG abnormalities occur in 50% of patients receiving SSG	Variation in total antimony (Sb) content; cannot assume that one drug will work like another; lot variations may contribute to safety and efficacy differences; storage conditions important (4°C in the dark optimal)
Miltefosine	2.5 mg/kg/day PO (max 150 mg/day × 28 days	The drug is contraindicated in breastfeeding and pregnant women; a negative pregnancy test before drug initiation and effective contraception during and for 4 months after treatment is recommended	Miltefosine (Impavido) is manufactured in 10- or 50-mg capsules by Paladin (Canada) and is available in the U.S. from the manufacturer through an investigative drug application from the FDA.
Pentamidine (as isethionate or methane sulfonate salt)	4 mg/kg daily 3 times/wk for 24 injections (8 wk); regimens of 4–6 mo have also been used	Pain, induration, sterile abscesses at injection site; hypotensive reactions if drug given too quickly; hypoglycemia diabetes may occur; high-dose, long-duration therapy more toxic than SbV and amphotericin B, giving it a limited role in treatment of VL	Provided as sterile powder, must be dissolved in DW; administered i.m. or slow i.v.; tends to be effective in Kenya with little toxicity; resistance in India now common; addition of SbV to pentamidine does not increase the cure rate
Aminosidine (paromomycin)	Parenteral (Kenya): 15 mg/kg/day for mean of 19 days (79% cure); parenteral (India): 20 mg/kg/day for 21 days (97% cure); accepted monotherapy for Indian VL at 16 mg/kg/day for 21 days	Possible auditory nerve damage and renal damage; vertigo and pancreatitis when given i.v.	Aminoglycoside with broad antiparasitic activity; if used in combination with standard doses of SbV, shorter duration (17–20 days) possible (Kenyan, Sudanese, Indian VL)
Immunotherapy	Has been used as monotherapy and adjunct therapy in SbV-resistant and primary VL in Kenya, Brazil, and India	Fever, chills, myalgias, fatigue, headache, depression	IFN-γ should be considered when faced with SbV-resistant VL and in selected cases of relapse; expensive (1, 7, 28, 30, 33)

[a] DW, distilled water (sterile); IFN-γ gamma interferon; i.m., intramuscular; i.v., intravenous; ECG, electrocardiogram; SbV, pentavalent antimonials; SSG, sodium stibogluconate.

Control programs for AVL often include elimination or treatment of infected dogs. Although attempting to remove seropositive dogs is insufficient as an eradication measure, data suggest that elimination of the majority of seropositive dogs may affect the cumulative incidence of seroconversion in dogs temporarily and may also diminish the incidence of human cases of AVL. The effectiveness of the use of vaccines plus repellents in preventing infection and subsequent disease development should be assessed by means of large-scale, randomized controlled field trials because this combined strategy may become the next frontier in the control of canine leishmaniasis (Fig. 27.22).

Trypanosomiasis

African trypanosomiasis

Trypanosoma brucei gambiense

Trypanosoma brucei rhodesiense

American trypanosomiasis

Trypanosoma cruzi

Trypanosoma rangeli

Trypanosomes are hemoflagellates, which are transmitted by tsetse flies (*Glossina* spp.) to a wide range of mammalian hosts (1) (Fig. 28.1). They cause serious medical problems for humans and livestock. Trypanosomes belong to the family *Trypanosomatidae*, which live in the blood and tissues of their human hosts (Table 28.1). The African trypanosomes belong to the subgenus *Trypanozoon* and as a group are referred to as the *Trypanosoma brucei* complex. *T. brucei brucei* strains are parasites of domestic and wild animals and are not known to be infectious for humans. Human infections are caused by *T. brucei gambiense* (West African trypanosomiasis) and *T. brucei rhodesiense* (East African trypanosomiasis). Infections caused by *T. brucei rhodesiense* are much more fulminant than those caused by *T. brucei gambiense*, the parasitemia is much higher, and the disease has a much faster progression. It is not possible to differentiate the three trypomastigotes of *T. brucei gambiense*, *T. brucei rhodesiense*, and *T. brucei brucei* on the basis of morphology, and all three organisms can be recovered in animal reservoir hosts. In the past, differentiation was based on clinical signs and geographic area of isolation. Differentiation is now based on isoenzyme characteristics and DNA and RNA methods in addition to the aforementioned factors. It is estimated that 60 million people in 36 countries are at risk, and there are approximately 50,000 new cases per year of African trypanosomiasis (2). Based on available information from western and central Africa, there appears to be no increased risk of African trypanosomiasis among those infected with HIV; however, this has not been totally confirmed. There are also unanswered questions concerning disease presentations and diagnostic test results in patients who are coinfected with both organisms. Human African trypanosomiasis is characterized by a polyclonal B-cell activation, constituting a risk for false-positive reactions to diagnostic tests, including HIV tests. Unless tests have been validated for interference with African trypanosomiasis, HIV diagnosis using standard algorithms in untreated trypanosomiasis patients should be avoided. Validated combinations of three HIV rapid tests can increase specificity (3).

Trypanosomes infecting humans in the Americas belong to the subgenus *Tejaraia* (*T. rangeli*) and *Schizotrypanum* (*T. cruzi*). *T. rangeli* infections are asymptomatic, with no evidence of pathology; however, *T. cruzi* infections (American trypanosomiasis) can cause considerable morbidity and mortality. Chagas' disease is caused by the protozoan parasite *T. cruzi*, which affects as

doi:10.1128/9781555819002.ch28

many as 10 million to 16 million people in North and South America. However, due to the recent emigration of people from areas of endemicity, cases of Chagas' disease have been reported in the United States, Canada, Australia, Japan, and Europe, extending the range of this parasitic disease throughout the developed world.

African Trypanosomiasis

Trypanosoma brucei gambiense

Although the first descriptions of human sleeping sickness were made by European colonists in the late 19th and early 20th centuries, Atkins described a "sleepy distemper" in 1742 and David Livingstone described a "fly disease" in 1857 (2). In 1901, *T. brucei gambiense* was seen in the blood of a European steamboat captain working on the Gambia River. After Forde's discovery in 1901, Dutton in 1902 proposed the name *Trypanosoma gambiense*. Although a trypanosome was discovered in 1903 in the spinal fluid of a patient suffering from sleeping sickness and Castellani named it *Trypanosoma ugandense*, it was soon clear that the two organisms were identical. By 1909, the mode of transmission by the tsetse fly, *Glossina palpalis*, was confirmed. The primary area of endemic infection with *T. brucei gambiense* coincides with the tsetse fly belt through the heart of Africa, where 300,000 to 500,000 people may be infected in western and central Africa (Fig. 28.2). The disease remains largely unchecked due to the sophisticated biological defense mechanisms adopted by the parasite, its tolerance to therapy, and the socioeconomic realities in a region where priorities may not include adequate surveillance and control (2).

Life Cycle and Morphology

Life Cycle. Trypanosomal forms are ingested by the tsetse fly (*Glossina* spp.) when a blood meal is taken (Fig. 28.3 and Fig. 28.4). Once the short, stumpy trypomastigote reaches the midgut of the tsetse fly, it transforms into a long, slender procyclic stage. The organisms multiply in the lumen of the midgut and hindgut of the fly. After approximately 2 weeks, the organisms migrate back to salivary glands through the hypopharynx and salivary ducts, where the organisms attach to the epithelial cells of the salivary ducts and then transform to their epimastigote forms. In the epimastigote forms, the nucleus is posterior to the kinetoplast, in contrast to the trypomastigote, in which the nucleus is anterior to the kinetoplast (Fig. 28.5). There is continued multiplication within the salivary gland, and metacyclic (infective) forms develop from the epimastigotes in 2 to 5 days. With development of the metacyclic forms, the tsetse fly becomes infective. During the act of feeding, the fly introduces the metacyclic trypanosomal forms into the next victim in saliva injected into the puncture wound. The entire developmental cycle in the fly takes about 3 weeks, and once infected, the tsetse fly remains infected for life.

Morphology. The trypanosomal (trypomastigote) forms can be found in the blood, cerebrospinal fluid (CSF), lymph

Figure 28.2 Distribution of trypanosomes in Africa. (Armed Forces Institute of Pathology map, modified from WHO Report Series 739, 1986; from reference 1.) doi:10.1128/9781555819002.ch28.f2

node aspirates, and fluid aspirated from the trypanosomal chancre (if one forms at the site of the tsetse fly bite). The trypomastigote forms multiply by longitudinal binary fission (Fig. 28.4). The organism is highly pleomorphic, having a variety of trypanosomal forms in the same blood smear. The forms range from long, slender-bodied organisms with a long flagellum (trypomastigote) that attain a length of 30 µm or more to short, fat, stumpy forms without a free flagellum that are approximately 15 µm long. The short, stumpy forms do not divide in the bloodstream but are the infective stage for the tsetse fly.

In blood, the trypanosomes move rapidly among the red blood cells (RBCs). An undulating membrane and flagellum may be seen with slower-moving organisms. The trypomastigote forms are 14 to 33 µm long and 1.5 to 3.5 µm wide (Fig. 28.6). With Giemsa or Wright's stain, the granular cytoplasm stains pale blue and contains dark blue granules and possibly vacuoles. The centrally located nucleus stains reddish. At the posterior end of the organism is the kinetoplast, which also stains reddish, and the remaining intracytoplasmic flagellum (axoneme), which may not be noticeable. The flagellum arises from the kinetoplast, as does the undulating membrane. The flagellum runs along the edge of the undulating membrane until the undulating membrane merges with the trypanosome body at the anterior end of the organism. At this point, the

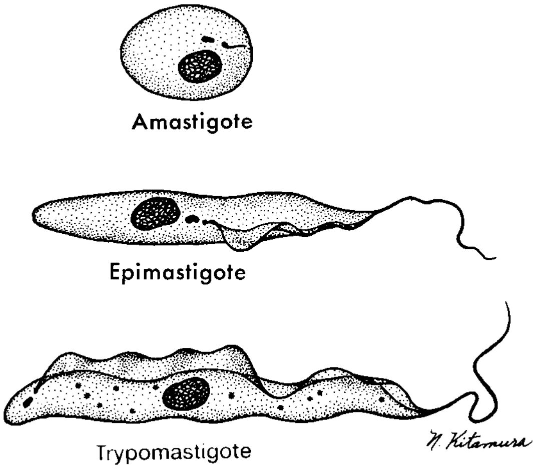

Figure 28.5 Life cycle stages of trypanosomes. Amastigotes have been confirmed in the life cycle of *Trypanosoma cruzi* as one of the stages in the human host, but this stage in humans in African trypanosomiasis is only suspected and not confirmed. (Illustration by Nobuko Kitamura.) doi:10.1128/9781555819002.ch28.f5

flagellum becomes free to extend beyond the body (Fig. 28.2). Although the trypomastigote is the diagnostic stage seen in clinical specimens, amastigotes have been seen in the choroid plexus in mice.

Antigenic Variation. A unique feature of African trypanosomes is their ability to change the surface coat of the outer membrane of the trypomastigote, helping to evade the host immune response. The trypomastigote surface is covered with a dense coat of approximately 10^7 molecules of the membrane-form variant surface glycoprotein (VSG). There are approximately 100 to 1,000 genes in the genome, responsible for encoding as many as 1,000 different VSGs. More than 100 serotypes have been detected in a single infection. It is postulated that the trypomastigote changes its coat about every 5 to 7 days (antigenic variation). This change is responsible for successive waves of parasitemia every 7 to 14 days and allows the parasite to evade the host humoral immune response (4). There is no evidence that the host immune system induces the VSG switches. During antigenic switching, VSG is both internalized by the trypomastigote and released or shed into the blood.

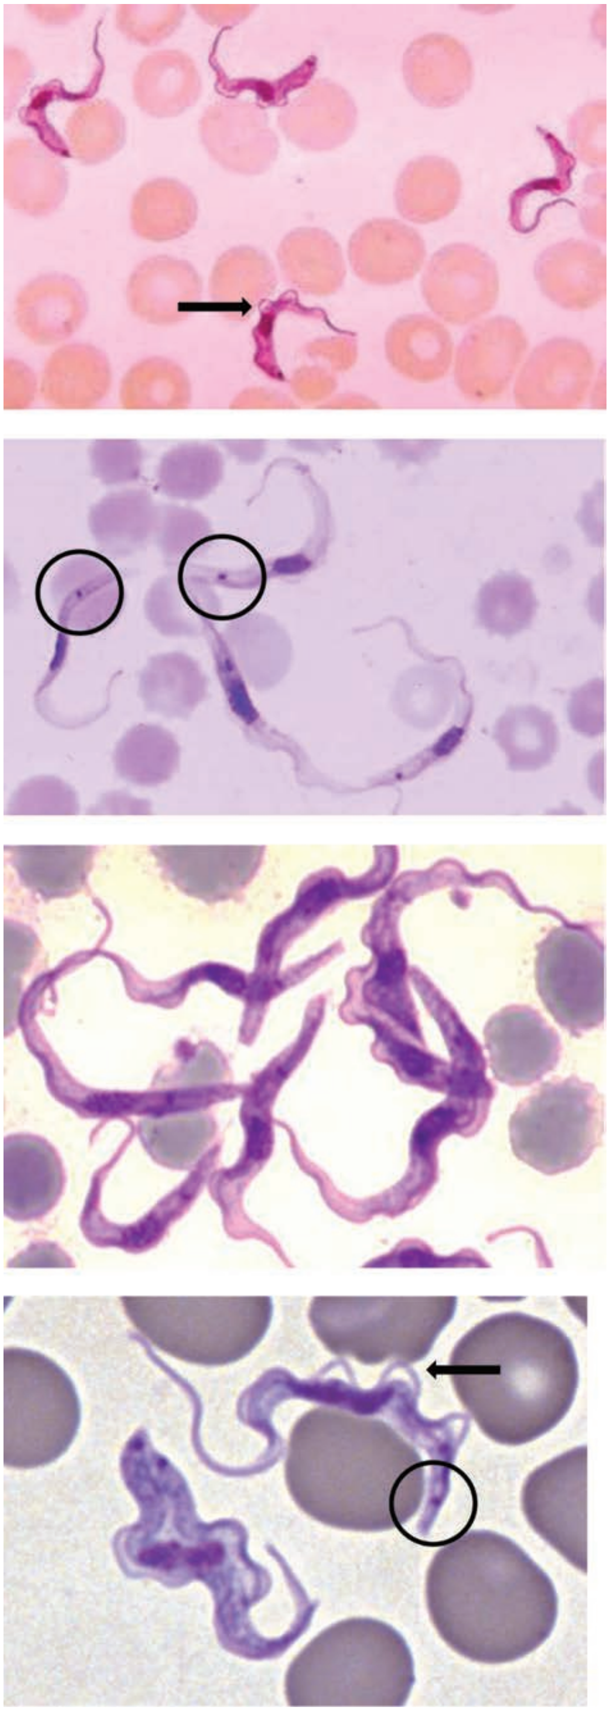

Figure 28.4 *Trypanosoma brucei gambiense* trypomastigotes in peripheral blood smears. Note the small kinetoplast (circle) and undulating membrane (arrows). Also, note in the second image, two of the trypomastigotes at the bottom appear to have just completed binary fission. Division can also be seen in the lower two images. (Bottom image courtesy of Armed Forces Institute of Pathology.) doi:10.1128/9781555819002.ch28.f4

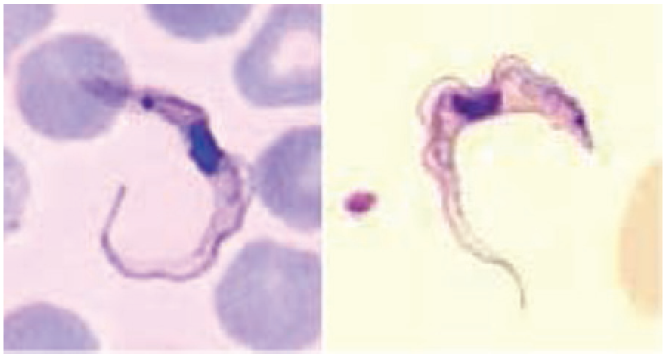

Figure 28.6 *Trypanosoma brucei gambiense* trypomastigotes in peripheral blood smears; note the undulating membrane.
doi:10.1128/9781555819002.ch28.f6

This shed VSG is most probably responsible for the immune dysfunctions noticed during infections. There is a release of gamma interferon (which stimulates parasite growth), suppression of interleukin-2, and hypergammaglobulinemia. Based on studies using *T. brucei*, bloodstream forms when aggregated in the presence of antibodies can subsequently disaggregate, and this mechanism may function to aid survival of the trypomastigotes in the presence of antibody in the host prior to the occurrence of a VSG switching event (5).

VSG is a 58-kDa glycophosphatidylinositol (GPI)-anchored glycoprotein, having predominantly an α-helical secondary structure, with highly variable sequences embedded at the N terminus and monoallelically expressed from a repertoire of hundreds of genes (4, 6). The disaggregation appears to be strictly energy dependent, and the organisms remain motile, metabolically active, and infective following this process.

Antigenic variation, however, is probably only one of several mechanisms enabling these parasites to thrive in spite of the host immune defenses. The ability to grow at high levels of gamma interferon, to avoid complement-mediated destruction, and to vary their susceptibility to a subclass of human high-density lipoproteins may also facilitate organism survival (7).

Genome. The genome of *T. brucei* has been defined with a complete analysis of the 11 megabase-sized chromosomes. The 26-Mb genome contains 9,068 predicted genes, including approximately 900 pseudogenes and approximately 1,700 *T. brucei*-specific genes. There are 806 VSG genes. Based on this research, a number of potential drug targets have been identified (8).

Clinical Disease

In general, African trypanosomiasis caused by *T. brucei gambiense* (West African sleeping sickness) has a long, mild, chronic course that ends fatally with central nervous system (CNS) involvement after several years' duration. This is unlike the disease caused by *T. brucei rhodesiense* (East African sleeping sickness), which has a short course and ends fatally within a year.

Stage I. After the host has been bitten by an infected tsetse fly, metacyclic trypomastigote stages are introduced into the skin, where they multiply and set up a local inflammatory reaction. A nodule or chancre at the site (3 to 4 cm) may develop after a few days (Fig. 28.7). However, this primary lesion will resolve spontaneously within 1 to 2 weeks. The chancre is seen frequently in white Europeans but rarely in patients indigenous to an area where the disease is endemic. Trypomastigotes may be detected in fluid aspirated from the ulcer. The trypomastigotes enter the bloodstream, causing a symptom-free low-grade parasitemia that may continue for months. This is considered stage I disease, where the patient can have systemic trypanosomiasis without CNS involvement. During this time, the parasites may be difficult to detect, even by thick blood film examinations. The infection may self-cure during this period without development of symptoms or lymph node invasion.

Symptoms may occur months to years after infection. The first distinct symptoms appear on invasion of the lymph nodes and are followed by the onset of remittent, irregular fevers with night sweats. Headaches, malaise, and anorexia frequently accompany the fevers. The febrile period of up to a week is followed by an afebrile period of variable duration and then another febrile period, and so on. Many trypomastigotes may be found in the circulating blood during fevers, but few are seen during afebrile periods. Lymphadenopathy is a consistent feature of Gambian trypanosomiasis. Enlarged lymph nodes are soft, painless, and nontender. Although any lymph node may be affected, posterior cervical regions are most frequently involved (Winterbottom's sign) (Fig. 28.7). Trypomastigotes can be aspirated from the enlarged lymph nodes. In addition to lymph node involvement, the spleen and liver become enlarged. With Gambian trypanosomiasis, the blood-lymphatic stage may last for years before the sleeping sickness syndrome occurs.

Transient edema is frequently seen and occurs in the face, hands, feet, and other periarticular areas. Pruritus is common, and in light-skinned individuals, an irregular erythematous rash, suggestive of erythema multiforme, can be seen. The rash occurs 6 to 8 weeks after the onset of infection and is typically located on the trunk, shoulders, buttocks, and thighs. It usually lasts only a few hours, and it appears and disappears during the febrile period. Patients may experience delayed sensation to pain (Kerandel's sign). Laboratory findings include anemia, granulocytopenia, reduction in platelet counts, increased sedimentation rate,

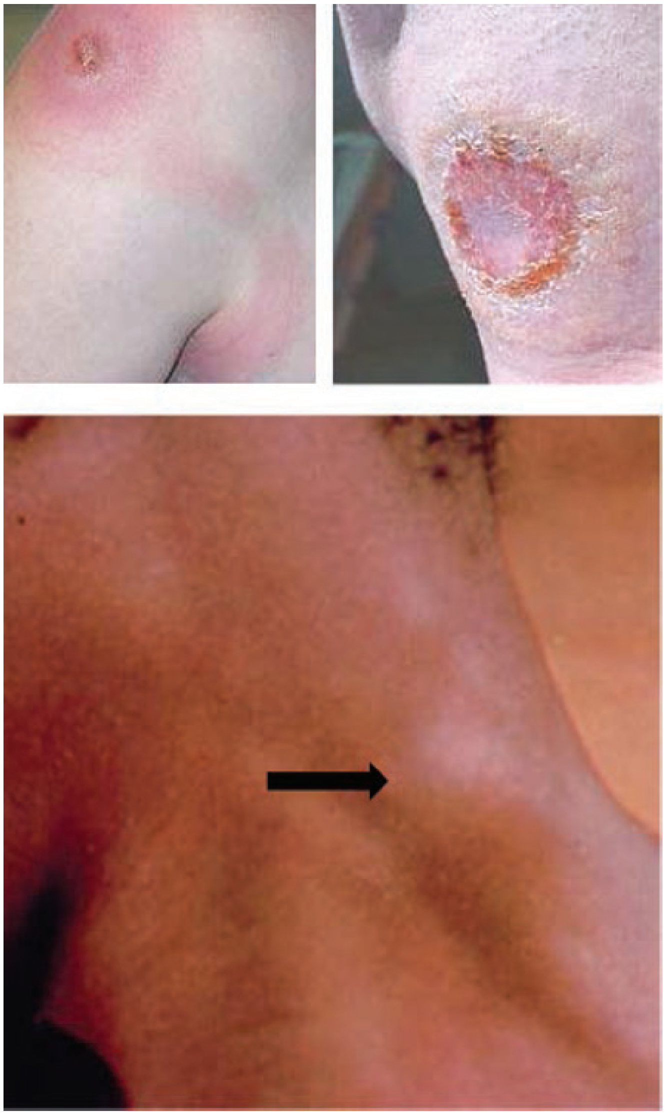

Figure 28.7 (Upper, left) Trypanosomal chancre on shoulder of patient, with lymphangitis toward axilla; (right) trypanosomal chancre on throat of patient (courtesy of CDC Public Health Image Library, Peter L. Chiodini, Hospital for Tropical Diseases, London). (Lower) Winterbottom's sign (enlarged cervical lymph nodes in the posterior cervical triangle; arrow) (Armed Forces Institute of Pathology photograph). doi:10.1128/9781555819002.ch28.f7

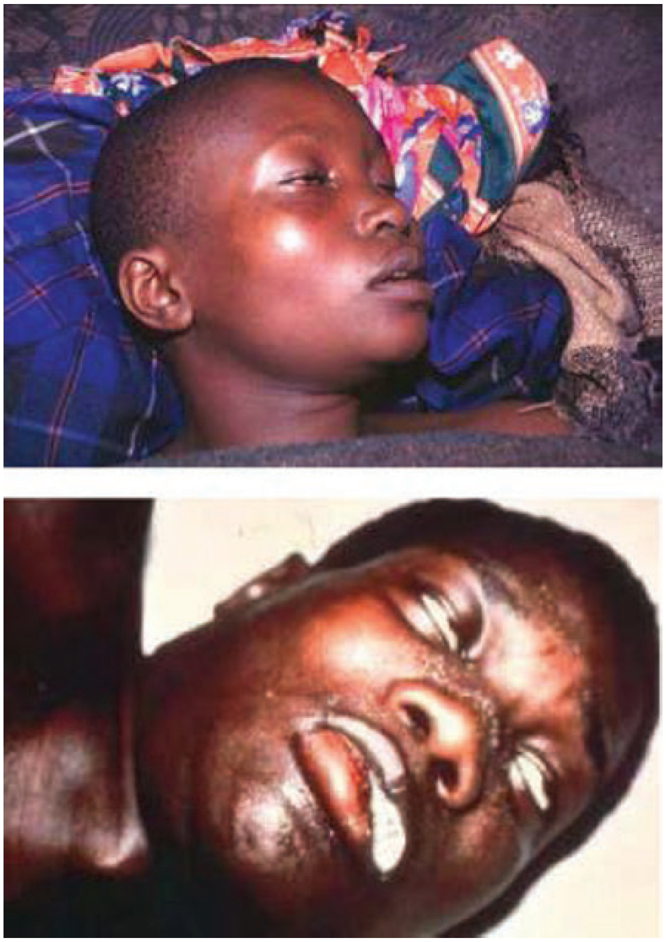
polyclonal B-cell activation with a marked increase in the levels of IgM, heterophile and anti-DNA antibodies, rheumatoid factor, and circulating immune complex in serum. The sustained high IgM levels are a result of the parasite producing variable antigen types which allow the organism to evade the patient's defense system. *In an immunocompetent host, the absence of elevated IgM levels in serum rules out trypanosomiasis.*

Stage II. Once trypomastigotes invade the CNS, the sleeping sickness stage of the infection is initiated (stage II disease). The trypomastigotes are found primarily in the frontal lobes, pons, and medulla. Behavioral and personality changes are seen during CNS invasion. Gambian trypanosomiasis is characterized by steady progressive meningoencephalitis, apathy, confusion, fatigue, coordination loss, and somnolence (Fig. 28.8). In the terminal phase of the disease, the patient becomes emaciated and progresses to profound coma and death, usually from secondary infection. Although this disease has always been considered as invariably fatal, it is now well documented that this outcome may not necessarily be the case. Information is found in a long-term follow-up (15 years) of a cohort of 50 human African trypanosomiasis patients from the Ivory Coast among whom 11 refused treatment after their initial diagnosis (9). In 10 out of 11 subjects who continued to refuse treatment despite repeated visits, parasite clearance was observed using both microscopy and PCR. Most of

Figure 28.8 Comatose patients with African sleeping sickness (courtesy of WHO). doi:10.1128/9781555819002.ch28.f8



these subjects (7/10) also displayed decreasing serological responses, becoming progressively negative to trypanosome variable antigens.

Immunosuppression in patients with Gambian trypanosomiasis is manifested by decreases in both cellular and humoral immunity. Apparently, increased prostaglandin D2 may in part account for the increased somnolence and the immunosuppression within the CNS. Measurement of these levels may provide confirmation for CNS involvement (10).

With invasion of the CNS (Fig. 28.9), there is a progressive leptomeningitis, and CSF findings include increased protein levels, elevated IgM levels, lymphocytosis, and morular cells of Mott (Fig. 28.10). Morular (mulberry) cells are altered plasma cells whose cytoplasm is filled with proteinaceous droplets. Morular cells are not seen in all patients; however, they are characteristic of African trypanosomiasis. The spherules of morular cells are not metachromatic with toluidine blue at pH 8, and most spherules stain yellow with phosphotungstic acid-hematoxylin stain. This distinguishes them from globule leukocytes. They differ from Russell bodies of plasma cells, which are Gram positive. Russell bodies are eosinophilic, large, homogeneous immunoglobulin-containing inclusions usually found in a plasma cell undergoing excessive synthesis of immunoglobulin.

In humans with African trypanosomiasis, autoantibodies have been found, including autoantibodies directed to RBCs, smooth muscle, liver and cardiolipid nucleic acids (DNA and RNA), and intermediate filaments of the cytoskeleton in smooth muscle cells. Autoantibodies to components of CNS myelin have also been found, as have those to neurofilament proteins in sera and CSF from untreated patients with stage II disease and CNS involvement (11). The CSF antibodies to neurofilament proteins were IgM in 22 of 25 patients and IgG in 8 of 25.

doi:10.1128/9781555819002.ch28.f10

Diagnosis

Physical findings and clinical history are very important in establishing the diagnosis. Diagnostic symptoms include irregular fever, enlargement of the lymph nodes (particularly those of the posterior triangle of the neck [Winterbottom's sign]), delayed sensation to pain (Kerandel's sign), and erythematous skin rashes. However, diagnosing imported human African trypanosomiasis outside areas of endemicity is difficult and diagnosis is often delayed. A recent case was reported with *T. gambiense* with an unusually long incubation period of at least 7 years (12). Definitive diagnosis depends on demonstration of trypomastigotes in blood, lymph node aspirates, sternum bone marrow, and CSF. Due to the greater frequency of high parasitemia, there is a better chance of detecting organisms in body fluids in infections caused by *T. brucei rhodesiense* than in those caused by *T. brucei gambiense*. Because of periodicity, parasite numbers in the blood may vary; therefore, multiple specimens should be collected and a number of techniques should be used to detect the trypomastigotes (Fig. 28.4 and 28.6; Tables 28.2 and 28.3). Health care personnel must adhere to standard precautions when handling specimens from patients with suspected cases of African trypanosomiasis because the trypomastigotes are highly infectious.

Chancre Aspirate. Organisms can be obtained from the chancre by using puncture techniques; the fluid is then examined as wet mounts and stained smears using any of the blood stains. This approach is seldom used; patients are generally not seen until after the chancre has already healed.

Lymph Node Aspirate. When enlarged cervical lymph nodes are seen, they can be punctured and the aspirate can be examined as a wet preparation for the presence of motile trypomastigotes. The aspirated material can also be stained using Giemsa or other blood stains. Depending on a number of factors, the sensitivity ranges from about 40 to 80% (2).

Blood. Blood can be collected from either finger stick or venipuncture. Venous blood should be collected in a tube containing EDTA (fill the tube to obtain correct anticoagulant/blood ratio). Multiple slides should be made for examination, and multiple blood examinations should be done before trypanosomiasis is ruled out. Parasites are found in large numbers in the blood during the febrile period and in small numbers when the patient is afebrile. In addition to thin and thick blood films, a buffy coat concentration method is recommended to detect the parasites. Parasites can be detected on thin blood films with a detection limit at approximately 1 parasite/200 microscopic fields (high dry power magnification, ×400); they can be detected on thick blood smears when the numbers are greater than 2,000/ml and when they are greater than 100/ml with hematocrit capillary tube concentration.

TABLE 28.2 Characteristics of East and West African trypanosomiasis

Characteristic	East African	West African
Organism	*Trypanosoma brucei rhodesiense*	*Trypanosoma brucei gambiense*
Vector	Tsetse fly, *Glossina morsitans* group	Tsetse fly, *Glossina palpalis* group
Primary reservoirs	Animals (wild and domestic)	Humans
Illness	Acute (early CNS invasion), <9 mo	Chronic (late CNS invasion), months to years
Lymphadenopathy	Minimal	Prominent
Parasitemia	High	Low
Epidemiology	Anthropozoonosis, game parks	Anthroponosis, rural populations
Diagnostic stage	Trypomastigote	Trypomastigote
Recommended specimens	Chancre aspirate, lymph node aspirate, blood, CSF	Chancre aspirate, lymph node aspirate, blood, CSF
Areas of high endemicity[a]	Western Africa	Western Africa
	None	Côte d'Ivoire
		Guinea
	Northeastern Africa	Northeastern Africa
	Ethiopia (endemicity unknown)	Chad
		Sudan (epidemics)
	Central Africa	Central Africa
	Democratic Republic of the Congo (epidemics)	Democratic Republic of the Congo (epidemics)
	United Republic of Tanzania	United Republic of Tanzania
	Uganda	Rwanda (endemicity unknown)
	Rwanda (endemicity unknown)	Cameroon
		Central African Republic
		Congo
	Southern Africa	Southern Africa
	Angola (epidemics)	Angola (epidemics)
	Namibia (unknown)	Namibia (unknown)
	Mozambique	

[a] Other African countries are also involved, but with low levels of endemicity. For a more complete list, see reference 3.

TABLE 28.3 Methods available for the diagnosis of African trypanosomiasis (*T. brucei gambiense*)

Method	Description	Comments
Chancre aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable).	Not commonly used; patients are often seen after the chancre has already healed.
Lymph node aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable).	Sensitivity varies between 40 and 80%; yield is very low with seronegative patients. Not recommended unless clinical signs are present.
Blood	Both wet films and stained thick and thin blood films can be examined.	Organism motility among red blood cells enhances detection; sensitivity about 1 organism per 200 microscopic fields (~10,000 trypomastigotes/ml) (using high dry objective). Stained thick blood film improves sensitivity with detection threshold of ~5,000 trypomastigotes/ml. Organism morphology better on thin blood film. Giemsa or other blood stains are acceptable.
Microhematocrit centrifugation	Centrifugation of capillary tubes containing anticoagulant filled with finger stick blood (end of tube sealed with plastic clay); tube examined under microscope, and organisms are concentrated at buffy coat layer	
Microhematocrit centrifugation (QBC)	High-speed centrifugation of blood in capillary tubes containing acridine orange; motile organisms identified by fluorescent nuclei and kinetoplasts in the buffy coat layer	The technique is used sporadically within the United States (cost is a factor).
Mini-anion-exchange centrifugation	Separation of trypomastigotes from venous blood using anion-exchange chromatography; subsequent concentration at tip of glass tube	Sensitivity of <100 organisms/ml; procedure is very time-consuming. The columns are produced in Belgium. Method validation is under way.
Cerebrospinal fluid	White blood cell count used to determine disease stage; cell-counting chambers should have a capacity of 1 µl (Fuchs-Rosenthal and Neubauer chambers); do not dilute CSF	Patients (trypomastigotes in lymph node or blood) with >20 cells/µl of CSF are treated as having second-stage disease; therapeutic approach depends on the geographic areas and drug selection. Trypomastigotes in CSF are confirmatory for second-stage disease; sensitivity is increased by centrifugation.
Antigen detection	A simple and rapid test, the card indirect agglutination trypanosomiasis test (TrypTect CIATT), is available, primarily in areas of endemic infection; an ELISA method has been used to detect antigen in serum and CSF.	Good sensitivity but possible specificity issues with CIATT; ELISA antigen is rapidly cleared after therapy.
Antibody detection	CATT fast/simple agglutination assay for *T. brucei gambiense*-specific antibodies; latex agglutination is another option; immunofluorescence excellent (sensitivity and specificity), but lower with filter paper eluates; ELISA available for serum, filter paper eluates, and CSF	Sensitivity reported on whole blood (87–98%); negative predictive value is excellent for mass screening. Both false positives and false negatives have been reported. Can be performed with blood-impregnated filter paper. Latex agglutination shows higher specificity but lower sensitivity than fluorescence. Latex is also more specific than CATT on diluted specimens.
Molecular methods	A number of methods have been reported; however, cost and technical issues have prevented their use in the routine clinical laboratory.	Some methods appear to be very sensitive; simplification of the method may lead to methods adaptable to routine clinical laboratory use. There have been a number of recently developed tests for molecular diagnosis of sleeping sickness (30).

Microhematocrit Centrifugation. The original microhematocrit centrifugation technique uses capillary tubes containing anticoagulant, filled with finger stick blood. The bottom of the tube is sealed with plasticine, and the tube is centrifuged in a hematocrit centrifuge for about 8 min. The trypomastigotes are concentrated at the buffy coat layer. The tubes are then placed in a special holder and examined through the glass at low magnification for motile organisms (13).

Microhematocrit centrifugation with use of the QBC malaria tube (glass capillary tube and closely fitting plastic insert; CBC malaria blood tubes [QBC Diagnostics, Inc., Port Matilda, PA]) has been used for the detection of blood parasites. At the end of centrifugation of 50 to 60 µl of capillary or venous blood (5 min in a QBC centrifuge; 14,387 × *g*), parasites or erythrocytes containing parasites are concentrated into a small, 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain which induces fluorescence in the parasites. This method automatically prepares a concentrated smear, which represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Paraviewer) and immersion oil is applied onto the top of the hematocrit tube (no coverslip is necessary), the tube is examined with a 40× to 60× oil immersion objective (there must be a working distance of 0.3 mm or greater) (refer to chapter 7).

The range of sensitivity for the QBC test has been as low as 55% up to >90% compared with microscopy. While most think the method is rapid, some think there are some disadvantages such as (i) the high cost of capillary tubes and equipment, (ii) problems in species identification and quantification, and (iii) technical problems, broken capillaries, and the fact that the capillaries cannot be stored for later reference. This may not be the most appropriate approach for a laboratory that receives a small number of specimens for blood parasite testing, but it could be helpful in other settings.

Mini-Anion-Exchange Centrifugation. The mini-anion-exchange method allows the separation of trypomastigotes from venous blood by anion-exchange chromatography, with subsequent low-speed centrifugation into the tip of the glass tube. The tube is then examined under the microscope with a sensitivity of <100 organisms/ml. To increase the sensitivity of this test, 350 µl of buffy coat withdrawn from 5 ml of blood is used instead of blood (14).

Cerebrospinal Fluid. If CSF is examined, a volume greater than 1 ml, preferably 5 ml or more, should be collected. CSF examination must be conducted with centrifuged sediments. The presence of Mott cells in the CSF is pathognomonic for trypanosomiasis (Fig. 28.10). Mott cells are rarely observed when there are few white blood cells in the CSF. When trypomastigotes are present in undetectable numbers in the blood, they may be seen in aspirates of inflamed lymph nodes; however, attempts to demonstrate them histopathologically are not practical. Blood and CSF specimens should be examined during therapy to evaluate the response and again 1 to 2 months after therapy. Patients treated for CNS disease should be monitored clinically for 2 to 3 years after completion of therapy to detect a relapse.

Antigen Detection. An enzyme-linked immunosorbent assay (ELISA) method has been used to detect antigen in serum and CSF (15). It was noted that antigen was rapidly cleared from the circulation following successful therapy. This method could also be used for clinical staging of disease to determine whether there was CNS infection and for follow-up to therapy.

A simple and rapid test, the card indirect agglutination trypanosomiasis test (TrypTect CIATT), is available, primarily in areas of endemic infection, for the detection of circulating antigens in persons with African trypanosomiasis. The test is normally performed on a drop of freshly collected heparinized blood and is followed by a more specific confirmation test on diluted blood, plasma, or serum. The sensitivity of the test (95.8% for *T. brucei gambiense* and 97.7% for *T. brucei rhodesiense*) is significantly higher than that of lymph node puncture, microhematocrit centrifugation, and CSF examination after single and double centrifugation (16). Its specificity is excellent, and it has a high positive predictive value. A complement-mediated prozone phenomenon may occur, causing lower test sensitivity at lower sample dilutions. A simple solution is the addition of a Ca^{2+} chelating agent such as EDTA to the diluted blood, plasma, or serum (17).

Using a panel of 80 randomized *T. brucei gambiense* infection and control sera, a lateral flow diagnostic device prototype showed reasonable sensitivity (88%) and specificity (93%) using visual readout in detecting *T. brucei gambiense* infections (18).

Antibody Detection. The card agglutination test for trypanosomiasis (CATT/*T. brucei gambiense*) is more sensitive than methods that require visualization of the trypomastigotes with clinical specimens and can be performed with blood, plasma, or serum. The test is produced by the Institute of Tropical Medicine in Antwerp, Belgium, and is widely used for mass population screening. This approach can also be used with blood-impregnated filter paper. It has been recommended that treatment with pentamidine should be considered for all serologically suspected individuals with a CATT-plasma end dilution titer of ≥1:16 in areas of moderate to high disease prevalence (19).

A semiquantitative ELISA, using VSG of *T. brucei gambiense* as the antigen, has been developed for the detection of antibodies of different immunoglobulin isotypes in serum and CSF of patients with sleeping sickness. In serum and CSF, a drastic increase in the level of IgG (basically IgG1) as well as in the IgM level was seen; an increase in the IgG3 level was also seen, while the IgA level remained relatively normal. Measurement of immunoglobulin and trypanosome-specific antibody concentrations in serum and CSF allows calculation of intrathecal antibody synthesis and may be a possible tool for the determination of clinical stages of sleeping sickness (20). Both latex agglutination and immunofluorescence tests are also available; however, sensitivity results have not been as good with the latex approach as with fluorescence. Specificity with the latex test appears to be better than the CATT with diluted blood; use of the latex test also decreased the workload and costs (21, 22).

Using ELISA, anti-trypanosome-derived lymphocyte triggering factor (TLTF) antibodies were detected in the serum of all African trypanosomiasis patients, the antibody levels being independent of clinical stage of the disease. This indicates that TLTF is released by *T. brucei gambiense* bloodstream forms early on in the infection in sufficient amounts to induce a humoral immune response. In the CSF samples, antibodies were only detectable in patients with evidence of trypanosome invasion of the CNS, suggesting TLTF release by intrathecally resident parasites and subsequent intrathecal antibody production (23).

Serologic techniques which have been widely used for epidemiologic screening include indirect fluorescent-antibody assays, ELISA, the indirect hemagglutination test, and the card agglutination trypanosomiasis test (see above). A major serodiagnostic problem in areas where the disease is endemic is that many in the population have elevated antibody levels due to exposure to animal trypanosomes that are noninfectious to humans. Serum and CSF IgM concentrations are of diagnostic value. CSF antibody titers should be interpreted with caution because of the lack of reference values and the possibility that the CSF contains serum as the result of a traumatic tap.

Molecular Methods. Accurate identification of trypanosome species is necessary in order to clarify the epidemiology of human and animal African trypanosomiasis, but this has proved difficult. Great progress has been made through the application of DNA probe technology, although this has also revealed greater complexity than was previously supposed (24). *T. brucei* organisms have been detected in human blood by using a nonradioactive branched-DNA-based method. Buffy coat specimens are used, and the results agree with those obtained using buffy coat microscopy. The assay can be performed with crude lysates without the need for extensive sample preparation. Also, because it amplifies the signal from a target molecule rather than the target itself, this technique is not prone to the artifact problems that can be seen with PCR-based tests (25). The development of a peptide nucleic acid fluorescence *in situ* hybridization probe appears to offer an excellent diagnostic tool. By combining this test with a cytospin step, the limit of detection from blood can be improved to 5 parasites/ml, a level of sensitivity that equals an optimal PCR detection limit with blood specimens (26). A newer PCR technique targets the gene encoding the small ribosomal subunit in order to identify and differentiate all clinically important African trypanosome species and some subspecies. This method appears to be more economical, simple, and sensitive than some other screening methods, and it yields more detailed information (27). Other real-time PCR options appear to be suitable for use within the routine clinical laboratory (28). The loop-mediated isothermal amplification (LAMP) reaction is a method that amplifies DNA with high specificity, efficiency, and rapidity under isothermal conditions with only simple incubators. An added advantage of LAMP over PCR-based methods is that DNA amplification can be monitored spectrophotometrically and/or with the naked eye without the use of dyes (29, 30).

Animal Inoculation and Culture. *T. brucei gambiense* isolation in small laboratory animals is usually unsuccessful; in contrast, *T. brucei rhodesiense* readily infects animals. Cultivation is not practical for most diagnostic laboratories but is more successful than animal inoculation.

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma brucei gambiense

1. Trypomastigotes are highly infectious, and health care workers must use blood-borne-pathogen precautions.
2. Trypomastigotes may be detected in aspirates of the chancre and enlarged lymph nodes in addition to blood and CSF.
3. Concentration techniques, such as centrifugation of CSF and blood, should be used in addition to thin and thick smears (Giemsa, Wright's, or other blood stains).
4. Trypomastigotes are present in largest numbers in the blood during febrile periods.
5. Examinations of multiple daily blood samples may be necessary to detect the parasite.
6. Blood and CSF specimens should be examined during therapy and again 1 to 2 months posttherapy.

Treatment

All drugs currently used in the therapy of African trypanosomiasis are toxic and require prolonged administration. Treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. The choice of antiparasitic drug depends on whether the CNS is infected. Suramin or pentamidine isethionate can be used when the CNS is not infected. Pentamidine is currently the drug of choice for the hemolymphatic stage, with suramin being an alternative; it appears that in early CNS involvement, the results of pentamidine (94% cure rate in a group of 52 patients observed for 2 years) are comparable to those obtained with melarsoprol or eflornithine in terms of tolerance and availability (31, 32). Pentamidine isethionate does not cross the blood-brain barrier and is administered intramuscularly; side effects include an immediate hypotensive reaction, nausea, vomiting, and Herxheimer-type (inflammatory) reactions. Suramin (Bayer 205), a diamidine, is effective in treating the hemolymphatic stage and CNS disease of *T. brucei gambiense*. When suramin is used, a test dose should be given to the patient to ensure that the drug can be tolerated. It should not be given to patients with renal disease, and if protein, RBCs, or casts are detected in the urine, treatment should be stopped. Suramin is given intravenously; its side effects include nausea, vomiting, loss of consciousness, seizures, pruritus, edema, and hepatitis. Although rare, fatalities have been reported during suramin therapy. Suramin can be obtained under an Investigational New Drug (IND) protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA, 30333; 404-639-3670 (evenings, weekends, or holidays: 404-639-2888) (32).

Melarsoprol, a toxic trivalent arsenic derivative, is effective for both hemolymphatic and neural stages but is recommended for treatment of late-stage sleeping sickness. It is administered intravenously, and its side effects include nausea, vomiting, encephalopathy, and exfoliative dermatitis. Melarsoprol has been used for CNS involvement for years; however, relapse occurs in up to 6% of patients. Arsenic-related encephalopathy occurs in 10% of patients, and prednisolone treatment may help reduce the incidence. The mortality due to this side effect depends on whether supportive treatment is given, but it is often above 50% (33). Resistance of both *T. brucei gambiense* and *T. brucei rhodesiense* to melarsoprol has been noted.

Eflornithine (DL-α-difluoromethylornithine; DFMO) has been used for more than 10 years to treat melarsoprol-resistant *T. brucei gambiense* infection with or without CNS involvement; treatment is started intravenously and is followed by oral therapy. In one study, 47 patients with a relapse following a first treatment were treated with a 7-day course of intravenous eflornithine (100 mg/kg every 6 h) and monitored for 2 years; the failure rate was 6.5% (34). This approach appears to provide adequate treatment in cases of Gambian trypanosomiasis relapsing after treatment with another drug. Disadvantages of eflornithine therapy include the prolonged course of treatment and frequent side effects of diarrhea and anemia. With adequate treatment, non-CNS disease has a cure rate of >80%. All treated patients should be followed up twice yearly for at least 2 to 3 years. Specific drug dosage information is provided in chapter 36; however, apparently eflornithine is no longer commercially available but is available in limited supply from the World Health Organization (32).

Nifurtimox (Lampit), a nitrofuran, has been used to treat patients infected with *T. brucei gambiense* who do not respond to melarsoprol. The relapse rate is quite high when nifurtimox is used alone, but the drug is quite effective when used in combination with eflornithine (35). It is given orally. Side effects include confusion, tremor, vertigo, anorexia, and weight loss. This drug is not recommended for the treatment of *T. brucei rhodesiense* infections. Nifurtimox can be obtained under an IND protocol from the CDC Drug Service (32).

Epidemiology and Prevention

T. brucei gambiense is transmitted from person to person by the bite of the tsetse fly (*G. palpalis* and *G. tachinoides*) after infectivity develops within the insect. The development cycle in the fly, depending on temperature and moisture, varies from 12 to 30 days and averages 20 days. Fewer than 10% of tsetse flies become infective after obtaining blood from infected patients, and vertical transmission from infected fly to offspring is not known to occur. *G. palpalis* and *G. tachinoides* can be found in areas of thick shrubbery and trees near the banks of rivers, streams, or water holes; therefore, transmission readily occurs when people frequent these areas. Both female and male tsetse flies can transmit the infection. In addition to biological transmission, the tsetse fly may mechanically transmit the infection with its proboscis if it bites an uninfected person within a few hours of biting an infected person. Congenital transmission in humans has also been documented.

Although *T. brucei gambiense* can be transmitted to animals, no animal reservoirs for West African sleeping sickness have been documented. Trypanosomal strains isolated from hartebeest, kob, chickens, dogs, cows, and domestic pigs in West Africa are identical to those isolated from humans in the same area. These findings suggest that animals may serve as reservoirs; however, there is no indication that these animal trypanosomal forms are directly transmitted to humans and that a patent infection will develop. Epidemiologic evidence suggests that in areas of endemic infection, transmission may be entirely from human to human. Asymptomatic individuals are thought to be the residual reservoir of the disease.

In areas where West African sleeping sickness is endemic, *T. brucei gambiense* has been controlled by eliminating the parasite through regular population-screening programs. This approach effectively reduces the prevalence of the disease to low levels; however, with interruptions in surveillance, resurgence of the disease will occur. An example of resurgence of West African trypanosomiasis was well documented in southern Sudan, where the disease prevalence found was among the highest ever documented.

Although game parks in Tanzania (Tarangire and Serengeti National Parks) were thought to be low-risk areas for African trypanosomiasis, during 2001 nine patients from these areas were diagnosed with *T. brucei gambiense* infection. All of the South African patients but one were European nationals. During their trip or shortly after their return, the patients, all febrile, were seen by general practitioners or emergency departments. Most patients were seen during the primary disease stage; however, several showed cerebral manifestations of the secondary stage. Most patients also showed a typical skin lesion, the trypanosome chancre. Diagnosis was established by examining thin and thick blood films. Although three patients had multiorgan failure, and specific medication was difficult to obtain, drug treatment proved successful in all but one patient, who died (36).

At present, there are no areas where *T. brucei gambiense* and *T. brucei rhodesiense* are endemic together. Although foci of both organisms exist in Uganda, they appear to be geographically separate. Based on evidence of the spread of cattle carrying *T. brucei rhodesiense* further north, a merger of the two foci could create tremendous problems since the diagnosis and treatment of the two diseases differ significantly (37).

Vector control measures have met with limited success. Methods have included clearing streams of underbrush, eliminating breeding grounds, using insecticides, using fly traps, and releasing sterile male flies. Because tsetse flies have a low reproductive rate and have not developed insecticide resistance, they are very tempting control targets. The most effective control measures include an integrated approach to reduce the human reservoir of infection and to use insecticides and fly traps.

In regions where the disease is endemic, natives appear to be more resistant to infection than are new arrivals to the area, even though there is no evidence of acquired immunity. West African sleeping sickness affects primarily the rural populations, and tourists are rarely infected. Chemoprophylaxis is not recommended because of drug toxicity, and vaccines are unavailable. It may be possible to develop a vaccine, because immunity to reinfection occurs with *T. brucei gambiense*. However, some believe that the almost unlimited capacity for antigenic variation of surface glycoproteins by the African trypanosomes may be the major hurdle for producing a vaccine (7). Others feel there may be additional factors required to induce Th1 memory cells specific for common antigens that enhance innate resistance.

Tourists are usually not at great risk unless they are traveling and spending long periods in rural areas of western and central Africa. Persons visiting areas where the disease is endemic should avoid tsetse fly bites by wearing protective clothing (long-sleeved shirts and long pants); khaki or olive-colored clothing is optimal, since the tsetse fly is attracted to bright colors and very dark colors. Because heavy clothing is not always practical owing to heat and humidity, other measures, including the use of insect repellents, bed netting, and screens, are recommended. It has also been recommended not to ride in the back of jeeps, pickup trucks, or other open vehicles; the tsetse fly is attracted to the dust created by moving vehicles and wild animals. Bushes should be avoided, since the tsetse fly is less active during the hot period of the day and rests in bushes but will bite if disturbed.

Trypanosoma brucei rhodesiense

T. brucei rhodesiense is closely related to *T. brucei gambiense*, and the two subspecies are morphologically indistinguishable. Stephans and Fantham in 1910 discovered *T. brucei rhodesiense* in the blood of a patient in Rhodesia with symptoms consistent with "sleeping sickness." In 1912, this organism was shown to be transmitted by a different species of tsetse fly (*Glossina morsitans*) from that associated with *T. brucei gambiense* (*G. palpalis*). *T. brucei rhodesiense* was also differentiated from *T. brucei gambiense* on the basis of virulence in rats and detection of a morphologic variant not previously found in *T. brucei gambiense*. Many investigators think that *T. brucei rhodesiense* is the human strain of *T. brucei*, a common trypanosome that is found in many game animals and causes a fatal disease known as nagana in cattle. In 1961, Ormerod indicated that the original strains of *T. brucei rhodesiense* probably arose in the Zambesi basins as mutants from *T. brucei* (38). In the early 1900s, human volunteer inoculation studies with *T. brucei* resulted in no human infections. Currently, it is accepted that there are two subspecies within the *T. brucei* species, and they have been designated *T. brucei gambiense* and *T. brucei rhodesiense*. *T. brucei rhodesiense* (which causes Rhodesian trypanosomiasis or East African sleeping sickness) is more limited in distribution than *T. brucei gambiense*, being found only in central East Africa, where the disease has been responsible for some of the most serious obstacles to economic and social development in Africa. Within this area, the vast majority of tsetse flies prefer animal blood, which therefore limits the raising of livestock. The infection has a greater morbidity and mortality than does *T. brucei gambiense* infection, and game animals, such as the bushbuck, and cattle are natural reservoir hosts. Biochemical evidence shows that the human-infective *T. brucei rhodesiense* differs from the human-infective *T. brucei brucei* because of its resistance to lysis by components in human serum. This resistance can be acquired by sensitive strains and is caused by the decreased internalization of a trypanolytic factor. Thus, *T. brucei rhodesiense* appears to be a host range variant of *T. brucei brucei* (2). While human- and nonhuman-infective strains are genetically closely related, very little gene flow appears to be occurring between these two host range variants in natural populations. Restricted gene flow could be due to a lack of genetic exchange caused by lack of opportunity or some type of biological barrier. Evidence also suggests that genetic exchange can occur in the tsetse fly; however, large-scale studies of *T. brucei* genotypes in tsetse flies are difficult, especially since only 0.1% of the flies are usually infected (2).

Life Cycle and Morphology

The life cycle and reproduction of *T. brucei rhodesiense* are similar to those of *T. brucei gambiense* (Fig. 28.4). The tsetse fly vectors for transmission of *T. brucei rhodesiense* are *G. pallidipes*, *G. morsitans*, and *Glossina tachinoides*. The morphology of *T. brucei rhodesiense* in tsetse flies and humans is similar to that of *T. brucei gambiense*, except that when the parasite is inoculated into laboratory animals, the posterior nucleate forms are more common.

Clinical Disease

T. brucei rhodesiense produces a more rapid, fulminating disease than does *T. brucei gambiense*. Fever, severe headaches, irritability, extreme fatigue, swollen lymph nodes, and aching muscles and joints are common symptoms. Progressive confusion, personality changes, slurred speech, seizures, and difficulty in walking and talking occur as the organisms invade the CNS. The early stages of the pathologic process parallel those of *T. brucei gambiense* infections; however, the disease progresses more rapidly, such that death may occur before there is extensive CNS involvement even though CNS invasion occurs early. The incubation period is short, often within 1 to 4 weeks, with trypomastigotes being more numerous and appearing earlier in the blood. Lymph node involvement is less pronounced, and Winterbottom's sign may be absent. Febrile paroxysms are more frequent, and the patients are more anemic and more likely to develop myocarditis or jaundice. Some patients may develop persistent tachycardia, and death may result from arrhythmia and congestive heart failure due to pancarditis. Myocarditis may develop in patients with Gambian trypanosomiasis but is more common and severe with the Rhodesian form. Review of a splenectomized patient with Rhodesian trypanosomiasis and CNS involvement revealed that the onset of symptoms, laboratory studies, and disease progression did not differ from those for reported cases in healthy individuals (39). However, the role of the spleen in trypanosomiasis is not well understood.

Diagnosis

The techniques used are similar to those for detecting Gambian trypanosomiasis; however, trypomastigotes are more numerous in the blood in the Rhodesian form (Table 28.2). A differential diagnosis may be possible on geographic grounds, but there are areas where the two forms overlap. Because infection with *T. brucei rhodesiense* is so fulminant, the immune response with humoral antibody will be weaker than that for *T. brucei gambiense* infections; therefore, serodiagnosis may be difficult. Blood and CSF specimens should be examined during and 1 to 2 months after therapy. Unfortunately, the lack of progress in diagnostic methods is often related to the many obstacles encountered in the modification of basic research to field-applicable diagnostics.

T. brucei rhodesiense is more adaptable to cultivation than is *T. brucei gambiense*. A number of media have been described; however, cultivation is not a practical diagnostic approach. See Algorithm 28.1, Table 28.4, and the "Key Points—Laboratory Diagnosis" presented below.

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma brucei rhodesiense

1. Trypomastigotes are highly infectious, and health care workers must use blood-borne-pathogen precautions.
2. Trypomastigotes may be detected in aspirates of the chancre and enlarged lymph nodes in addition to blood and CSF; trypomastigotes tend to be more numerous in the blood in Rhodesian trypanosomiasis, and diagnosis is normally confirmed from blood examination.
3. Concentration techniques, such as centrifugation of CSF and blood, should be used in addition to thin and thick smears (Giemsa, Wright's, or other blood stains). However, concentration methods may not be required, since organisms tend to be numerous in the blood.
4. Trypomastigotes are present in the blood in largest numbers during febrile periods.
5. Examinations of multiple daily blood samples may be necessary to detect the parasite.
6. Blood and CSF specimens should be examined during therapy and 1 to 2 months posttherapy.
7. Culture is possible using well-described media but is probably not practical for most diagnostic laboratories; again, the use of blood-borne-pathogen precautions is mandatory.

Treatment

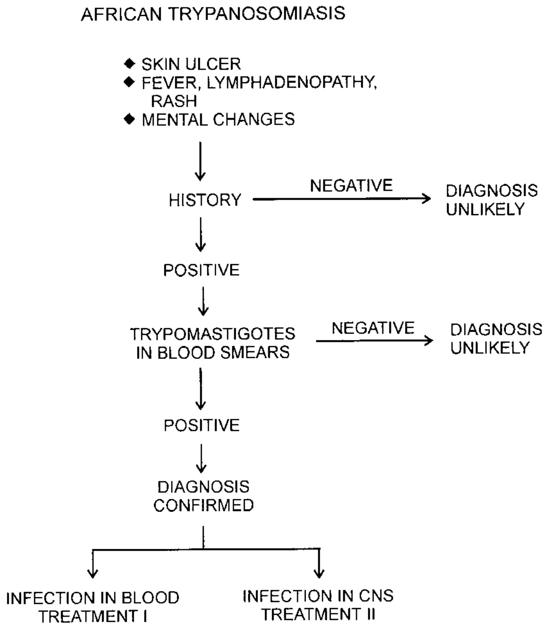
Because East African trypanosomiasis is such a serious illness, treatment should be started as soon as possible and is based on the patient's symptoms and laboratory findings. Within the United States, medication and therapeutic advice is available through the CDC. Without treatment, nearly all patients develop neural involvement and die; however, in treated patients, cure rates are above 80%, even in those with CNS infection. The choice of antiparasitic drug depends on whether the CNS is infected; usually patients are hospitalized during treatment. Suramin can be used early in the course of the infection, when the CNS is not infected.

TABLE 28.4 Methods available for the diagnosis of African trypanosomiasis (*T. brucei rhodesiense*)

Method	Description	Comments
Chancre aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable).	Not commonly used; patients are often seen after the chancre has already healed.
Lymph node aspirate	Puncture; fluid obtained is examined as wet preparation and Giemsa-stained smears (other blood stains are acceptable).	Normally not required, disease presents as acute febrile illness.
Blood	Both wet films and stained thick and thin blood films can be examined.	Organism motility among red blood cells enhances detection; trypomastigotes are generally numerous. Organism morphology better on thin blood film. Giemsa or other blood stains acceptable.
Microhematocrit centrifugation	Centrifugation of capillary tubes containing anticoagulant filled with finger stick blood (end of tube sealed with plastic clay); tube is examined under microscope; organisms are concentrated at buffy coat layer.	Simple method, widely used for epidemiology studies; based on large numbers of organisms in *T. brucei rhodesiense* infections. Buffy coat should be highly motile with organisms.
Microhematocrit centrifugation (QBC)	High-speed centrifugation of blood in capillary tubes containing acridine orange; motile organisms identified by fluorescent nuclei and kinetoplasts in the buffy coat layer.	The technique is used sporadically within the United States (cost is a factor).
Mini-anion-exchange centrifugation	Separation of trypomastigotes from venous blood using anion-exchange chromatography; subsequent concentration at tip of glass tube	Sensitivity of <100 organisms/ml; procedure is very time-consuming. The columns are produced in Belgium. Method validation is under way. Not required for diagnosis of *T. brucei rhodesiense* (many organisms present).
Cerebrospinal fluid	White blood cell count used to determine disease stage; cell-counting chambers should have a capacity of 1 µl (Fuchs-Rosenthal and Neubauer chambers); do not dilute CSF.	Patients (trypomastigotes in lymph node or blood) with >20 cells/µl of CSF are treated as having second-stage disease; therapeutic approach depends on the geographic areas and drug selection. Trypomastigotes in CSF are confirmatory for second-stage disease; sensitivity is increased by centrifugation.
Antigen detection	Not relevant for *T. brucei rhodesiense* due to large numbers of trypomastigotes in blood	Diagnostic method much more relevant for *T. brucei gambiense* infections
Antibody detection	No equivalent to CATT available for screening for *T. brucei rhodesiense*; development and testing under way for agglutination card tests and particle agglutination tests; immunofluorescence tests and ELISA for antibody available, but the sensitivity varies	Immunofluorescence tests and ELISA available in reference centers (highly skilled individuals are required for testing and interpretation)
Molecular methods	Molecular markers (serum resistance-associated gene, *T. brucei rhodesiense*; receptor-like flagellar pocket glycoprotein, *T. brucei gambiense*) may be helpful in monitoring the distribution of both species.	Could also be helpful for targeting therapy for cattle infected with *T. brucei rhodesiense*, as well as distinguishing species in humans exposed to both organisms.

Suramin is the drug of choice for treating the hemolymphatic stage *of T. brucei rhodesiense* infections. When suramin is used, a test dose should be given to the patient to ensure that the drug can be tolerated. It should not be given to patients with renal disease, and if protein, RBCs, or casts are detected in the urine, treatment should be stopped. Suramin is given intravenously; its side effects include nausea, vomiting, loss of consciousness, seizures, pruritus, edema, and hepatitis. Although rare, fatalities have been reported during suramin therapy. Suramin can be obtained under an IND protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA, 30333; 404-639-3670 (evenings, weekends, or holidays: 404-639-2888) (32).

Melarsoprol is capable of penetrating the blood-brain barrier and is the drug of choice when *T. brucei rhodesiense* CNS disease is suspected; it is effective for both hemolymphatic and neural stages. Melarsoprol has been used for CNS involvement for years; however, relapse occurs in up to 6% of patients. Arsenic-related encephalopathy occurs



Algorithm 28.1 African trypanosomiasis.
doi:9781555819002.ch28.Alg1

in 10% of patients; prednisolone treatment may help reduce the incidence. The mortality due to this side effect depends on whether supportive treatment is given, but it is often above 50% (33). Resistance of both *T. brucei gambiense* and *T. brucei rhodesiense* to melarsoprol has been noted. Melarsoprol can be obtained under an IND protocol from the CDC Drug Service (32). All treated patients should be followed up twice yearly for at least 2 to 3 years. Specific drug dosage information is provided in chapter 36.

Epidemiology, Epidemics, and Prevention

The incidence of *T. brucei rhodesiense* infections is considerably lower than that of *T. brucei gambiense* infections, and the extent of distribution is smaller. East African trypanosomiasis is usually found in woodland and savannah areas away from human habitation. The tsetse fly vectors of Rhodesian trypanosomiasis are game feeders that may incidentally transmit the disease from human to human or animal to human. Because the infection results in acute rather than chronic disease, asymptomatic carriers are not a source of transmission as they are in Gambian trypanosomiasis. The disease is an occupational hazard for persons working in game reserves and a threat to visitors to game parks. *T. brucei rhodesiense* has been isolated from a variety of game animals (bushbuck, hartebeest, and lion) and domestic animals (cattle and sheep), a group that may prove to be the more important group of reservoir animals.

The incidence of East African trypanosomiasis is characterized by short epidemics interspersed with long periods of low (often undetectable) endemicity (40). The reasons for such outbreak situations have been widely discussed and debated. Studies of the composition of trypanosome strains present during epidemics have been directed at answering the following questions. (i) Are human-infective trypanosomes (*T. brucei rhodesiense*) distinct from those infecting animals (*T. brucei brucei*)? (ii) Are new strains responsible for the outbreaks? (iii) Are animals an important reservoir for strains that cause human disease? (iv) Can the occurrence of new outbreaks be traced to the movement of new "virulent" strains into the area?

Distinguishing the Two Organisms. Field data using restriction fragment length polymorphism analysis of repetitive DNAs and isoenzymes confirm that the subspecific distinction of *T. brucei rhodesiense* and *T. brucei brucei* appears to be correct (40). Although isoenzyme analysis had incorrectly detected taxonomy identity caused by convergent evolution, DNA patterns in restriction fragment length polymorphism indicate that strains of *T. brucei rhodesiense* from Zambia and from Kenya and Uganda are very different and have independent origins.

Animal Reservoirs of Sleeping Sickness. In the past, it was assumed that wild animals, particularly bushbuck, were the most important reservoir host of the parasites. More recently, cattle have been implicated in several outbreaks (40). Data show that between 21 and 33% of infected domestic animals (particularly cattle) can be infected with trypanosomes that are also infective for humans during an epidemic. Probabilities of transmission indicate that a fly infected with *T. brucei rhodesiense* is five times more likely to have picked up that infection from domestic cattle than from a human.

"New Strains" and Epidemics. In looking at changes in the ecology of a region, the appearance of a new strain, and the generation of new zymodemes by genetic exchange, it appears that there is little evidence to support the idea of new strains as a mechanism for the generation of epidemics but that the spread of a single existing strain group is more likely to be responsible.

Movement of People and Trypanosomes. It was originally thought that *T. brucei rhodesiense* originated in Zambia in the early 1900s and spread north to cause epidemics in Uganda and Kenya in the 1940s. However, analysis of trypanosomes from various locales does not support this idea. It is more likely that the origins of Rhodesian sleeping sickness in the Uganda foci were there all the time and actually coexisted with the outbreaks in Zambia (40).

Model for the Origin and Maintenance of Disease Foci in East Africa. A model can be proposed as follows: (i) each sleeping sickness focus has a single strain of human-infective trypanosome associated with it; (ii) this strain is maintained within the ecosystem of the focus, even in times of endemicity; and (iii) when favorable epidemiologic conditions are present, this strain generates an epidemic (2). A number of stages can be involved: (i) a new genotype arises that can be maintained in the population; (ii) once a transmission cycle is established, selection may maintain a single human-infective strain or a small number of such strains; and (iii) epidemic selection of this strain may occur when the tsetse fly biting rate increases. When the overall density of the infected human population increases, a full-blown epidemic caused by a single trypanosome strain occurs. A period of endemicity then follows as control measures decrease the number of cases. The human-infective strains are left circulating until such time as ecologic changes trigger another epidemic.

Control Measures. Because Rhodesian trypanosomiasis is a zoonosis, control measures are more difficult to attain than with the Gambian form. In the past, reduction or elimination of game animals has been a major control method, although more recent information suggests that cattle are more relevant as reservoir hosts. Other measures used were the reduction of human contact in areas of endemic infection, reduction of vegetation around human settlements, insecticide spraying, use of fly traps, and prophylactic treatment of domestic animals. Tourists are usually not at great risk unless they are traveling and spending long periods in rural areas of eastern and central Africa. Persons visiting areas where the disease is endemic should avoid tsetse fly bites by wearing protective clothing (long-sleeved shirts and long pants); khaki or olive-colored clothing is optimal, since the tsetse fly is attracted to bright colors and very dark colors. Because heavy clothing is not always practical owing to heat and humidity, other measures, including the use of insect repellents, bed netting, and screens, are recommended. It has also been recommended not to ride in the back of jeeps, pickup trucks, or other open vehicles; the tsetse fly is attracted to the dust created by moving vehicles and wild animals. Bushes should be avoided, since the tsetse fly is less active during the hot period of the day and rests in bushes but will bite if disturbed.

With constant political change in Africa, vector control, mass treatment, prophylaxis, and population movement tracking will remain very difficult. Unfortunately, constant monitoring of areas of endemic infection is very difficult to accomplish and trained personnel continue to be scarce as other issues take priority.

American Trypanosomiasis

Trypanosoma cruzi

American trypanosomiasis (Chagas' disease) is a zoonosis caused by *T. cruzi*, which was discovered in the intestine of a triatomid bug in Brazil in 1909 by Carlos Chagas, who described the entire life cycle in reservoir hosts. After infected bugs were allowed to feed on a monkey, the trypomastigote form was found in the blood of the animal. Chagas then found the organisms in the blood of a child who had fever, anemia, and enlargement of the lymph nodes; he proved that the parasites were the cause of this common illness endemic in areas of Brazil. It is interesting that this represents the first example where an animal parasite causing the disease and the insect vector were discovered prior to the disease itself. Based on his assumption that the organism multiplies by schizogony, Chagas named the parasite *Schizotrypanum cruzi*, a name that is still used by some. *T. cruzi* causes an acute or chronic parasitemia and invades the cells of many organs (e.g., the heart, esophagus, and colon). Chagas' disease has been found in a 15th- or 16th-century Peruvian mummy with megacolon and megaesophagus. It is one of the major health problems in Latin American countries.

It is estimated that 100 million persons are at risk of infection; between 16 million and 18 million are actually infected. There are approximately 200,000 new cases each year and 50,000 deaths per year due to Chagas' disease. In certain areas of endemic infection, approximately 10% of all adult deaths are due to Chagas' disease. Two-thirds of reported cases occur in the Southern Cone countries (Argentina, Bolivia, Brazil, Chile, Paraguay, southern Peru and Uruguay), the stimulus for the development of the Southern Cone Initiative, one of the largest disease control programs ever established (41). The southern United States, particularly Texas, is also now identified as having a number of cases. The geographic distribution of *T. cruzi* infection overlaps that of *T. rangeli* infection; therefore, the trypomastigotes may be misidentified (Table 28.5).

Using a number of molecular markers, the *T. cruzi* population has been divided into a number of evolutionary lineages, also called discrete typing units. Some markers allow the distinction of two or three major lineages, while other experimental strategies, such as random amplified polymorphic DNA and multilocus isoenzyme electrophoresis, support the distinction of six subdivisions originally designated as DTUs I, IIa, IIb, IIc, IId, and IIe. Recently, this nomenclature was revised as follows: TcI, TcII (former TcIIb), TcIII (IIc), TcIV (TcIIa), TcV (TcIId), and TcVI (TcIIe) (42). Prior to 2005, epidemiological and immunological data suggested that chronic infections occurring in Brazil and Argentina were caused primarily by *T. cruzi* II strains. Using PCR techniques, this hypothesis has been confirmed, and future studies can establish which strains are responsible for Chagas' disease in other geographic locations (43, 44). Infections by the same species cause different clinical outcomes, which is believed to be determined, at least in part, by the genetic background of the parasite (infection by different strains).

TABLE 28.5 Characteristics of American trypanosomiais

Characteristic	*Trypanosoma cruzi*	*Trypanosoma rangeli*
Vector	Reduviid bug	Reduviid bug
Primary reservoirs	Opossums, dogs, cats, wild rodents	Wild rodents
Illness	Symptomatic (acute, chronic)	Asymptomatic
Diagnostic stage		
Blood	Trypomastigote	Trypomastigote
Tissue	Amastigote	None
Recommended specimens	Blood, lymph node aspirate, chagoma	Blood, but organisms rarely recovered

Life Cycle and Morphology

The disease is transmitted to humans through the bite wound caused by reduviid bugs (triatomids, kissing bugs, or conenose bugs) (Fig. 28.11 and 28.12). Humans are infected when metacyclic trypomastigotes are released with the feces while the insect is taking a blood meal and the feces are rubbed or scratched into the bite wound or onto mucosal surfaces such as eyes or mouth, an action stimulated by the allergic reaction to the insect's saliva. The organisms can also be transmitted as congenital infections, by blood transfusion, or by organ transplantation. On entry into the body, the metacyclic forms invade local tissues, transform to the amastigote stage, and begin to multiply within the cells. The local inflammatory process continues, forming the primary lesion, the chagoma, which blocks the lymphatic capillaries and causes edema (Fig. 28.13).

A number of receptors have been identified that are involved in the invasion process of the trypomastigote into the host cell. In humans, *T. cruzi* can be found in two forms, amastigotes and trypomastigotes (Fig. 28.3, 28.14, and 28.15). The trypomastigote does not divide in the blood but carries the infection to all parts of the body. The amastigote form multiplies within virtually any cell, preferring cells of mesenchymal origin such as reticuloendothelial, myocardial, adipose, and neuroglial cells. The parasites also occur in histiocytes of cutaneous tissue and in cells of the epidermis, as well as in the intestinal mucous membrane.

The trypomastigote (Fig. 28.14) is spindle shaped and approximately 20 µm long, and it characteristically assumes a C or U shape in stained blood films. Trypomastigotes occur in the blood in two forms, a long slender form and a short stubby one. The nucleus is situated in the center of the body, with a large oval kinetoplast located at the posterior extremity. The kinetoplast consists of a small blepharoplast and a large oval parabasal body. A flagellum arises from the blepharoplast and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with Giemsa stain, the cytoplasm stains blue and the nucleus, kinetoplast, and flagellum stain red or violet.

On invasion of a cell, the trypomastigote loses its flagellum and undulating membrane and divides by binary fission to form an amastigote (Fig. 28.15). The amastigote continues to divide and eventually fills and destroys the

infected cell. Both amastigote and trypomastigote forms are released from the cell. The amastigote is indistinguishable from those found in leishmanial infections. It is 2 to 6 µm in diameter and contains a large nucleus and rod-shaped kinetoplast that stains red or violet with Giemsa stain. The cytoplasm stains blue. Only the trypomastigotes are found free in the peripheral blood.

Trypomastigotes are ingested by the reduviid bug as it obtains a blood meal. The trypomastigote transforms into an epimastigote which multiplies in the posterior portion of the midgut (Fig. 28.16). After 8 to 10 days, metacyclic trypomastigotes develop from the epimastigotes and are passed in the feces to infect humans when rubbed into the insect's puncture wound or rubbed onto exposed mucous membranes.

Clinical Disease

In addition to contracting *T. cruzi* infections through the insect's bite wound or exposed mucous membranes, persons can be infected by blood transfusion, organ transplantation, placental transfer, and accidental ingestion of parasitized reduviid bugs. The clinical syndromes associated with Chagas' disease can be broken down into acute, indeterminate, and chronic stages. The acute stage is the result of the first encounter of the patient with the parasite, whereas the chronic phase is the result of late sequelae. In children younger than 5 years, the disease is seen in its severest form, whereas in older children and adults, the disease is milder and is commonly diagnosed in the subacute or chronic form rather than in the acute form. Overall, the incubation period in humans is about 7 to 14 days but is somewhat longer in some patients.

doi:10.1128/9781555819002.ch28.f14

Early Disease. A localized inflammatory reaction of variable intensity may ensue at the infection site. In most cases, the reaction is mild and may not be apparent. An erythematous subcutaneous nodule (chagoma), seen most frequently on the face, may form. The chagoma is painful and may take 2 to 3 months to subside. In early stages of infection, amastigotes or trypomastigotes may be aspirated from the chagoma; if the route of inoculation is the ocular mucosa, edema of the eyelids and conjunctivitis may occur (Romaña's sign) (Fig. 28.13). The edema does not pit on pressure, and the skin is dry. Although Romaña's sign is thought to be almost pathognomonic for early Chagas' disease, in an analysis of 300 patients with early disease, unilateral periorbital edema was found in only 48.7% of patients (38). The infective stages spread to the regional lymph nodes, which become enlarged, hard, and tender. Similar chagoma lesions may develop in other body areas as the infection spreads hematogenously. Trypomastigotes appear in the blood about 10 days after infection and persist through the acute phase. These stages are rare or absent during the chronic phase.

doi:10.1128/9781555819002.ch28.f15

Acute-Stage Disease. Acute-stage symptoms only occur in about 1% of patients, are usually seen in younger children, and are less obvious in older individuals because of the nonspecific nature of the symptoms and the lack of availability of health care. In general, symptoms last for 4 to 8 weeks and then may subside, even without therapy. Acute systemic signs occur around week 2 to 3 of infection and are characterized by high fevers, which may be intermittent, remitting, or continuous; hepatosplenomegaly; myalgia; erythematous rash; acute myocarditis; lymphadenopathy; keratitis; and subcutaneous edema of the face, legs,

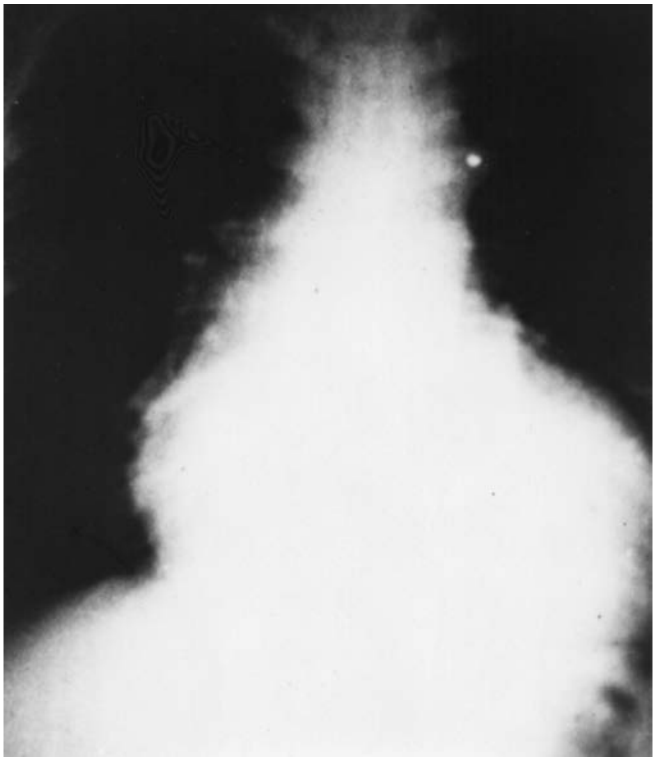

Figure 28.17 An enlarged heart in a 46-year-old man 13 days after onset of acute Chagas' disease. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch28.f17

and feet. There may be signs of CNS involvement including meningoencephalitis, which has a very poor prognosis. Myocarditis is manifested by electrocardiographic changes, tachycardia, chest pain, and weakness. Amastigotes proliferate within and destroy the cardiac muscle cells, leading to conduction defects and a loss of heart contractility (Fig. 28.17 to 28.19). Death may occur due to myocardial insufficiency or cardiac arrest. In infants and very young children with acute Chagas' disease, swelling of the brain can develop, causing death. Also, in some areas of endemic infection, a high frequency of early electrocardiographic abnormalities in children who are *T. cruzi* seropositive suggests a rapid evolution from infection to disease. Under such conditions, a public health chemotherapy program targeted to this population would be recommended (45).

All patients with acute Chagas' disease probably show some degree of myocarditis, which is apparently directly related to the presence of parasitic antigens. Both CD4 and CD8 cells participate in the pathogenesis of myocarditis, possibly leading to chronic heart failure (46). The numbers of CD4 and CD8 cells may actually correlate better with myocarditis than does the presence of parasite antigens.

Indeterminate Stage. Patients in the acute stage of Chagas' disease may die within a few weeks or months, may recover, or may enter the chronic stage of infection. The patient may have a subpatent parasitemia and will develop antibodies to a variety of *T. cruzi* antigens. Chronic Chagas' disease is diagnosed more commonly than the acute disease. The chronic stage may be initially asymptomatic (indeterminate stage), and even though trypomastigotes are seldom seen in peripheral blood, transmission by blood transfusion is a serious problem in areas where the disease is endemic. There are regional variations in disease severity, which may account for the geographic differences in morbidity. Approximately 8 to 10 weeks after infection, the indeterminate stage begins, during which the patients do not have any symptoms. Patients infected with low-virulence strains may remain infected for years with few to no problems.

Chronic Stage. Chronic Chagas' disease demonstrates close interaction between the parasite and the host, causing a number of different clinical syndromes. Approximately 30% of patients develop chronic Chagas' disease and experience cardiomyopathy, megacolon, and megaesophagus. Symptoms of the chronic stage are related to the damage

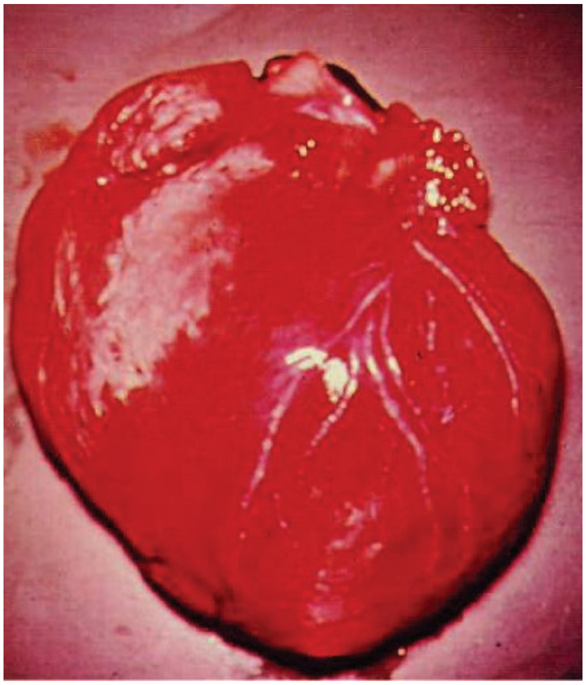

Figure 28.18 Acute chagasic myocarditis. (Original photograph by B. H. Kean; from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch28.f18

sustained during the acute stage of the disease, the state of the host's immune system, and the inflammatory response. Other contributing factors include the host genetic background, environmental and social factors, the genetic composition of the parasite, mixed infections, and reinfections (47). The inflammatory response undergoes periods of exacerbation and is probably responsible for neuronal damage, microcirculatory changes, heart matrix deformations, and possible cardiac failure (48). Selenium deficiency has also been linked to some cardiomyopathies and appears to be a biological marker for Chagas' disease and related to progressive pathology (49).

Chronic Chagas' disease may develop years or decades after undetected infection or after the diagnosis of acute disease. The most frequent clinical sign of chronic Chagas' disease in 25 to 30% of patients is cardiomyopathy manifested by cardiomegaly and conduction changes. This may present as congestive heart failure, thromboembolic phenomena, cardiac arrhythmias and sudden death. Cardiac pathology includes mononuclear inflammatory infiltrate, focal myocarditis, epicarditis, and neuroganglionitis, associated with variable focal fibrosis and widely variable autonomic dysfunction. Apparently, the immune inflammatory response causes the autonomic dysfunction, which may lead to life-threatening arrhythmias and sudden death. A review of the potential influence of associated risk factors

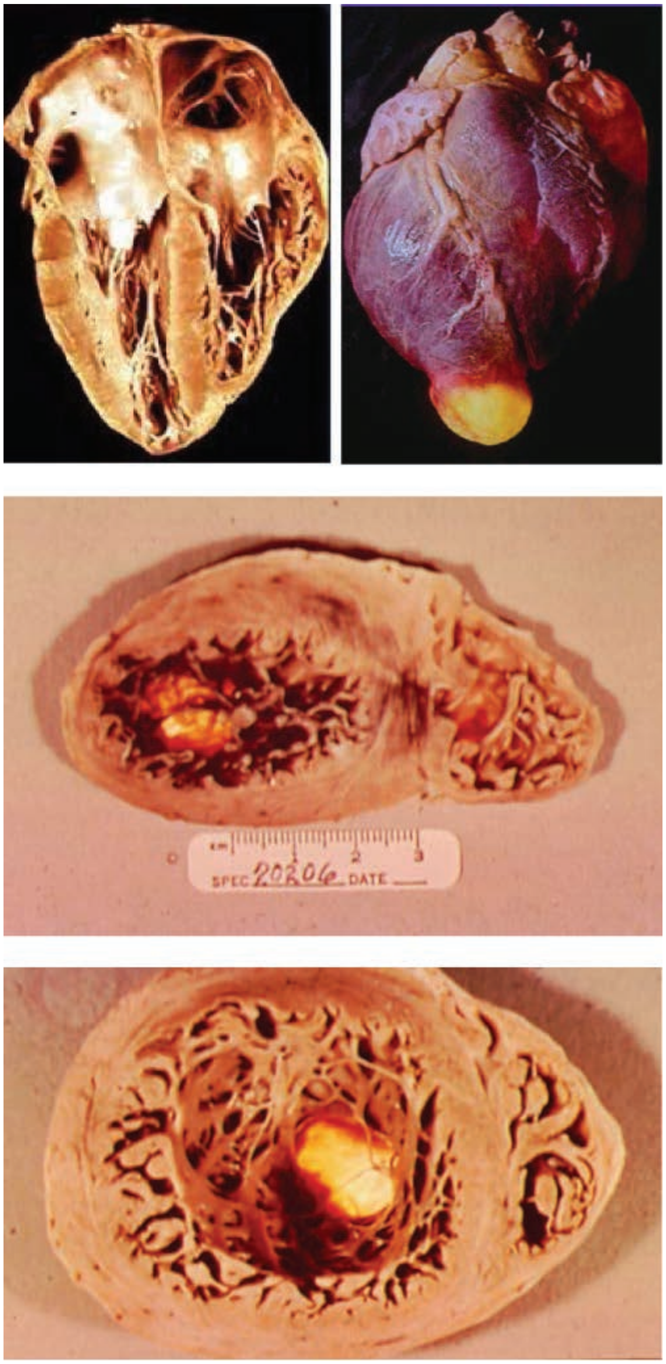

Figure 28.19 (Top left) Open chagasic heart with thinning of wall; (right) note the dilation of the apical myocardium. (Middle) Aneurysmal dilatation and thinning of the apical myocardium, plus marked concentric muscular hypertrophy. (Bottom) Same heart with thin apical myocardium. Note the light shining through the thinned muscle. (Upper right, middle, and bottom photographs by J. H. Edgecome, from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch28.f19

such as smoking, alcoholism, obesity, and hypertension on the establishment of chronic chagasic cardiomyopathy showed that these factors apparently were not associated with increased risk (50).

It is not understood why some patients in the indeterminate phase of *T. cruzi* infection develop chronic disease, while most remain asymptomatic. Although genetic susceptibility of the host is probably a factor, it has been also speculated that the phylogenetic lineage of the infecting *T. cruzi* strain and/or heterogeneity of the parasite population may also influence the varying clinical manifestations of Chagas' disease. It appears that the *in vivo* persistence of *T. cruzi* over many decades is related to parasite invasion of a large number of different cell types. The intracellular location of *T. cruzi* in vertebrates and the remarkable plasticity of its infective developmental forms—alternating between highly motile trypomastigotes and intracellularly replicating amastigotes—are likely to play a central role in ensuring parasite survival, despite the presence of immunity (51).

Autoimmunity Hypothesis (Pros and Cons). The merits of the autoimmunity hypothesis for the pathogenesis of Chagas' disease have been debated for years. Although several auto- or cross-reactive antibodies have been identified in chagasic patients, no convincing evidence exists for their ability to induce the lesions seen in infected patients (52). Because so few organisms are isolated or seen in heart tissue, much of the cardiac tissue destruction is thought to be related to autoimmune antibodies, possibly due to cross-reactivity with related *T. cruzi* antigens (molecular mimicry) (53–60). There is massive lymphocyte polyclonal activation, which results in the generation of autoantibodies cross-reacting with parasites and host tissues. Degenerative abnormalities occur in cardiac, esophageal, and colon tissues, leading to megasyndrome. The mechanism that triggers the megasyndrome is unknown. An antibody that reacts with endocardium, vascular structures, and interstitium of striated muscle (EVI antibody) has been detected in patients with Chagas' disease. The EVI antibody has been detected in a significant number of patients with chagasic cardiomyopathy. Antibodies that react with the Schwann sheaths of somatic and autonomic peripheral nerves have also been detected. A correlation of prevalence and serologic titers was detected for the antinerve and EVI antibodies. These antibodies could be absorbed from the sera by using *T. cruzi* epimastigotes, which suggests the presence of cross-reacting antibodies between parasite and hosts. These antibodies may play a large role in the denervation that occurs with megaesophagus, megacolon, and cardiomegaly.

Abnormalities of the coronary microcirculation have been seen in patients with acute chagasic myocarditis and may cause transient ischemia consistent with the hypothesis of a microvascular factor as a cause of myocardial changes. These changes are linked to endothelium structure and integrity. If the protective capability of the endothelial cells is reduced, vasospasm and platelet aggregation within coronary microvessels may lead to focal pathology.

Various mechanisms have been proposed for the pathogenesis of chronic chagasic cardioneuromyopathy. Chronic interaction of chagasic IgG with myocardial muscarinic acetylcholine receptors, behaving as a muscarinic agonist, might lead to cell dysfunction or tissue damage. Also, these antibodies could produce desensitization, internalization, or degradation of cardiac muscarinic acetylcholine receptors, explaining the progressive blockade of these receptors in the myocardium with parasympathetic denervation. Data also suggest that cardiac autonomic impairment and early myocardial damage involving the right ventricle are independent phenomena in Chagas' disease (61). Cross-reactive antibodies to cardiac and parasite immunogenic glycolipids have been detected and may be involved in Chagas' disease autoimmunity (62). Increases in the levels of asialoganglioside and monosialoganglioside-reactive antibodies have also been detected in patients with chronic Chagas' disease (63). Molecular mimicry has also been proposed on the basis of data related to cross-reactive antibodies between cardiac myosin and the *T. cruzi* B13 protein.

Human chronic Chagas' cardiomyopathy appears to fulfill many of the criteria for autoimmune diseases, similar to insulin-dependent diabetes mellitus or rheumatoid arthritis. However, validation of the target antigens must involve the induction of cardiac lesions after immunization or passive transfer of antigen-specific T cells. Aberrant T-cell activation may also play a role in cardiac injury (64). Not all researchers agree that autoantibodies play a role in pathogenesis (65, 66). Also, some propose a multifactorial or "combined" theory to explain the sequence of events leading to chronic myocarditis. The actual clinical course may vary from heart failure to a slow but continuing loss of cardiac function, with possible ventricular rupture and thromboemboli.

Tissue Involvement Other than Cardiomyopathy. Although it is less common than cardiac involvement, patients from certain areas are more likely to have dilation of the digestive tract with or without cardiomyopathy. These symptoms are most frequently seen in the esophagus and colon as a result of neuronal destruction (Fig. 28.20 and 28.21). Megaesophagus, characterized by dysphagia, chest pain, regurgitation, and malnutrition, is related to loss of contractility of the lower esophagus. Hypersalivation may occur, leading to aspiration with repeated bouts of aspiration pneumonia. Leiomyosarcoma of the esopha-

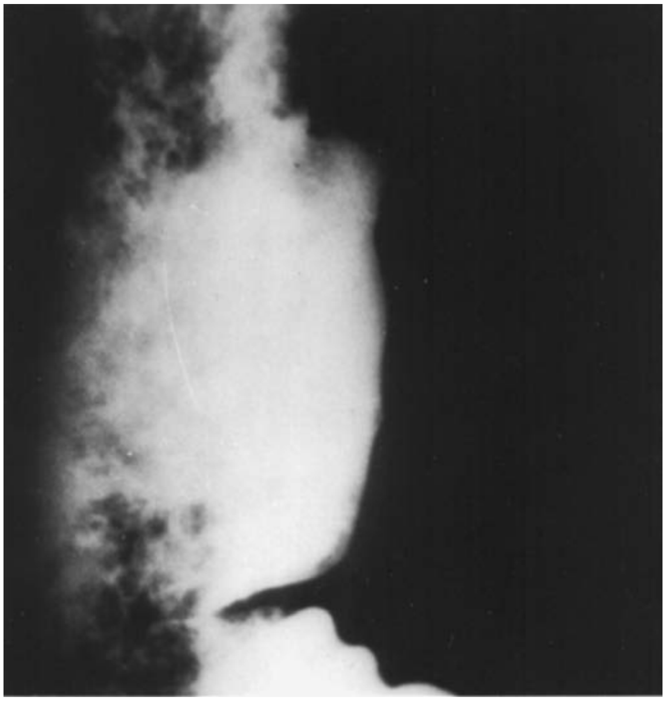

Figure 28.20 Chagasic megaesophagus. (Original photography by D. N. Reifsnyder, from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch28.f20

gus in a patient with chagasic megaesophagus has been reported (67). Megacolon results in constipation, abdominal pain, and the inability to discharge feces. In some individuals, there may be acute obstruction leading to perforation, septicemia, and death. Cases of colon cancer have also been associated with chagasic megacolon.

Congenital Transmission. Congenital transmission can occur in both the acute and chronic stages of the disease. Common clinical findings of congenital infection are stillbirth, low birth weight, myocarditis, neurologic alterations, and death shortly after birth. Infants of seropositive mothers should be monitored for up to 1 year after birth. Monitoring should include examination of blood for parasites and serologic tests.

Immunocompromised Patients. Chagas' disease has been found in HIV-positive patients, and neurologic sequelae due to *T. cruzi* have been major findings in these patients (68). Individuals who were previously infected with *T. cruzi* and later become positive for HIV are at risk of reactivation of their Chagas' disease. These patients develop a severe multifocal or diffuse meningoencephalitis with numerous tissue parasites (69). Meningoencephalitis is a rare event in non-AIDS patients and is seen most frequently in immunocompetent children younger than 4

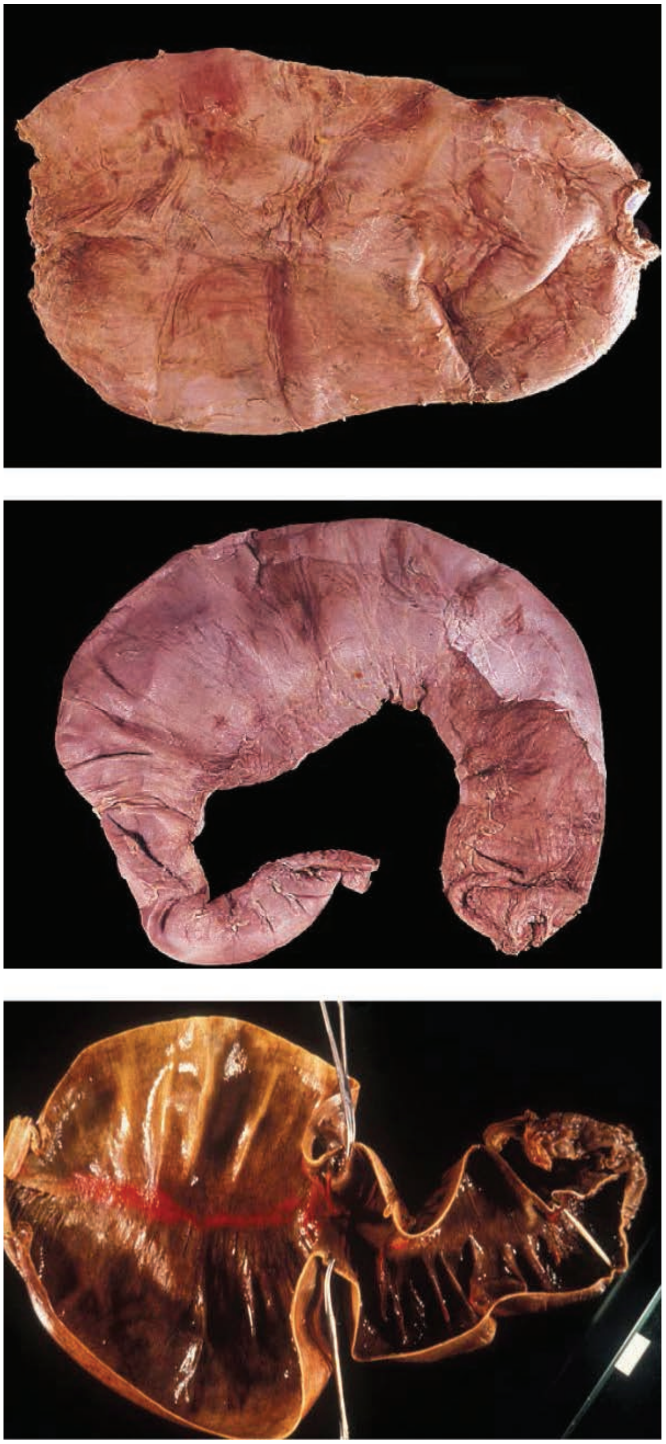

Figure 28.21 (Top) Megaesophagus in 34-year-old Brazilian patient with chronic Chagas' disease; (middle) megacolon in an adult male with Chagas' disease (Armed Forces Institute of Pathology photographs). (Bottom) Megacolon, cut image (original photograph by B. H. Kean; from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). doi:10.1128/9781555819002.ch28.f21

years. Because of the immunodeficiency associated with HIV infections, concomitant infection with *T. cruzi* may be difficult to recognize, particularly in individuals who have moved to areas where the disease is not endemic. *T. cruzi* infection may also have a protracted asymptomatic course in immunosuppressed HIV patients (70). Although a positive blood smear has been considered the key indicator of Chagas' disease reactivation in immunocompromised patients with chronic disease, this finding may occur late, rather than early, in the reactivation process (71). Apparently, there is no association between given *T. cruzi* genotypes and specific clinical forms of Chagas' disease-HIV associations (72).

Recrudescence of *T. cruzi* infections in immunosuppressed patients, particularly transplantation patients, is a grave concern. Transplant recipients can also become infected through receipt of infected organs (73). For patients with end-stage Chagas' cardiomyopathy, heart transplantation is an option which has had variable success (74). Reactivation of the disease with the development of cutaneous lesions has been seen. Bone marrow transplant recipients are also at risk of Chagas' disease due to reactivation or transfusion. Prophylactic treatment of these patients has led to favorable outcomes.

In studies of the Indians in western Paraguay, there appears to be a link between *T. cruzi* seropositivity and human T-cell leukemia virus type 2 (HTLV-2) infection. In this particular group, an individual infected with HTLV-2 is 2.28 times more likely to be *T. cruzi* positive than an HTLV-2-negative person. The public health significance of these findings is emphasized by the fact that approximately 18 million people are infected with *T. cruzi* in the Americas and the frequency of HTLV-2 infection continues to increase (75).

The high levels of IgM present in patients with African trypanosomiasis are not found in patients with either acute or chronic Chagas' disease. Antigenic variation, which is characteristic of infections with African trypanosomes, is less common in *T. cruzi* disease. In spite of humoral and cellular immunity against *T. cruzi*, the infection is able to persist in the host. As occurs in African trypanosomiasis, there is suppression of the immune response, with decreases in the levels of gamma interferon and interleukin-2, which help regulate cellular and humoral responses.

Diagnosis

Health care personnel working with specimens from patients suspected of having Chagas' disease must use standard precautions. Trypomastigotes are highly infectious, and certain strains of the parasite are more virulent than others. The diagnosis of Chagas' disease should be considered if there is a history of consistent exposure to reduviid bug bites, residence in or travel to areas where the disease is endemic, laboratory accident, or recent blood transfusion in an area where the disease is endemic. Chagomas appear similar to injury caused by trauma, insect bites, or bacterial and mycotic infections. The differential diagnosis of acute Chagas' disease should include brucellosis, endocarditis, salmonellosis, schistosomiasis, toxoplasmosis, tuberculosis, connective tissue diseases, and leukemia. Chronic Chagas' disease with cardiomyopathy may be confused with endocarditis, ischemic heart disease, and changes associated with rheumatic heart disease.

Routine Laboratory Methods. Acute Chagas' disease should be suspected in any individual from an area where the disease is endemic who develops an acute febrile illness with lymphadenopathy and myocarditis. The presence of a chagoma or Romaña's sign may be diagnostic; however, allergic reactions to insect bites may produce similar lesions. The definitive diagnosis depends on demonstration of trypomastigotes in the blood, amastigote stages in tissues, or positive serologic reactions (Table 28.5). Methods used for examination of blood are similar to those used for the diagnosis of African trypanosomiasis discussed earlier in this chapter. Trypomastigote stages (Fig. 28.14) may be easily detected in the blood in young children; however, in chronic disease, this stage is rare or absent except during febrile exacerbations. Trypomastigotes may be detected in blood by using thin and thick blood films or by buffy coat concentration techniques. The most sensitive methods for detection of trypomastigotes are concentration techniques such as the Strout method of buffy coat preparations (see chapter 7 for a discussion of concentration methods). With the Strout method, blood is collected without anticoagulant and allowed to clot. The serum is centrifuged at low speed to remove the remaining blood cells and then at a higher speed (600 × *g*) to concentrate the parasites in the sediment. Giemsa stain is often used for both trypomastigote and amastigote stages; however, any of the other blood stains are also acceptable.

Because of the overlap of geographic distribution, infections with *T. rangeli* trypomastigotes may have to be differentiated from those with *T. cruzi* trypomastigotes. *T. cruzi* trypomastigotes are usually C or U shaped on fixed blood films and have a large oval kinetoplast at the posterior end. *T. rangeli* trypomastigotes have a smaller kinetoplast a short distance from the posterior end, and there is no amastigote stage. In areas where kala azar occurs, amastigote stages (Fig. 28.15) appear similar, and infections with *Leishmania donovani* and *T. cruzi* must be differentiated. This can be done by PCR, immunoblotting, culture (epimastigote in *T. cruzi* versus promastigote in *L. donovani*), serologic tests, animal inoculation, or xenodiagnosis.

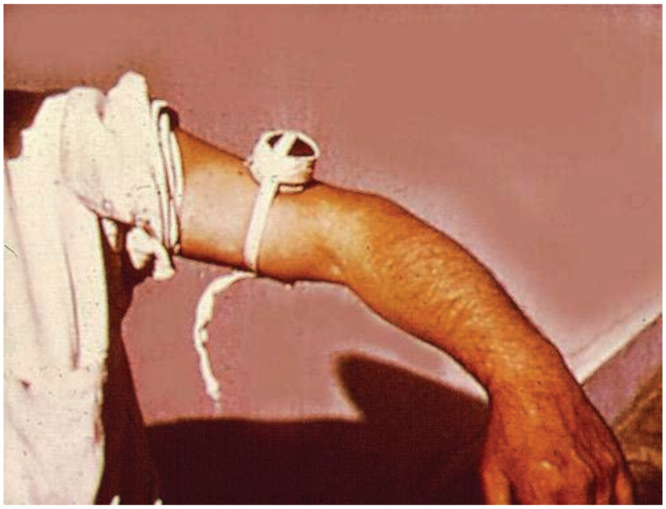
Aspirates from chagomas and enlarged lymph nodes can be examined for amastigotes and trypomastigotes. Histologic examination of biopsy specimens may also be done. Aspirates, blood, and tissues can also be cultured, which is valuable in detecting low-grade parasitemias. The medium of choice is Novy-MacNeal-Nicolle medium. Cultures should be incubated at 25°C and observed for epimastigote stages for up to 30 days before they are considered negative. If available, laboratory animals (rats or mice) can be inoculated and the blood can be observed for trypomastigotes.

In the chronic stage of Chagas' disease, trypomastigotes are very rare or absent in the peripheral blood except during febrile exacerbations. Diagnosis depends primarily on culture, xenodiagnosis, or serologic tests. Some individuals with chronic Chagas' disease may have a depressed humoral immune response, being serologically negative. This response has been correlated with specific zymodemes. Chronic disease should be considered in individuals from areas of endemic infection who show signs of cardiomegaly, cardiac conduction defects, severe constipation, or dysphagia.

Follow-up blood specimens should be reexamined 1 to 2 months after therapy. If available, xenodiagnosis may be performed (Fig. 28.22). The patient may also be monitored through serologic tests and electrocardiograms (see Algorithm 28.2).

PCR. Although not routinely available except in specialized centers, PCR has been used to detect positive patients with as few as one trypomastigote in 20 ml of blood (76–78). PCR may be very useful for the diagnosis of patients with chronic Chagas' disease because of the lack of sensitivity and specificity of serologic tests and the lack of sensitivity of xenodiagnosis. PCR testing may be very useful for monitoring patients who have received therapy in order to validate cures (79, 80). It has also been used to diagnose congenital infections by detecting *T. cruzi* in neonatal blood (81). PCR has been used in combination with xenodiagnosis as a more sensitive replacement for the microscopic examination of triatomine fecal samples (82). Systematic monitoring of transplant recipients with organs from *T. cruzi*-infected donors has been very effective in providing an early diagnosis allowing timely therapy (83).

Figure 28.22 Xenodiagnosis for detection of positive Chagas' disease patient (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). doi:10.1128/9781555819002.ch28.f22



Immunoassays. Immunoassays have been used to detect antigens in the urine and sera of patients with congenital infections and those with chronic Chagas' disease (84). Determination of antigenuria can be valuable for early diagnosis of Chagas' disease and also for diagnosis of chronic cases in patients with conflicting serologic test results. A highly sensitive and specific chemiluminescent ELISA has been developed for blood bank screening and to monitor patients who are undergoing chemotherapy (85). Another ELISA using a recombinant antigen consisting of four different peptides has also been developed for screening blood donors and for epidemiologic studies and diagnosis (86).

Xenodiagnosis. In areas of endemic infection where reduviid bugs are readily available, xenodiagnosis can be used to detect light infections; this technique is most valuable for chronic infections when there are few trypomastigotes in the blood. Trypanosome-free bugs are allowed to feed on individuals suspected of having Chagas' disease. If organisms are present in the blood meal, the parasites multiply and can be detected in the bug's intestinal contents, which should be examined monthly for flagellated forms over a period of 3 months. To optimize this method, 20 third- or fourth-instar nymphs per day are allowed to feed on a patient for three consecutive days. A significant disadvantage of this technique is that not all triatomids are equally susceptible to infection and development of the epimastigote stage. Individuals who have been previously bitten by triatomids may be sensitized to their salivary secretions and may develop an anaphylactic reaction. Because the epimastigotes of *T. cruzi* and *T. rangeli* have heterogeneous morphologies, it may not be possible to make a definitive diagnosis microscopically. Alternative diagnostic techniques such as PCR and use of a monoclonal antibody may be needed, particularly in areas where there is geographic overlap (82).

Serologic Testing. Serologic tests used for the diagnosis of Chagas' disease include complement fixation (Guerreiro-Machado test), indirect fluorescent-antibody tests, indirect hemagglutination tests, and ELISA (87). The use of synthetic peptides and recombinant antigens has improved the sensitivity and specificity of these diagnostic techniques, particularly in the diagnosis of congenital disease by using IgM and IgA antibody detection and in the evaluation of cure (88). Depending on the antigens used, cross-reactions have been noted to occur in patients with *T. rangeli* infection, leishmaniasis, toxoplasmosis, schistosomiasis, syphilis, leprosy, hepatitis, infectious mononucleosis, systemic lupus erythematosus, and rheumatoid arthritis. The Western blot method has been recommended for confirmatory serologic diagnosis of Chagas' disease (89). Another potential confirmatory assay using preserved protein antigens of *T. cruzi* discriminates chagasic from nonchagasic infections and may be useful for elucidating inconclusive results obtained by standard serologic tests; this is particularly relevant to blood bank testing (90). Long-lasting antibodies detected by a *trans*-sialidase inhibition assay and antibody responses to certain heat shock proteins can serve as sensitive markers for previous *T. cruzi* infection in patients who are parasite free and serologically cured (91). ELISA procedures have also been used to detect specific antibodies in naturally infected dogs (92).

Although Bolivian donor screening studies using indirect hemagglutination tests, indirect fluorescent-antibody tests, and four different ELISAs demonstrated 96.5 to 100% sensitivity and 87.0 to 98.9% specificity, use of a single test results in unacceptable numbers of false-negative samples in areas of highly endemic infection or in at-risk populations. Use of two tests would miss only 1 infected unit per 10,000 screened; however, the selection of tests depends on costs and feasibility (93).

The common occurrence of inconclusive results in blood donor screening for anti-*T. cruzi* antibodies should be interpreted with caution. Blood transfusion services in Brazil and some other Latin America countries simultaneously perform two tests that use different methodologies to detect anti-*T. cruzi* antibodies; this is determined by legislation currently in force in Brazil. Unfortunately, total understanding of the results of low reactivity screening tests has not been achieved; thus serology screening information must be considered in association with epidemiological data (94–97). The use of riboflavin and UV light to reduce the levels of infectious *T. cruzi* in whole blood could be effective in preventing transfusion of these parasites (98). Currently, it is estimated there may be as many as 300,000 individuals with Chagas' disease within the United States, almost all of whom involve people moving into the U.S.

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma cruzi

1. Laboratory workers should use blood-borne-pathogen precautions when examining blood from Chagas' disease patients, because the trypomastigotes are infective.
2. Trypomastigotes are prevalent in the blood of patients with acute Chagas' disease; however, organism numbers are much smaller in the indeterminate and chronic stages of the infection.
3. *T. rangeli* cannot be differentiated from *T. cruzi* on the basis of parasite morphology; patient information regarding geographic exposure is required for more appropriate interpretation of laboratory results.
4. In addition to thin and thick blood smears, concentration methods should be used to concentrate the trypomastigotes in the blood.
5. Immunoassays for antigen detection are now available and are highly sensitive and specific. Alternative methods such as culture and serologic testing can be used; however, these approaches may not be feasible without the use of a reference laboratory. Molecular methods are also being more widely used.

Treatment

Although numerous drugs have been tried, including those used to treat African trypanosomiasis and leishmaniasis, few have proven to be effective for therapy of Chagas' disease. In acute and congenital Chagas' disease and infections caused by laboratory accidents, treatment should be administered as soon as possible, even though in some cases symptoms are self-limited. Drug therapy has little effect on reducing the progression of chronic Chagas' disease.

Benznidazole (RO-7-1051, Rochagan, Radanil), an imidazole derivative, is effective in reducing or suppressing parasites in the acute stages of disease but has limited capacity to produce a parasitic cure. It appears to be slightly more active and better tolerated than nifurtimox and is currently the drug of choice (32, 99). Benznidazole is taken orally for prolonged periods and, similarly to nifurtimox, has little effect on changing clinical manifestations or reducing the progression of chronic Chagas' disease. Side effects include peripheral polyneuropathy, abdominal pain, nausea, vomiting, and severe skin reactions. The drug should be taken with meals to minimize gastrointestinal adverse effects and is contraindicated during pregnancy (32).

Nifurtimox (Lampit), a nitrofurfurylidine derivative, is tolerated better in younger than older patients and should not be used during pregnancy. It reduces the duration and severity of illness and decreases mortality due to acute and congenital Chagas' disease. Reversible gastrointestinal, cutaneous, and neurologic adverse effects are common. Treatment success varies from one country to another, possibly indicating differences in the susceptibility of strains of *T. cruzi*. There is no indication that treatment of patients with chronic Chagas' disease is beneficial. Nifurtimox must be taken orally for prolonged periods, and there can be severe side effects including abdominal pain, nausea, vomiting, anorexia, and neurologic symptoms.

Allopurinol, a purine analog, was found in limited clinical trials to be as effective as nifurtimox and benznidazole in treating Chagas' disease. The drug is taken orally, and its side effects include skin rashes in patients with renal impairment, epigastric pain, transient diarrhea, and pruritus. In a study using itraconazole or allopurinol in patients with chronic Chagas' disease, parasitologic cure was evident in 44% of those treated with allopurinol and 53% of those treated with itraconazole. Electrocardiographic evaluation showed normalization in 36.5 and 48.2%, respectively, of patients with chronic or recent cardiopathy (100).

Symptoms associated with megaesophagus and megacolon may be treated with dietary measures or may require surgery. Patients with chronic chagasic heart disease may receive supportive therapy or be managed in some cases with pacemakers.

Epidemiology and Prevention

Epidemiology. Chagas' disease is a zoonosis occurring throughout American continents and involves reduviid bugs living in close association with human reservoirs (dogs, cats, armadillos, opossums, raccoons, and rodents) (Table 28.5) (44, 101). The most ubiquitous sylvatic reservoir host is the opossum, *Didelphus* sp., which is found throughout much of the range of *T. cruzi* in the Americas. Multiple nesting or resting sites of the opossum encompass many types of triatomine habitat. High *T. cruzi* prevalence rates are partly due to the fact that opossums eat triatomines and may also transmit infection via anal gland secretions. Sylvatic cycles of *T. cruzi* transmission extend from southern Argentina and Chile to northern California. Housing conditions are extremely important in transmission; the prevalence and incidence of infection are very high in human dwellings where the vector has adapted to living in the mud and in thatch walls and palm leaf roofs.

The reduviid bug has easy access to humans to obtain blood meals and transmit the infection in this type of dwelling. A significant reduction in transmission was noted to occur in houses with walls made of plaster where cracks and crevices were covered, in contrast to houses with mud or thatch walls. Human infections occur mainly in rural areas where poor sanitary and socioeconomic conditions and poor housing provide excellent breeding places for reduviid bugs. These conditions allow maximum contact between the vector and humans. Although 12 species of reduviids occur within the United States, they have not adapted themselves to household habitation (102). Humans should avoid sleeping in thatch, mud, or adobe houses; bed nets should be used by persons sleeping in these types of houses. Travelers planning to stay in hotels, resorts, or other well-constructed housing facilities are not at high risk for contracting Chagas' disease. Insecticides can be used to kill the vectors and reduce the risk of transmission. Also, one must remember that in some countries, the blood supply may not always be screened for Chagas' disease and so blood transfusions may carry a risk of infection. The severity of Chagas' disease varies with the geographic area and may be related to strain differences in *T. cruzi*.

Transmission to humans is highly dependent on the defecation habits of the insect vector. In areas where the local species of reduviid bug does not ordinarily defecate while feeding, there are no human infections. This may explain why there are few human infections originating in the United States, even though sylvatic infections are known to occur in southern states. A number of autochthonous cases have been reported in the United States, in Texas, California, and the Southwest (103, 104). The reduviid species involved in transmitting the infection to humans vary with the geographic area. Various species involved include *Panstrongylus megistus*, *Rhodnius prolixus*, *Triatoma brasiliensis*, *T. infestans*, *T. protracta*, *T. guasayana*, and *T. sordida* (Table 28.6).

Approximately 90 million people within the United States participate in wildlife activities, thus increasing their potential exposure to the *T. cruzi* vector. Another possible exposure mechanism could be direct contact of hunters with infectious blood and tissues of wild animal reservoirs. A study of healthy people who were discovered via blood donor screening to be positive for Chagas' disease revealed the surprising observation that 6 of 17 (36%) acquired their infection in the U.S. rather than endemic Latin America. Also, most individuals (67%) reported hunting and camping activities over a 10+-year period. Therefore, time spent in outdoor activities in rural settings certainly appears to increase the chances for exposure to the vector and/or the parasite itself (110).

Several outbreaks with acute Chagas' disease in the Brazilian Amazon basin have been linked to the consumption of Amazonian palm berry or açaí juice, probably contaminated with triatomid bug feces on the fruit or with bugs that were accidentally crushed during the preparation process. Without subsequent pasteurization, the organisms remain viable, especially if the juice is not frozen. Although these outbreaks occurred in 2005 and 2007, reports from the 1960s were highly suggestive for food transmission of *T. cruzi* in Brazil (111).

Prevention and Control. Until recently, control of Chagas' disease has been mainly through the use of insecticides to eliminate the reduviid vector. In certain areas, insecticide resistance in triatomids has been noted. In addition to residual insecticide-spraying programs, construction of reduviid-proof dwellings and education are essential for effective control programs. Improvements in unsanitary living conditions, plastering of walls to obtain a smooth, crack-free surface, and replacement of palm-thatched roofs with metal roofing have been shown to considerably reduce the number of reduviids in houses. Although control of Chagas' disease is feasible, few countries have initiated control programs because of both political and economic constraints.

Transmission can occur through organ transplants and blood transfusion (105). Some of the countries in areas where the disease is endemic have laws mandating serologic testing of blood donors. Financial constraints may

TABLE 28.6 *Trypanosoma cruzi*: principal vectors

Species	Geographic area
Panstrongylus megistus	Eastern seaboard of Brazil
Rhodnius prolixus	Venezuela, Colombia, French Guiana, Guyana, Suriname; most important vector in northern South America and Central America
Triatoma brasiliensis	Central and eastern Brazil
T. dimidiata	Ecuador, Colombia, western Central America, Mexico
T. gerstaeckeri	Arizona, Texas, southern United States, Mexico
T. indictiva	Arizona, Texas
T. infestans	Brazil, Bolivia, Peru, Chile, Argentina, Paraguay, Uruguay
T. lectularia	Arizona
T. protracta	Arizona, Texas, California
T. recurva	Arizona
T. rubida	Arizona, California
T. sanguisuga	Arizona, Texas, southeastern United States
T. sordida	Brazil, Argentina, Bolivia, Paraguay, Uruguay; often associated with chickens
T. guasayana	Argentina

hinder the implementation of these laws, and there is a lack of standardization of currently available serologic tests. An alternative approach to serologic screening in the United States is the use of a questionnaire to identify prospective donors who may have resided in high-risk areas. This approach may not be practical, since even in vector-free areas in countries with endemic infection a significant portion of the donor blood units were positive for antibodies to Chagas' disease. In areas where seroprevalence is high, rather than discarding all positive blood units, laboratorians add gentian violet to the units and store them at 4°C for 24 h before use to kill the organism.

Evaluation of electrocardiographic (ECG) changes among urban workers in Sao Paulo, Brazil, showed that there were 2.2% positive sera for *T. cruzi* among 27,081 workers. A much higher percentage of workers with ECG abnormalities (42.7%) were seropositive for *T. cruzi* compared with the percentage of workers with ECG abnormalities (19.8%) who were seronegative. Based on these data, it appears that the high frequency of ECG abnormalities emphasizes the importance of providing medical assistance to this group (106).

Chagas' disease has been identified as an important emerging infection within the United States. In a pilot study from 2007 to 2012 of blood donors in Texas who had tested positive for Chagas' disease, those with confirmed infection were investigated for (i) infection source, cardiac symptoms, and health comorbidities, (ii) electrocardiography, (iii) echocardiography if required, and (iv) measurement of a highly sensitive troponin T biomarker. In participants with confirmed infection, 41% (7 of 17) had electrocardiographic abnormalities consistent with Chagas' cardiomyopathy. Also, 36% (6 of 17) were thought to have acquired the infection locally. Troponin T serum levels increased with cardiac severity. Based on these findings, the authors strongly recommended that cardiologists consider Chagas' disease in patients with electrocardiographic changes or cardiomyopathy consistent with Chagas' disease, even if there is no history of living in areas of endemicity (112).

Laboratory personnel working with *T. cruzi* must be aware of the hazard involved in handling the highly infectious trypomastigote form. Precautions would include the use of gloves and eye protection. All clinical specimens must be handled by using standard precautions.

Another potential source of infection involves veterinarians who may be handling dogs with *T. cruzi* infections, all of which may be infectious for humans coming in contact with the canine blood.

Trypanosoma rangeli

T. rangeli was first described by Tejera during an examination of intestinal contents from the reduviid *R. prolixus*. The infection in human blood was first found by DeLeon in Guatemalan children. *T. rangeli* infections are encountered in many areas where *T. cruzi* also occurs; consequently, the two parasites may be confused and must be differentiated morphologically (Table 28.5). No pathology is associated with *T. rangeli* infections. In a study conducted in Venezuela, the relatively high frequency of *T. rangeli* infections detected in patients with acute-stage Chagas' disease (18.6%) complicated the diagnosis of *T. cruzi* infection. More than 2,600 cases of human infection have been documented in Venezuela, Guatemala, Panama, Colombia, El Salvador, Costa Rica, Peru, and Brazil, the majority of which have been in Venezuela and Guatemala (107).

Life Cycle and Morphology

After the reduviid bug is infected during a blood meal, *T. rangeli* migrates from the intestine to the hemolymph and then to the salivary glands, where infective metacyclic forms can be found (Fig. 28.23). Transmission to humans is through the bite of the reduviid (triatomid) bug *R. prolixus* and related species by inoculation of metacyclic try-

pomastigotes into the wound from the infected saliva. Infections with *T. rangeli* and *T. cruzi* can coexist in the reduviid vector. The trypomastigote is approximately 30 µm long and has a free flagellum (Fig. 28.24). The nucleus is anterior to the middle of the body, and the small kinetoplast is subterminal.

Clinical Disease

Human infections are apparently asymptomatic, and trypomastigotes have been noted in the blood for longer than a year. No evidence of pathogenicity has been detected in human volunteers (108).

Diagnosis

Trypomastigotes can be detected in the blood of infected patients by using thin and thick blood smears and buffy coat concentration techniques (Table 28.5). The parasites can be stained with any of the blood stains. Infections can also be detected by xenodiagnosis, in which the reduviid vector is allowed to obtain a blood meal from an infected patient and then the hemolymph and salivary glands are examined for epimastigotes and metacyclic trypomastigotes. In addition, blood can be cultured (Tobie's medium and Novy-MacNeal-Nicolle medium) or injected into laboratory animals (mice), then examined for epimastigotes and trypomastigotes, respectively. Although there are no serologic tests for *T. rangeli*, serologic cross-reactions have been noted to occur with tests for *T. cruzi*. A 48-kDa protein has been identified that is a specific and abundant intracellular antigen for *T. rangeli* epimastigotes. Results suggest that this antigen may be a useful marker for the identification and characterization of *T. rangeli* isolates (109).

KEY POINTS—LABORATORY DIAGNOSIS

Trypanosoma rangeli

1. *T. rangeli* trypomastigotes can be detected in the peripheral blood by using thin and thick blood smears and concentration techniques; however, in practice *T. rangeli* is rarely seen in human blood.
2. *T. rangeli* trypomastigotes are morphologically similar to African trypanosome trypomastigotes (small kinetoplast).
3. *T. rangeli* infections can occur together with *T. cruzi* infections; therefore, *T. rangeli* trypomastigotes must be differentiated from trypomastigotes of *T. cruzi* in the peripheral blood.

Epidemiology and Prevention

T. rangeli infections have been found in both Central and South America and often overlap with *T. cruzi* infections. In some areas, *T. rangeli* infections are five to six times more frequent than *T. cruzi* infections in the population.

Animals naturally infected with *T. rangeli* include opossums, rodents, anteaters, raccoons, dogs, and nonhuman primates. The organisms appear to be harmless to animals; however, they do reduce the life span of the reduviid vector (108).

Unusual Parasitic Infections

Aquatic protist

Rhinosporidium seeberi

Protozoa

Lophomonas blattarum
Dictyostelium polycephalum
Myxozoan parasites
Trypanosoma evansi, *Trypanosoma lewisi*

Nematodes (the roundworms)

Ancylostoma ceylanicum
Halicephalobus gingivalis
Oesophagostomum spp.
Eustrongylides spp.
Mermis nigrescens
Dioctophyma renale
Ternidens deminutus
Mammomonogamus laryngeus (*Syngamus laryngeus*)
Ascaris suum
Gongylonema pulchrum
Haycocknema perplexum

Cestodes

Diplogonoporus spp.
Bertiella studeri
Inermicapsifer madagascariensis
Raillietina celebensis
Mesocestoides spp.
Taenia crassiceps

Trematodes

Alaria americana
Plagiorchis spp.
Neodiplostomum seoulense
Spelotrema brevicaeca
Brachylaima sp.
Nanophyetus (*Troglotrema*) *salmincola*
Stellantchasmus falcatus
Phaneropsolus spinicirrus, *Phaneropsolus bonnei*, and *Prosthodendrium molenkempi*
Haplorchis taichui
Gymnophalloides seoi
Metorchis conjunctus (North American liver fluke)
Schistosoma mattheei
Philophthalmus lacrimosus
Achillurbainia spp.

Pentastomids

Armillifer spp., *Linguatula serrata*, and *Sebekia* spp.
Acanthocephalans
Macracanthorhynchus hirudinaceus and *Moniliformis moniliformis*

Most parasites infecting humans are recognized as being able to survive easily within the human host and to possibly cause disease, but there are some organisms that only rarely infect humans. Perhaps humans are only accidental hosts. In any case, because these infections, being so rare, are not reported frequently, such parasites may not be considered possible etiologic agents. It is important to at least be aware of such parasites and of the possible disease process created by these relatively benign organisms, because they can become a problem in immunocompromised patients. Examples of these unusual infections are summarized in Table 29.1.

Aquatic Protist

Rhinosporidium seeberi

Rhinosporidiosis is a granulomatous disease of humans and animals that is characterized by slow-growing tumorlike polyps, affecting primarily the nasal mucosa and ocular conjunctiva. The causative agent is *Rhinosporidium seeberi*, an organism that has undergone several reclassifications. Although it was thought to be a fungus or protozoan, it is now placed in a novel clade of aquatic protistan parasites, the Mezomycetozoea; this occurs at the divergence between animals and fungi (1, 2). Since this organism cannot be grown in synthetic media or human or animal cell lines, diagnosis is established by seeing the organism in tissue biopsy specimens. Two stages are seen in tissue: the larger endosporulating spherical form, or sporangia, and the smaller trophocyte (Fig. 29.1). The genus *Rhinosporidium* may include multiple host-specific strains (3). Infection generally occurs after swimming in stagnant freshwater ponds, lakes, or rivers, but is also suspected to occur from dust or air.

The sporangium is the mature form and measures 100 to 350 µm; contained within the sporangium are numerous endospores (sporangiospores). The zonal arrangement of sporangiospores is characteristic, with the immature ones forming a crescent-shaped mass at the periphery, the maturing ones arranged sequentially toward the center, and the mature ones in the center. This arrangement of the sporangiospores separates *R. seeberi* from other spherical endosporulating organisms seen in tissue.

Rhinosporidiosis has been found in young men between 20 and 40 years old; the lesions tend to be slow-growing polyps or tumor-like masses, usually

doi:10.1128/9781555819002.ch29

TABLE 29.1 Unusual parasitic infections

Organism	Body site	Diagnosis	Comments
Aquatic protist			
Rhinosporidium seeberi	Nasopharynx, ocular conjunctiva, genitalia	Identification of sporangium and/or trophocytes in tissue biopsy specimens	Cannot be grown in synthetic media or animal/human tissue cell lines; classification has been difficult over a number of years
Protozoa			
Lophomonas blattarum	Bronchopulmonary disease	Recovery of flagellate in pulmonary specimens	Can easily be confused with ciliated epithelial cells; metronidazole
Dictyostelium polycephalum	Eye, keratitis	Clinical picture identical to that caused by *Acanthamoeba*	Growth on nonnutrient agar plate with *Escherichia coli* overlay
Myxozoa: *Myxobolus* spp.	Intestine	Recovery of spores in stool	The morphology can mimic normal human spermatozoa, causing confusion with possible sexual abuse situations; true human infection is still somewhat unclear
Trypanosoma evansi, *Trypanosoma lewisi*	Blood	Thick and thin stained blood films	Molecular methods may be required to definitively identify the causative organism
Nematodes			
Ancylostoma ceylanicum	Intestine; mimics clinical picture seen in normal hookworm infections	Eggs in the stool; eggs resemble those of other hookworms, peripheral eosinophilia	Primarily seen as infections in dogs and cats; second most common hookworm infecting humans
Halicephalobus gingivalis (formerly *Micronema deletrix* or *H. deletrix*)	Brain; meningoencephalitis	Routine histologic test with consultation	Free-living worms living in soil, manure, humus; occasionally parasitize horses
Oesophagostomum spp.	Intestine or abdominal cavity (nodular mass lesions)	Examination of nodule (dissection or aspirate); definitive diagnosis depends on identification of worm (may be difficult)	Carcinoma, tuberculosis, or Crohn's disease often suspected; mass often attached to bowel wall or ileum or colon; infection via ingestion of larvae
Eustrongylides spp.	Abdominal cavity	Identification of larvae (bright red)	Rare but may increase with consumption of raw fish; infective larval form also found in amphibians and reptiles
Mermis nigrescens	Mouth	Identification of larvae or adults	Soil nematodes with eggs deposited on plants and larvae in grasshoppers; adult worm accidentally transmitted to infant, probably by dog or cat
Dioctophyma renale	Primarily right kidney (may be in left kidney or body cavities)	Identification of worm in autopsy specimens or living worms passed from the urethra	Route of infection probably ingestion of raw freshwater fish and frogs; widely reported in dogs
Ternidens deminutus	Large intestine	Identification of eggs in stool; ulcers and/or cystic nodules may be seen in the large intestine	Third-stage larvae will develop in soil; probably infective for humans; life cycle not known
Mammomonogamus laryngeus	Trachea	Identification of Y-shaped male and female worms (*in copulo*) from coughed-up sputum or from eggs in sputum or stool	Third-stage larvae thought to be infective for the vertebrate host; normal host cattle, felines; life cycle not known
Ascaris suum	Intestine or liver, lungs; intestine but worms do not mature (can be serious disease)	Identification based on size and shape of denticles and patient history of exposure to pigs raised on farms; dose required for symptoms of pneumonitis very minimal; large doses can lead to severe disease	Ingestion of infective eggs probably more common than thought, particularly in people who live and/or work on farms where pigs are raised
Gongylonema pulchrum	Mucosa or submucosa of buccal cavity; esophageal mucosa	Identification based on worm recovery and egg morphology	Accidental ingestion of insect intermediate hosts, possibly cockroaches or other infected insects

(continued)

TABLE 29.1 *(continued)*

Organism	Body site	Diagnosis	Comments
Haycocknema perplexum	Skeletal muscle fibers	Identification of adults or larvae in muscles	Symptoms of progressive muscle weakness, eosinophilia, active polymyositis
Cestodes			
Diplogonoporus spp.	Intestine	Identification of proglottids or eggs (similar to those of *Diphyllobothrium latum*)	Ingestion of infected fish; usual parasites of whales
Bertiella spp.	Intestine	Identification of chains of proglottids or very characteristic eggs	Accidental ingestion of mites containing the infective form; most infections seen in children
Inermicapsifer madagascariensis	Intestine	Identification of proglottids, eggs, or egg packets in stool	Very difficult to differentiate from *Raillietina* spp.; patient is asymptomatic to mild symptoms; usually seen in children; infection probably from ingestion of arthropod vector (unknown)
Raillietina celebensis	Intestine	Identification of proglottids, eggs, or egg packets in stool	Intermediate hosts are ants (accidental ingestion)
Mesocestoides spp.	Intestine	Identification of proglottids in stool	Infection probably due to ingestion of raw meat of some animal (unknown) carrying the intermediate larval form in the tissue; usually found in children; symptoms minimal
Taenia crassiceps	Eye, subcutaneous paravertebral infiltrate (AIDS)	Identification of small, white, spherical masses (2–3 mm) of larval worms	Common parasite of the red fox; in animals, larval forms found under skin and in body cavities; human cases very rare but very serious
Trematodes			
Alaria americana	Disseminated throughout many tissues including eye, organs, central nervous system; can be very serious disease	Recovery of mesocercariae at surgery or autopsy	Ingestion of inadequately cooked frogs or frog legs
Plagiorchis spp.	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of insect grubs containing the infective stage; raw fish also implicated in transmission
Neodiplostomum seoulense	Intestine	Recovery of adult worms and/or eggs in stool	Associated with ingestion of raw or poorly cooked snake meat, frogs, or house rats
Spelotrema brevicaeca	Intestine or disseminated to other tissues	Recovery of adult worms in stool and/or eggs in stool or tissues	Ingestion of raw crabs containing infective metacercariae; reported to cause severe illness in compromised patients
Brachylaima sp.	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of raw snails containing infective metacercariae; may be mild abdominal pain and diarrhea
Nanophyetus (Troglotrema) salmincola	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of raw fish viscera and/or giant salamander; rickettsia associated with infection causes severe illness in dogs, may also be human pathogen
Stellantchasmus falcatus	Intestine	Recovery of adult worms and/or eggs in stool	Ingestion of raw brackish-water fish; reported from Hawaii after ingestion of raw mullet
Phaneropsolus spinicirrus, *Phaneropsolus bonnei*, *Prosthodendrium molenkempi*	Intestine	Recovery of adult worms and/or eggs in stool; eggs resemble those of *Opisthorchis viverrini* or each other	Ingestion of raw small fish infected with naiads (water nymphs of dragonflies)

(continued)

TABLE 29.1 Unusual parasitic infections *(continued)*

Organism	Body site	Diagnosis	Comments
Haplorchis taichui	Small intestine	Identification of eggs or adult worms	Musosal ulceration, mucosal and submucosal hemorrhages, fusion and shortening of the villi, chronic inflammation, and fibrosis of the submucosa
Gymnophalloides seoi	Intestine	Recovery of adult worms and/or eggs in stool	New human intestinal trematode; southwestern island of Korea; bivalves serve as first or second intermediate hosts; eggs smaller than *Clonorchis* eggs
Metorchis conjunctus (North American liver fluke)	Biliary tree	Recovery of adult flukes and/or eggs in stool	Ingestion of raw white sucker fish (sashimi) containing infective metacercariae
Schistosoma mattheei	Venules of the bladder and/or intestine	Recovery of eggs in urine and/or stool; eggs resemble those of *S. intercalatum*	Skin penetration of infective cercaria from freshwater snail; *S. mattheei* and *S haematobium* may evolve into a single species
Philophthalmus lacrimosus	Eye, conjunctivitis	Sensation of having a foreign body in the eye	Identification of adult worm, generally from the eye, rare
Achillurbainia spp.	Granulomata, retroauricular cysts or abscesses	Identification of eggs or adult worms from biopsy specimens	Symptoms may or may not be present
Pentastomids (tongue worms)			
Armillifer spp., *Linguatula serrate*, *Sebekia* spp.	Infective larvae die *in situ* (tissues, including the eye); ingestion of mature larvae may lead to development of adults in nasopharyngeal tissues (halzoun syndrome)	Identification of the worm/larvae in biopsy or autopsy specimen	Most infections acquired from ingestion of raw, infected snakes; liver, lung, spleen involved; often not discovered until autopsy; lung involvement may cause congestion
Sebekia spp.	Dermatitis, serpiginous burrow, erythema	Larvae in burrow	Adult parasites of respiratory tract of reptiles, immature forms found in viscera, muscles, along spinal cord of freshwater fish
Acanthocephalans			
Macracanthorhynchus hirudinaceus	Intestine	Identification of adult worms; immature worms very difficult to identify	Infections acquired by ingestion of raw beetles; clinical manifestations are intestinal obstruction and perforation; eggs often not seen in feces
Moniliformis moniliformis	Intestine	Identification of adult worms; immature worms very difficult to identify; eggs can be used to identify the helminth	Infections acquired by ingestion of raw cockroaches; symptoms can be diarrhea, pallor, anorexia, weight loss, weakness

of the nasal mucosa or conjunctiva. Lesions have been found in the paranasal sinuses, larynx, and external genitalia. Dissemination appears to be rare. Symptoms include nasal obstruction and epistaxis. Surgical excision of the lesions is generally recommended as the treatment of choice; if total excision is not possible, recurrences are typical. As an ocular disease, it often presents as a benign conjunctival tumor but may mimic other ocular conditions.

Over 90% of rhinosporidiosis cases occur primarily in India and Sri Lanka; however, cases have been reported from the Americas, Europe, Africa, and Asia. Three cases have been reported from the southeastern United States. Various studies have linked infection to swimming or bathing in freshwater ponds, lakes, or rivers (1–3).

Protozoa

Lophomonas blattarum

The natural habitat of the multiflagellate protozoon *Lophomonas blattarum* is as an endocommensal in the hindgut of insects such as cockroaches. However, it also causes bronchopulmonary disease in humans. A total of 61 cases have been identified in the literature. Most of the reports were from China, with some cases from Peru and Spain. Although most cases were seen in adult males, some pediatric cases were reported from Peru. Clinical presentation was nonspecific, including symptoms and complaints such as fever, cough, and being out of breath. This protozoan appears as a more round structure (20 to 25 μm in diameter) and contains coarse cytoplasmatic granules and some vacuoles, with a tuft of wavy flagella which are longer and more varied in length, occurring at one end of the cell, and without a terminal bar (Fig. 29.2). Bronchial ciliated epithelial cells include the following features: a columnar cellular shape; a clear nucleus at the end of the cytoplasm; fine nuclear chromatin; clearly delineated thin nuclear membrane; and cilia that are straight, combed, of uniform length, at the apex of the cell, and inserted into a terminal bar (4, 5). Therapeutic response with metronidazole has been documented.

Dictyostelium polycephalum

Members of the genus *Dictyostelium* (social amebas or cellular slime molds) are divided into four high-level taxa with several species on the basis of DNA phylogeny. The life cycle of *Dictyostelium* spp. consists of an ameboid vegetative phase, a cyst phase, and a plant-like fruiting phase. In culture, it grows at a temperature of 34 to 35°C, which is higher than that for other species of *Dictyostelium*. Most myxamoebae aggregate to form sporocarps; however, some may round up in individual cells to form microcysts. The *D. polycephalum* isolated from a patient with keratitis grew at 36°C on nonnutrient agar with an *Escherichia coli* overlay. After 48 hours of incubation, a nonnutrient agar plate showed growth of double-walled, spherical cysts 6 to 7 µm in diameter that had different morphologic features than those of *Acanthamoeba* spp. cysts (Fig. 29.3). The clinical picture for keratitis caused by *D. polycephalum* tends to be indistinguishable from that caused by *Acanthamoeba* spp. Based on DNA extraction and PCR, the organism was confirmed as *D. polycephalum* (6). Infection with this organism could have come from contaminated water or soil. Treatment is the same for this infection as for *Acanthamoeba* keratitis; in serious infections, keratoplasty is required.

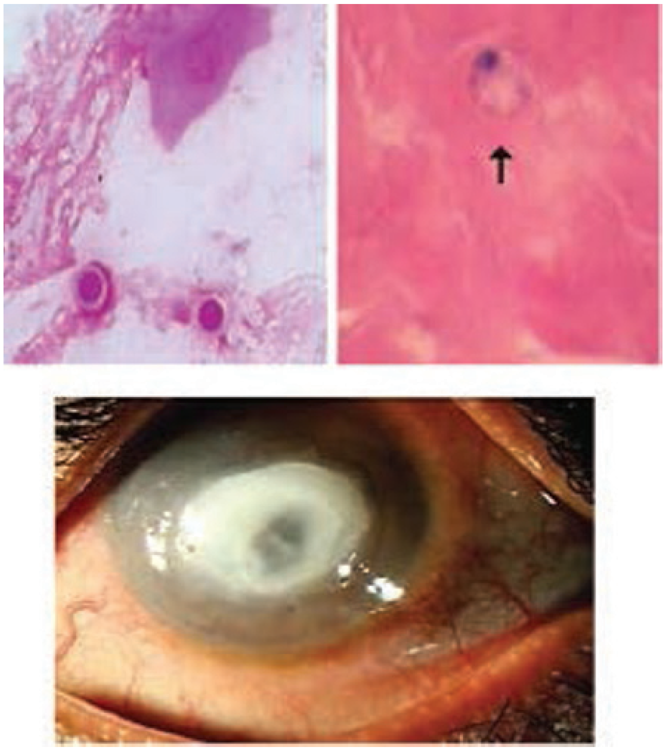
doi:10.1128/9781555819002.ch29.f3



Myxozoan Parasites

Myxozoans (*Myxobolus* spp.) are commonly found as parasites in aquatic vertebrates (especially fish) and invertebrates. They are recognized as a separate phylum with two classes: the Myxosporea, which infect fish, amphibians, and reptiles, and the Actinosporea, which infect aquatic invertebrates (primarily oligochaetes and sipunculids) (7–9). Classification has been difficult, and it has been recommended that a number of factors be used in making taxonomic decisions, including determination of 18S rRNA gene sequences combined with information on tissue tropism, host species infected, and developmental cycles in the fish and alternate host (when known). There are over 1,000 species, and new ones are being described each year; however, many of the life cycles have not yet been defined. Alternation between actinosporean stages in oligochaetes and myxosporean stages in fish may occur (10). These organisms parasitize a variety of fish tissues, where they produce pseudocysts that contain hundreds of thousands of small spores. As marine netpen farming of salmonid fish continues to expand in many countries, more unusual host-parasite relationships may be seen in the future (11).

Many of these myxozoan spores contain chitin in their spore coat, and the spores can be passed intact through the vertebrate gastrointestinal tract (12). There is no evidence that these organisms cause human disease; however, spores have been recovered in stool samples from patients with gastrointestinal tract symptoms, including abdominal pain and/or diarrhea (13). There is also speculation that these parasites could be potentially infectious and pathogenic in immunocompromised patients. Coinfections with other parasites such as *Cryptosporidium* spp., *Cystoisospora belli*, *Giardia lamblia*, *Hymenolepis nana*, *Strongyloides stercoralis*, and *Ascaris lumbricoides* have been found, thus complicating the determination of the pathogenic role of *Myxobolus* spp.

Spores of a myxosporean parasite (*Henneguya salminicola*) have been detected in fecal samples from two human patients (7), in one case being mistaken for human spermatozoa and leading to suspicion of sexual abuse (Fig. 29.4). The spores were passed undigested in feces after the consumption of infected salmon and were not thought to have any causal relationship to the patient's symptoms. True infections with myxosporean parasites in humans have not previously been recorded, other than this case. Organisms resembling human spermatozoa have been seen in fecal

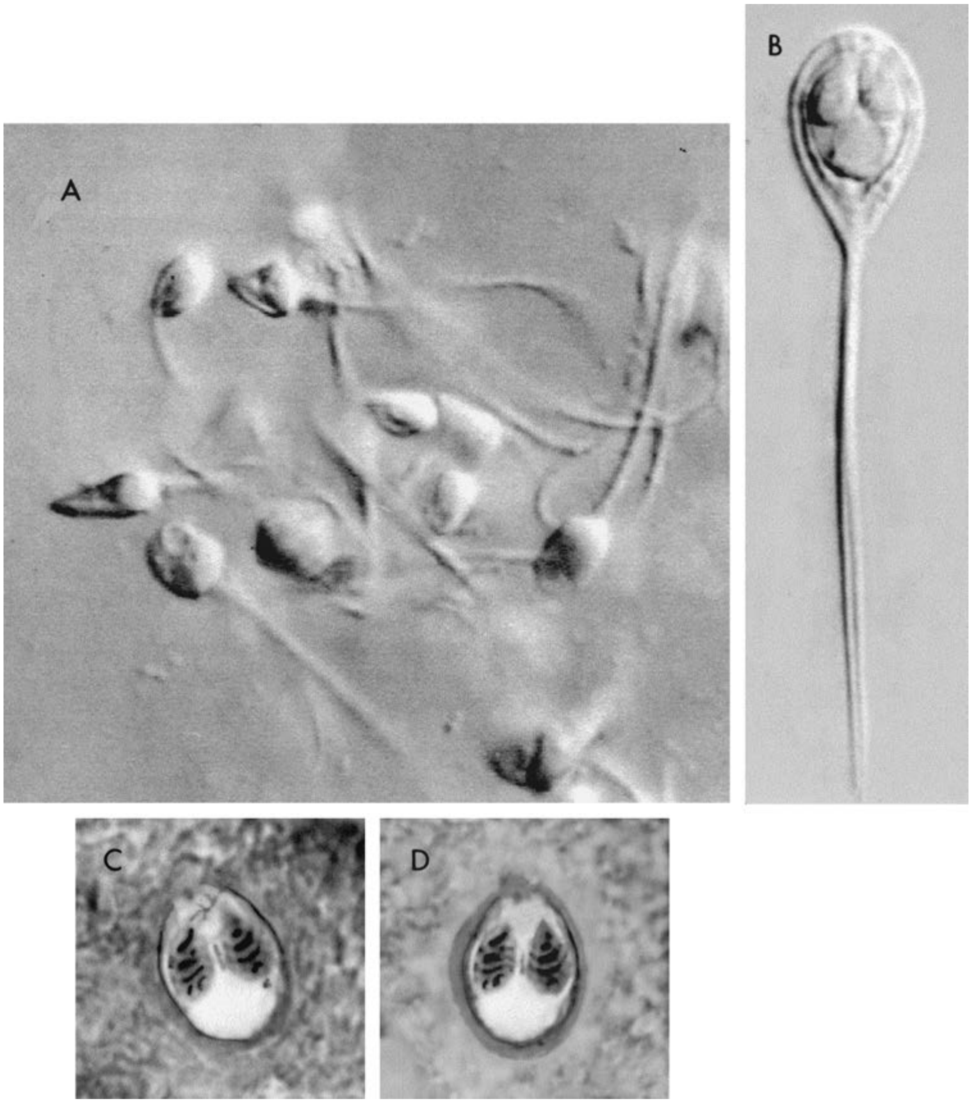


Figure 29.4 (A) Normal human spermatozoa. (B) Myxosporean spore from salmon. Note the similarities between panels A and B. (C and D) Two spores demonstrating the polar filaments. (Reprinted from reference 7 with permission.)
doi:10.1128/9781555819002.ch29.f4

concentrates at high dry magnification (×400). They measured about 40 µm in total length with a teardrop-shaped spore body of approximately 10 µm, which tapered gradually to one or two caudal filaments. Most of the spores had two pyriform polar capsules situated in the anterior region of the spore body. Although routine iron hematoxylin and trichrome staining failed to stain the spores, the modified trichrome stain was effective.

A second report discussed the detection of a second myxosporean species in stool samples from three additional patients (13). It is very likely that additional cases will be recorded; it is important that clinicians and microbiologists understand the possible presence of myxozoan spores in stool samples, particularly in patients with a high dietary intake of fish.

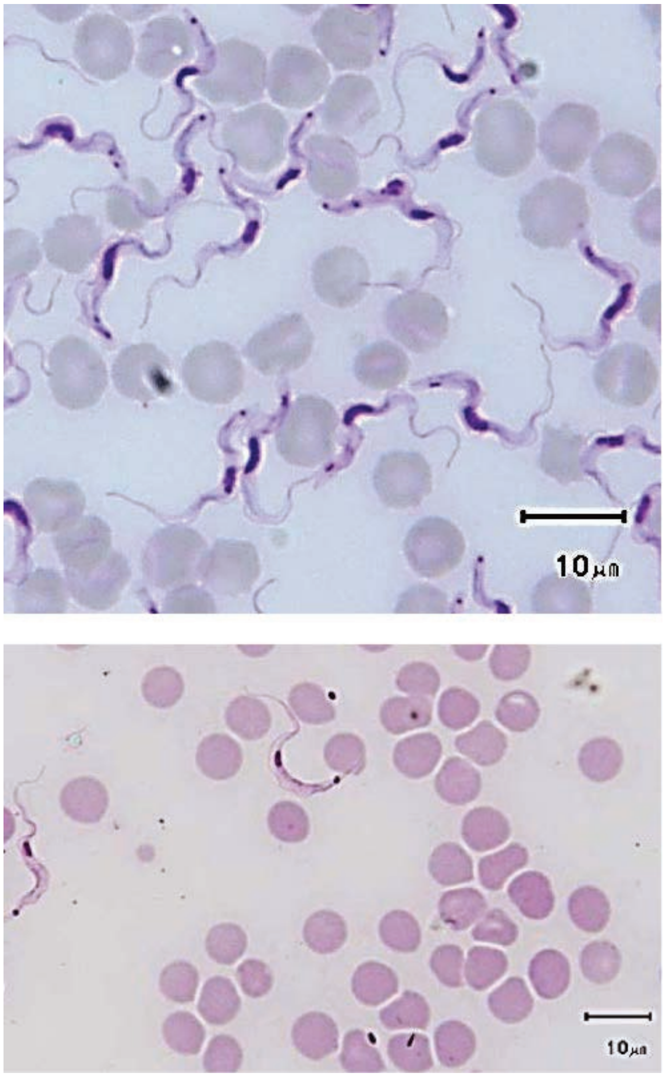
In an iodine preparation, the spores appear as dark pyriform bodies, while in modified acid-fast stains, the spore wall and enclosed sporoplasmic and capsulogenic cells stain acid fast. When the fecal specimen is stained with trichrome stain, the spores appear as darkly stained pear-shaped bodies measuring 11 to 12 µm by 7 to 8 µm with two polar capsules each measuring 5 by 2 µm. It is important to use the modified acid-fast stains, since these methods allow the visualization of the convolutions of the polar filament.

Trypanosoma evansi, Trypanosoma lewisi

T. evansi is responsible for a widely distributed disease called "surra" in domestic and wild animals found in Asia, Africa, South America, and even Europe. *T. lewisi* is a worldwide nonpathogenic parasite of rats transmitted by fleas. In recent years, *T. evansi* and *T. lewisi* have emerged as potentially pathogenic for humans (Fig. 29.5). While some of these cases reviewed herein were transient, six required trypanocidal treatments that were mostly successful, although two patients died.

In 1977, an accidental infection by a syringe containing *T. evansi*-infected blood was reported in India. In 1999, a human suspected of being infected with *T. evansi* was reported in Sri Lanka. He suffered from headache and episodes of hyperthermia consistent with high parasitemias. Unfortunately, the case was not thoroughly documented. In 2005, another case of *T. evansi* was reported in West Bengal State, India. The patient died 2 days after admission to a Kolkata hospital, but it is only suspected that death was caused by the related trypanosome infection. In 2010, in Egypt, a cattle farmer was infected with *T. evansi* and cured; however, this case remains doubtful because no attempts were made to ascertain the parasite species using molecular techniques and no clinical details or the drug used for treatment were given. Criteria such as the size and the position of the kinetoplast, the location of the nucleus, the development of the undulating membrane, the shape of the posterior end of the parasite, and the existence of a free flagellum may allow subgenus identification based on the morphological features of the parasites. However, species identification is not possible, and the parasitemia is sometimes too low for such observations to be conclusive. Consequently, molecular identification of trypanosomes is most often necessary. In 2004, the first molecularly confirmed case caused by *T. evansi* was described in Seoni, India, in a farmer showing a fluctuating trypanosome parasitemia associated with febrile episodes over the course of 5 months. The same signs were observed in a Sri Lankan patient in 1999.

Figure 29.5 (Upper) *Trypanosoma evansi* in a peripheral blood film. (Lower) *Trypanosoma lewisi* in a blood smear. (From reference 14, with permission, images courtesy of Marc Desquesnes.) doi:10.1128/9781555819002.ch29.f5



T. lewisi was found in the blood of three patients suffering from short febrile episodes in Malaysia and India. Infection was only transient and patients recovered without treatment. In 2006, trypanosomes were detected in blood of a 7-week-old baby living in Mumbai (India). She was suffering from fever and presented hepatosplenomegaly. Morphological examination of trypanosomes indicated *T. lewisi* or *T. lewisi*-like. The patient self-cured in 15 days. Several patients infected with *T. lewisi* had these infections confirmed using molecular methods (14).

Nematodes (the Roundworms)

Ancylostoma ceylanicum

Of the zoonotic hookworms, only *Ancylostoma ceylanicum* can develop to adulthood in humans; infections are found primarily in Asian countries and have been confirmed using molecular methods (15). These hookworms are endemic in Southeast Asia and are primarily seen as infections in dogs and cats (16). Recent molecular-based surveys in Asia, however, have demonstrated that *A. ceylanicum* is the second most common hookworm species infecting humans, comprising between 6% and 23% of total patent hookworm infections. *A. ceylanicum* infection mimics the clinical picture produced by normal hookworms in humans, including "ground itch" and moderate to severe abdominal pain in the acute phase (17). *A. ceylanicum* adults within the jejunum can produce chronic infections that produce anemia. In addition, the hookworm can act much like *Ancylostoma caninum* and be found lower in the gastrointestinal tract, leading to abdominal disten-

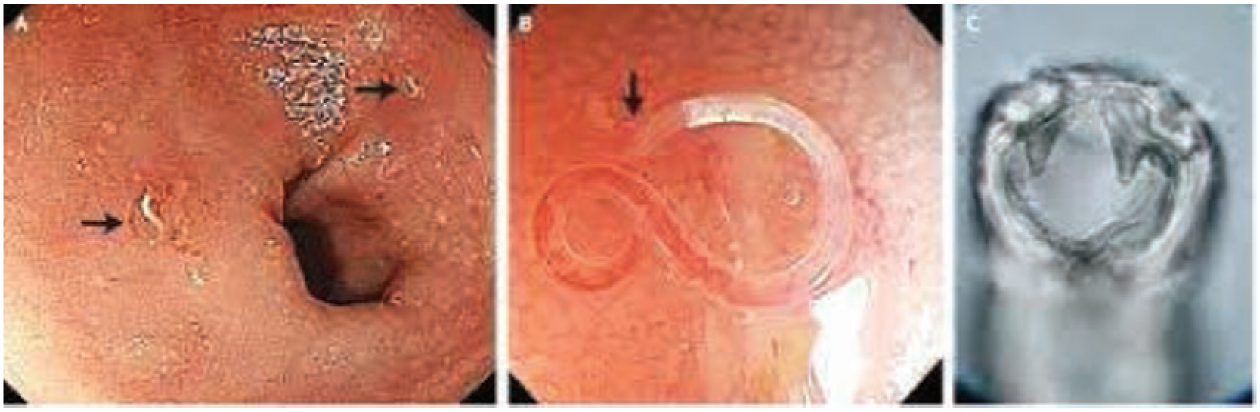


Figure 29.6 *Ancylostoma ceylanicum*. (A) Threadlike worms at the terminal ileum. (B) By magnifying endoscopy, hookworm is seen hooking its head into the intestinal mucosa and engulfing blood. (C) Characteristic hookworm mouthparts. (Courtesy of reference 16, with permission.) doi:10.1128/9781555819002.ch29.f6

sion and pain, diarrhea, and occult blood in the feces, accompanied by peripheral eosinophilia (Fig. 29.6). Whether *A. ceylanicum* is capable of producing both classical hookworm disease and evoking morbidity through an uncontrolled allergic response in some individuals remains unknown.

Halicephalobus gingivalis

The genus *Halicephalobus* consists of eight species of free-living nematodes. Only one species (*H. gingivalis*; formerly *Micronema deletrix* or *Halicephalobus deletrix*) infects vertebrates (18). Human infection is extremely rare, and only four cases have been reported in the literature. These nematodes tend to exhibit neurotropism, but their life cycle, mode of infection, and risk factors are poorly understood. Neurohelminthiases are not generally recognized in the United States, and when they do occur, the diagnosis is often missed. One report concerns a case of meningoencephalomyelitis caused by a *Halicephalobus* sp., in which the patient had a rapidly deteriorating clinical course. Although eosinophils were seen in the cerebrospinal fluid, the case did not raise any clinical suspicion of neurohelminthiases (19).

These roundworms are free-living and are normally found in soil, manure, or decaying humus. *H. gingivalis* is reported to have caused a fatal meningoencephalomyelitis in a 5-year-old boy who accidentally fell into a manure spreader and passed through the mechanism. He sustained multiple severe wounds and fractures, all of which had been heavily contaminated with manure. Although his lesions appeared to heal satisfactorily, 18 days after the injury he became lethargic. Lumbar puncture revealed over 300 cells per ml and equal numbers of lymphocytes and macrophages. The child died of meningoencephalitis 24 days after the accident (20). The autopsy revealed extensive inflammatory foci in the brain, each of which contained various developmental stages of the worms (Fig. 29.7) (21).

Another fatal case of human meningoencephalitis caused by *M. deletrix*/*H. gingivalis* was reported. The patient had severe granulomatous meningoencephalitis with many foci of hemorrhage and encephalomalacia. Many adult female and larval worms were found in the brain. The organisms probably live in decaying organic material but occasionally parasitize the kidneys, nose, or central nervous system of the horse. In its parasitic form, the nematode reproduces parthenogenetically (22).

Oesophagostomum spp.

The roundworms of *Oesophagostomum* spp. infect the intestine or abdominal cavity of humans or animals, normally ruminants, primates, or swine. The disease is most common in the tropics or subtropics, with approximately 60 human cases being reported, primarily from Africa. Several species of *Oesophagostomum* have been implicated in human disease; however, accurate species identification is very difficult if one cannot examine an intact whole worm. The life cycle is seen in Fig. 29.8. Usually, the worms are unable to complete their life cycle in humans; however, there have been instances in which stunted adult worms have been recovered. In northern Togo and Ghana, this infection is found in humans, with the recovery of both adult males and females passed in the stool after therapy (Fig. 29.9 to 29.12) (23). The parasite is *Oesophagostomum bifurcum*, which apparently does not require an animal reservoir. The eggs passed in the stool closely resemble

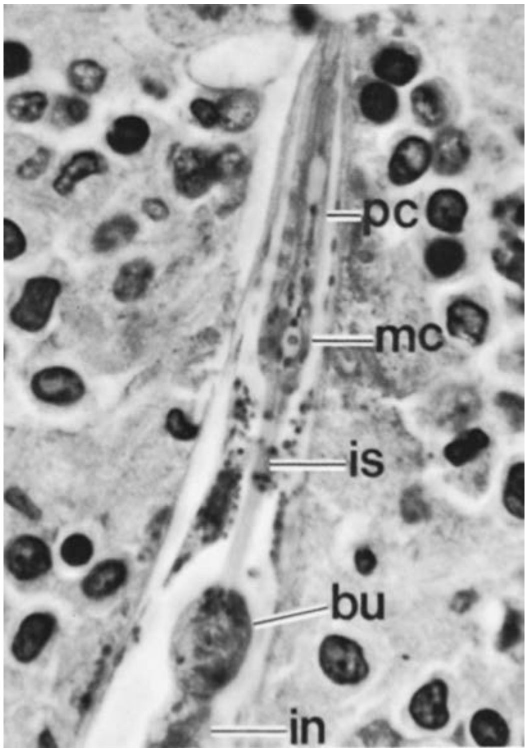

Figure 29.7 Longitudinal section through the rhabditiform esophagus in the anterior end of a mature female *Micronema deletrix* (renamed *Halicephalobus gingivalis*) worm in the brain. The procorpus (pc), metacarpus (mc), isthmus (is), bulb (bu), and intestine (in) are indicated (×1,040). those of hookworm (23), and both infections are found in this population (Fig. 29.7).

The infection can develop in humans at any age. Most of the worms recovered from humans are immature. Symptoms include abdominal pain, with localized tenderness (usually right lower quadrant). There may be gradual onset of pain, with a low-grade fever and no diarrhea, vomiting, or anorexia (24). Careful examination of the patient may reveal a mass in the abdominal cavity, adhering to the abdominal wall (Fig. 29.11) (25). Although these nodular mass lesions usually do not cause intestinal obstruction, other complications, such as hernia, intussusception, or worm penetration of the bowel wall, may occur (26). The mass is often attached to the bowel wall of the ileum or colon (27). Nodules usually measure 4 to 6 cm. Often carcinoma, tuberculosis, or Crohn's disease may be suspected. In one patient, the worm produced a cutaneous lesion, the first report of a lesion outside of the gastrointestinal tract and without evidence of bowel infection (28).

If oesophagostomiasis is suspected, confirmation can be made by immediate examination of the nodule, either by nodule dissection (Fig. 29.12) or by examination of aspirate material. Definitive diagnosis depends on identifying the whole worm or serial sections of it. At present, surgical resection of the involved tissue or removal of the worm from the nodules is the only means of treatment. However, both pyrantel pamoate and albendazole have been effective in removing adult worms from the intestine (23). It is very likely that a single dose of albendazole will cure an *O. bifurcum* infection (29).

Oesophagostomum spp., as well as hookworm infections, are hyperendemic among the population in northern Togo and Ghana (30, 31). In northern Togo, all the villages examined contained residents who were infected with hookworm, with a patchy distribution of *Oesophagostomum* spp. Women were infected with *O. bifurcum* more often than men were, while infections with hookworm were the opposite. The prevalence and intensity of infection with both parasites were clearly age dependent. It is estimated that more than 100,000 people in Togo are infected with *O. bifurcum* and more than 230,000 are infected with hookworm.

Using a panel of 155 well-defined fecal and DNA samples, a new PCR assay achieved a sensitivity of 94.6% and a specificity of 100% in the identification of *O. bifurcum*. This PCR assay will be useful for the diagnosis of *O. bifurcum* infection, as well as being a molecular biology tool to help clarify the epidemiology of human disease with this parasite (32). When using routine diagnostic methods to estimate the intensity of infection, it is sufficient to make repeated coprocultures from only a single stool

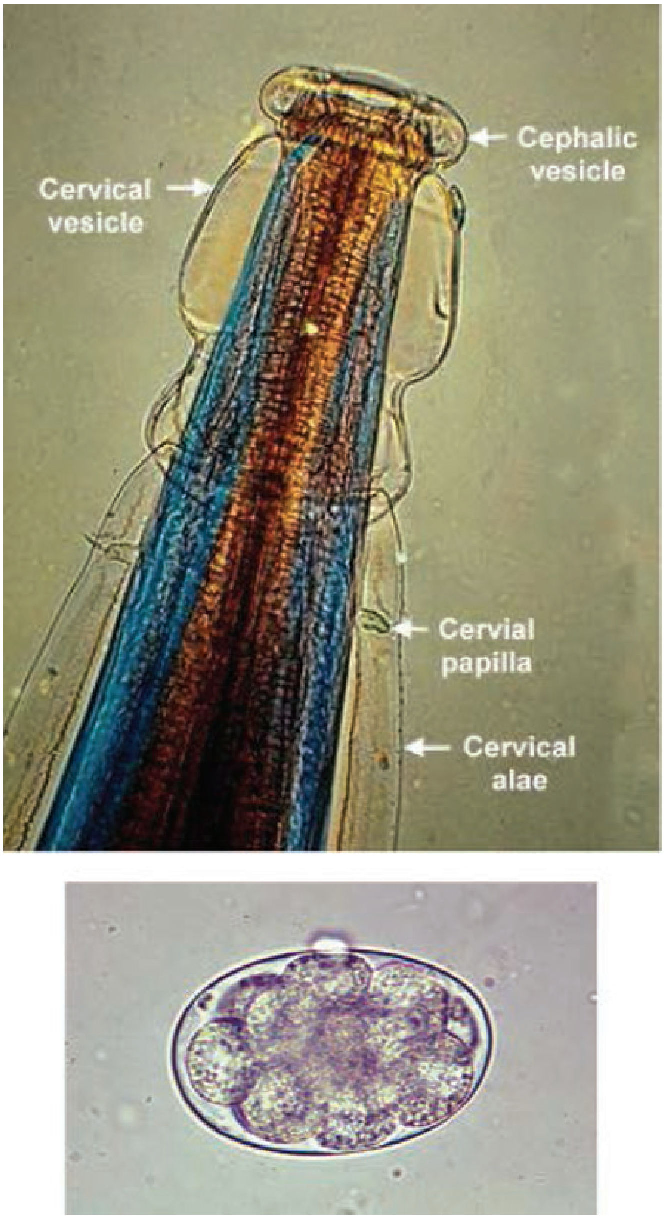

Figure 29.9 (Upper) Anterior end of an adult *Oesophagostomum bifurcum* worm recovered from human feces. Note the cephalic groove, characteristic of the genus (×115). (Reprinted from Merial U.S./animal health company, cited as original source from http://cal.vet.upenn.edu/projects/merial/Strongls/strong_6.htm.) (Lower) *Oesophagostomum* egg; this egg cannot be differentiated from that of hookworm (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch29.f9

sample; collection of multiple samples on subsequent days does not give better estimates of the individual infection status (32). It is also important to remember that coproculture can also yield larvae of *Oesophagostomum* and *Ternidens* species, as well as the more common hookworm and *Strongyloides stercoralis* (33).

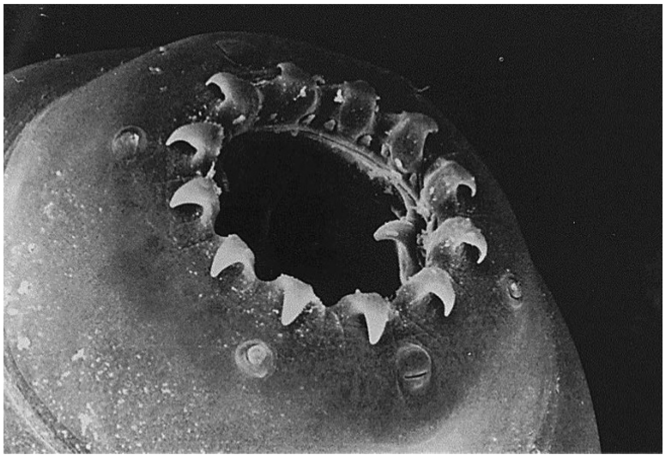

Figure 29.10 Scanning electron micrograph of the cephalic end of a female *Oesophagostomum bifurcum* worm recovered from human feces. Note the inner and outer leaf crowns with 12 and 24 (sometimes 10 and 20) lips, respectively, and the papillae (×630). Eustrongylides spp.

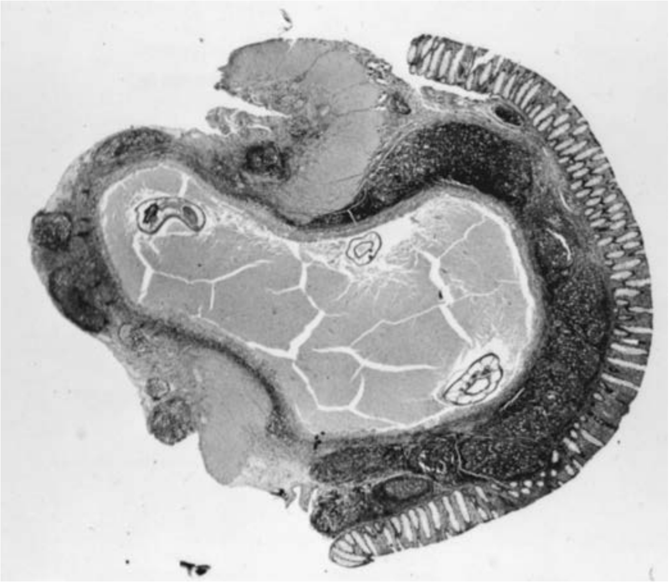
The larvae of *Eustrongylides* nematodes are found in raw fish and in amphibians and reptiles. Although not all fish hosts are known, it was assumed that, in one case, the

Figure 29.11 Nodular lesion of oesophagostomiasis seen as a paraumbilical mass in an otherwise healthy 5-year-old girl in Nigeria. At laparotomy, the lesion was found to have arisen in the ascending colon and was adherent to the muscles and fascia of the anterior abdominal wall (×11). (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch29.f11



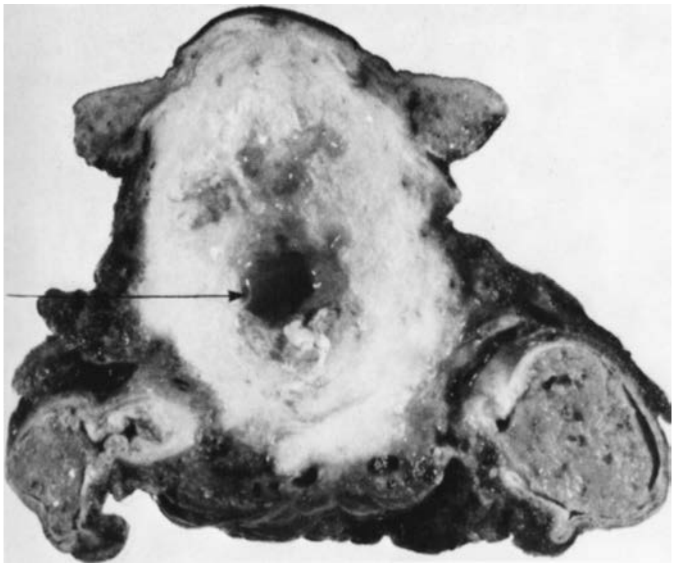


Figure 29.12 Surgically resected nodule of oesophagostomiasis. Note the worm protruding into the cavity. Specific identification of these worms is difficult, because intact specimens are rarely obtained. (Armed Forces Institute of Pathology photograph.) doi:10.1128/9781555819002.ch29.f12

patient most probably acquired the infection by eating raw fish (sashimi and sushi) approximately once a month (Fig. 29.13). He usually ingested the fish in restaurants; however, the day prior to admission, he had eaten raw fish of an unknown species from a neighborhood fish market. He presented with a history of pain in the right lower quadrant. On the basis of the symptoms, the patient underwent an appendectomy, at which time the appendix and distal ileum were found to be normal. However, prior to closure of the incision, a pinkish red worm was seen crawling onto the surgical drapes from the abdominal cavity. The patient's recovery was unremarkable. On the basis of larval morphology, the worm was determined to be in the *Eustrongylides* group, which includes parasites that are commonly found in fish-eating birds (34). A second patient also presented with symptoms simulating acute appendicitis. The patient had consumed two live minnows obtained from Big Timber Creek, Bellmawr, NJ. The parasite *Eustrongylides ignotus* was recovered surgically from this patient (35). Human infection with *Eustrongylides* spp. is certainly uncommon, but with the increased consumption of raw or improperly cooked fish, additional cases may be seen. The majority of cases have been related to anisakine larvae such as those of *Anisakis*, *Phocanema*, *Contracaecum*, and *Pseudoterranova* spp., which are indigenous to marine fish found off both coasts of the United States as well as in Japan and Europe.

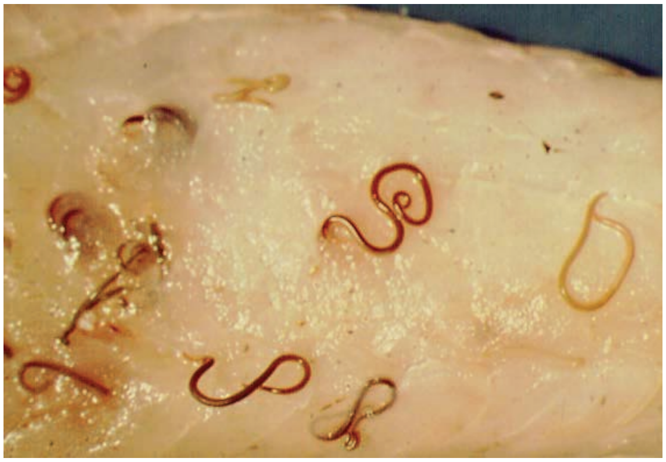

Figure 29.13 *Eustrongylides* nematode larvae in raw fish (from *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman). doi:10.1128/9781555819002.ch29.f13

Two large, living worms were collected as they emerged from the lower limb of each of two persons in South Sudan. The worms measured 7 and 8 cm in length and were identified as fourth-stage larvae of *Eustrongylides*. This is the first report of such worms emerging from the skin; all five previous reports of human infection involved surgical removal of worms from the peritoneal cavity (36).

Mermis nigrescens

Mermis nigrescens nematodes are found in the soil and have a unique life cycle. After mating and egg maturation, the females leave the soil and deposit eggs on the aboveground portions of plants. The normal hosts are grasshoppers, which become infected by ingesting eggs while feeding on vegetation. After completing their development in the grasshoppers, the worms emerge and enter the soil, where mating occurs (Fig. 29.14). One specimen that was removed from the mouth of a 1-month-old infant was identified as a gravid female *M. nigrescens* (Fig. 29.15). On the basis of the parasite life cycle, it was assumed that the female was ovipositing on vegetation and was carried, perhaps on the fur of a dog or cat present in the house, to the vicinity of the child. The parasite was possibly attracted to the moisture of the mouth (37).

Dioctophyma renale

The large (14 to 20 cm long by 46 mm wide) roundworm *Dioctophyma renale* is widely reported to have been isolated from dogs. Infection in humans is acquired from the ingestion of raw freshwater fish and frogs. The adult

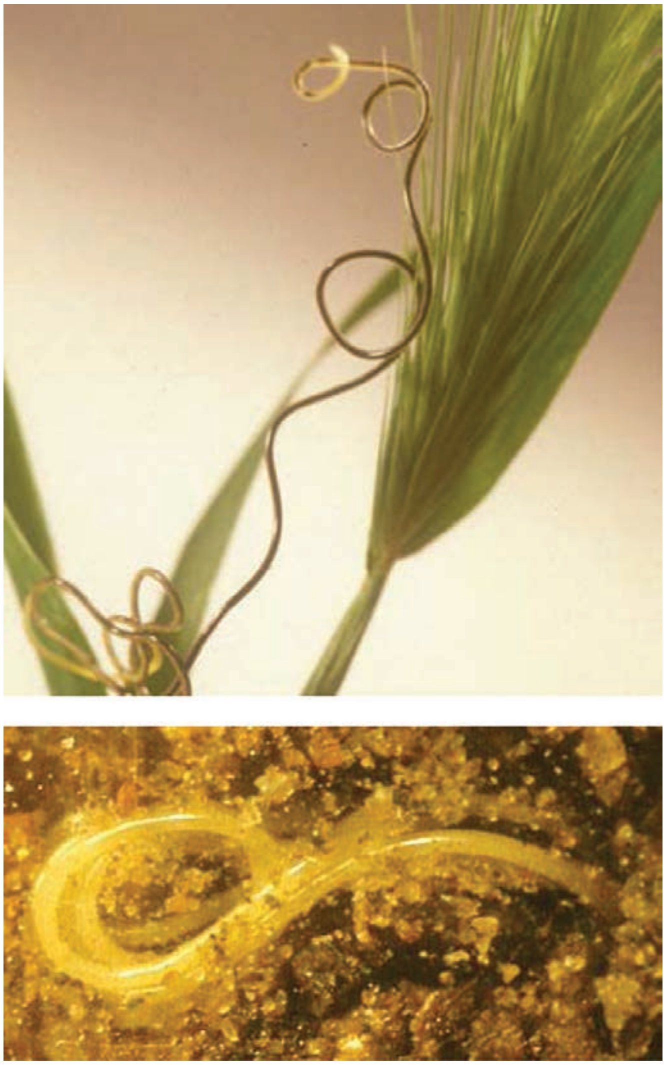

Figure 29.14 (Upper) Adult female grasshopper nematode, *Mermis nigrescens*, climbing vegetation in preparation for depositing eggs. (Lower) Juvenile grasshopper nematode, *M. nigrescens*, that has descended into the soil after exiting a grasshopper (courtesy of University of Florida, photograph by John Capinera: http://entnemdept.ufl.edu/creatures/beneficial/misc/mermis_nigrescens.htm). doi:10.1128/9781555819002.ch29.f14

worms usually live in the pelvis of the right kidney or in body cavities. The kidney parenchyma is gradually destroyed, leaving only the capsule. In all but 1 of the approximately 13 reported human cases, the kidney was involved (38). Infections were discovered at autopsy, by detection of worms migrating from the urethra, by detection of a worm discharged through the skin over an abscessed kidney (25), and by recovery of eggs in the urine (25) (Fig. 29.16).

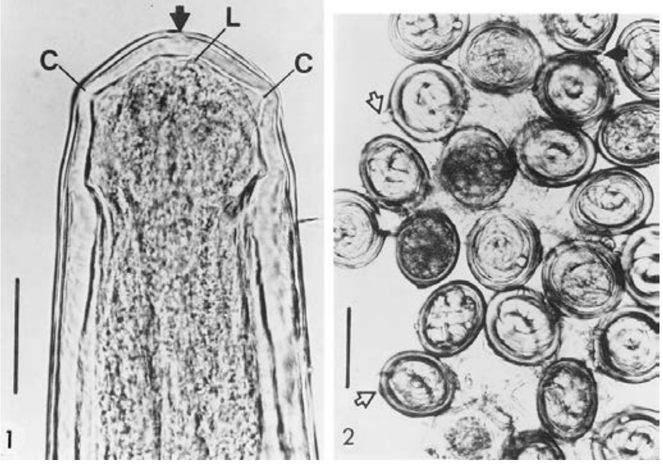

Figure 29.15 (1) Head of *Mermis nigrescens* removed from the mouth of an infant. Note the mouth opening (arrow), lip papilla (L), and cephalic papillae (C). Bar, 80 µm. (2) Eggs of *M. nigrescens* inside the uterus of the specimen. Note the thick, double-walled shell surrounding the fully developed embryos. Arrows point to poles containing collapsed byssi. Bar, 55 µm. (Reprinted from reference 37 with permission.)
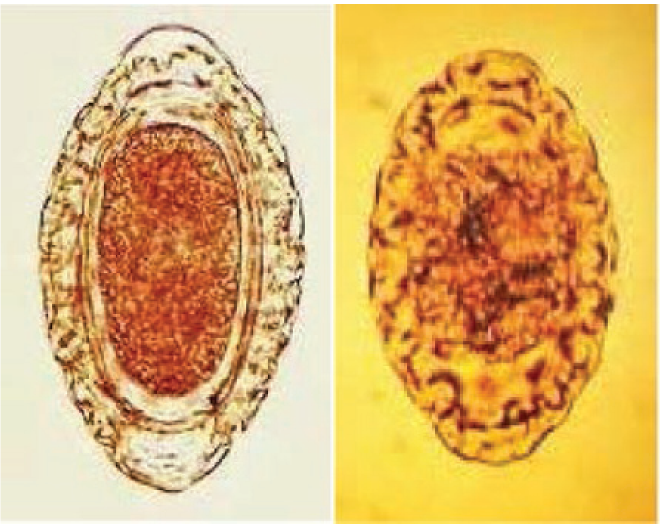
doi:10.1128/9781555819002.ch29.f15

A 50-year-old Chinese man was found to have a retroperitoneal mass in the right upper quadrant of the abdomen by ultrasonography and computed tomography. At surgery, a hemorrhagic cyst was seen at the upper pole of the right kidney adjacent to the adrenal gland. Histologic examination revealed that the granulomatous cyst wall was filled with eggs and cross sections of parasites that were subsequently identified as *D. renale*. The eggs had a

Figure 29.16 *Dioctophyma renale* eggs. These eggs measures 60 to 80 µm by 39 to 46 µm and have a thick shell that appears wrinkled; the ends of the egg are usually lighter in color (see egg on the left). doi:10.1128/9781555819002.ch29.f16



birefringent striated double wall (Fig. 29.17). The right kidney was intact, and no eggs were seen in the urine (39).

Liesegang rings (LR) are acellular, laminated structures that may be deposited within and around cysts and inflamed or necrotic tissue. Previous reports have shown that the kidney and breast are organs commonly affected with LR (Fig. 29.18 and 29.19). LRs in tissue are periodic precipitation zones from supersaturated solutions in colloidal systems. They are formed by a process involving interplay of diffusion, nucleation, flocculation or precipitation, and supersaturation. In a description of LRs from the lesions of 29 patients, the LRs formed in cysts or in fibrotic, inflamed, or necrotic tissue. Special stains and energy-dispersive radiographic analysis or scanning electron microscopy revealed that some LRs contained calcium, iron (hemosiderin), silicon, and sulfur. Some pathologists have mistaken LRs for eggs, larvae, or adults of *D. renale*. It is important to remember that these LRs can be mistaken for parasites and have been found in tissues and from renal cyst fluid (40–42). LRs are most commonly seen in fine-needle aspiration cytology preparations, but they can also be seen in histological tissue sections.

Ternidens deminutus

The nematode *Ternidens deminutus* is found as a parasite of the large intestine of several simian hosts and is occasionally found in humans. Human infection occurs when food contaminated with infective filariform larvae is ingested. The larvae molt in the intestinal wall and become adults. They pass eggs in feces, and eggs in contaminated soil hatch and become rhabditiform larvae and then infective filariform larvae. The worms inhabit the wall of the large intestine and may produce ulcers or cystic nodules (43). In one case, a *T. deminutus* infection was reported in a 33-year-old Thai female who was admitted to the hospital because of abdominal pain and a right lower quadrant mass. Exploratory laparotomy revealed an omental mass with attached terminal ileum. Resection of the mass together with the terminal ileum and the right-sided colon was performed. Histologically, the omental mass was an abscess containing an immature male *T. deminutus* (44).

doi:10.1128/9781555819002.ch29.f18

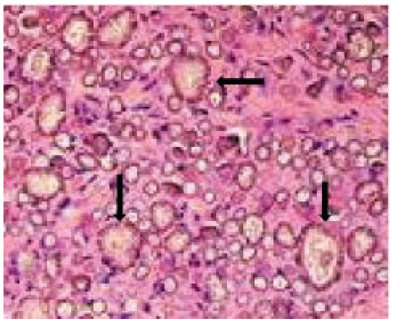

Figure 29.19 Liesegang rings in the wall of a hemorrhagic renal cyst (arrows) (hematoxylin and eosin, ×200) (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman.) doi:10.1128/9781555819002.ch29.f19

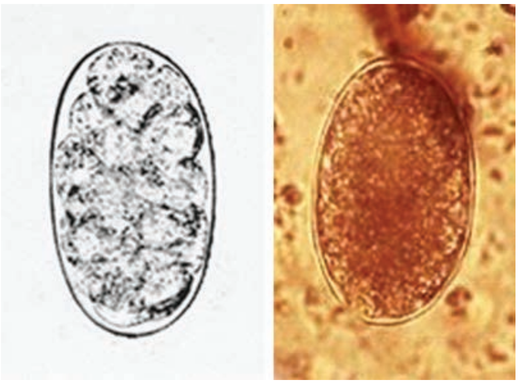
The geographic range includes Africa, India, and Indonesia; human infections have been reported in Southeast and South Africa. Although it is apparently fairly common in natives of Zimbabwe and has been found in large numbers in certain specific communities, it is not found in Europeans (43). Morphologically, *T. deminutus* resembles a hookworm; however, the anterior buccal capsule is guarded by a double crown of 22 stout bristles. The oval eggs closely resemble those of human hookworms but are larger (84 by 51 µm) (Fig. 29.20). Third-stage larvae develop in soil or Harada-Mori cultures in 8 to 10 days; however, the complete life cycle is unknown. Newly identified genetic markers provide a foundation for an improved PCR-based diagnosis of these infections (45). Both thiabendazole and pyrantel pamoate produce cure rates over 90%.

Figure 29.20 *Ternidens deminutus* egg. This egg measures 85 by 50 µm and closely resembles the egg of hookworm and *Oesophagostomum*; however, it is larger. (Left) Drawing; (right) iodine preparation direct mount.
doi:10.1128/9781555819002.ch29.f20



Mammomonogamus laryngeus (*Syngamus laryngeus*)

Mammomonogamus laryngeus is commonly found in the upper respiratory tract of some mammals, including cattle and felines. There have been approximately 100 cases of human infection, with almost all cases being reported from the Caribbean islands; more than half of the cases occurred in Martinique or in France in people who had traveled to Martinique (44, 46). Other reports have mentioned Puerto Rico, Dominica, St. Lucia, Trinidad, Guyana, Brazil, and the Philippines. Although third-stage larvae are probably infective for the vertebrate host, little is known about the life cycle.

The worm is red to reddish brown because of the ingestion of blood (46). The male and female worms are permanently joined *in copula* and present a Y shape. The short arm of the Y is the male worm, and the longer arm and base of the Y is the female worm (Fig. 29.21.) Both worms have a thick-walled buccal capsule which is armed in the inner base with eight small teeth. Male worms measure 3.0 to 6.3 mm long and 360 to 380 µm wide. Female worms measure 8.7 to 23.5 mm long and 550 to 570 µm wide. The eggs are oval, have a thick cortical shell, and measure 78 to 95 µm long by 42 to 54 µm wide (Fig. 29.22).

The worms in the trachea are often associated with a severe, nonproductive cough; the cough is often accompanied by hemoptysis and occasionally asthma, possibly because of obstruction of the bronchi or bronchioles. Eosinophilia may or may not be present. Diagnosis can be performed by examination either of worms or eggs coughed up in the sputum or of eggs that may be swallowed and recovered in the stool. Direct visual examination of the throat and/or endoscopy may also reveal the presence of worms; worms can be removed by using forceps or surgical techniques. There have been no controlled studies of specific therapy of human infections with *M. laryngeus*. In one case reported, an Italian tourist returning from the Caribbean presented with chronic cough and episodes of hemoptysis. The patient had many diagnostic procedures and was repeatedly, yet unsuccessfully, treated for asthma, bronchitis, and gastroesophageal reflux disease before the correct diagnosis was reached. During a fiber optic bronchoscopy, a Y-shaped red object was extracted and identified as a pair of *Mammomonogamus laryngeus* worms. After this procedure the patient improved, although a dry cough persisted and two other minor episodes of hemoptysis occurred. The patient was treated with ivermectin and thiabendazole and recovered after 3 months; the second fiber optic bronchoscopy was negative (47). In another case, a pair of *M. laryngeus* roundworms *in copula* was recovered from the duodenum of a 72-year-old male Thai

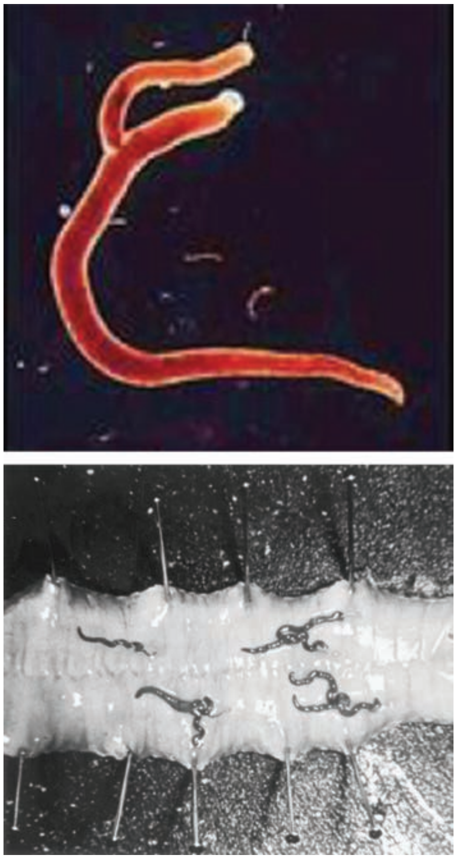


Figure 29.21 *Mammomonogamus laryngeus* (*Syngamus trachea*). (Upper) “Y” configuration. doi:10.1128/9781555819002.ch29.f21

patient from Kanchanaburi Province, Thailand. Eggs were also found in the stool. Apparently, this is the first case of infection originating in Thailand, since the previous two reports attributed the infection as originating in Malaysia. The occurrence of adult worms in the duodenum is unusual and differs from previous findings in the larynx, posterior pharynx, tracheal wall, and bronchi (48).

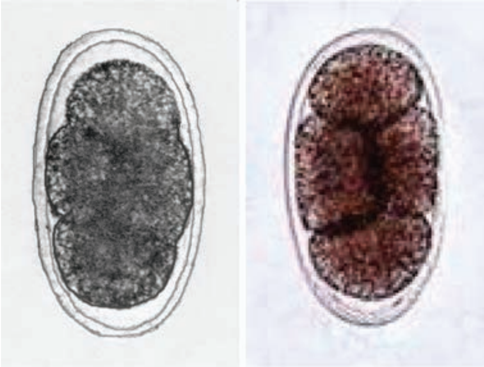

Figure 29.22 *Mammomonogamus laryngeus* eggs. This egg measures 78 to 95 µm by 42 to 54 µm. (Left) drawing; (right) iodine preparation direct mount.
doi:10.1128/9781555819002.ch29.f22

M. laryngeus is a common veterinary parasite, and the adult worms are normally found in the laryngotracheal region of ruminants. The eggs are coughed up and swallowed and can be found in the sputum or stool. Once the eggs are outside the host, they undergo development until the larva becomes infective; the larva can remain in the egg or be released into the environment. Ruminants become infected through the ingestion of food or water contaminated with infective larvae. Carrier hosts such as earthworms, snails, or arthropods may also play a role in infection. Apparently, the larvae are released in the digestive tract, cross the intestinal wall to the mesenteric veins, and migrate to the tracheolaryngeal area, where the adult worms mate and begin reproduction (46).

Ascaris suum

Human infection with adult *Ascaris suum* is occasionally documented, based primarily on very specific worm morphology and relevant history with potential exposure to pigs. Generally, *Ascaris lumbricoides* and *A. suum* are morphologically so similar that individual worms usually cannot be identified as one or the other.

Of much greater concern are the human infections with *A. suum* in which the larvae cause visceral larva migrans (VLM) and invade the liver, lungs, and the intestine but do not mature to adult worms (49). In some cases, encephalopathy can also be associated with VLM caused by *A. suum*. In one case, the patient suffered from drowsiness, quadriparesis, eosinophilia, and elevated IgE levels in serum. Magnetic resonance imaging revealed multiple cerebral cortical and white matter lesions, and serologic test results indicated recent infection with *A. suum*.

Patients with VLM have respiratory symptoms; although eosinophilia is marked, no eggs or larvae have been found in stool specimens. Multiple small mass lesions can be seen on magnetic resonance imaging; they all disappear after anthelmintic therapy. Although liver tissue biopsy specimens showed marked infiltrations by eosinophils in the portal tracts and hepatic sinusoids, no larvae or eggs were seen (50). Hepatic nodules have been located mainly in periportal or subcapsular regions, which may represent periportal eosinophilic granuloma (51).

The number of infective eggs required to initiate an infection is apparently quite small; massive infections with *A. suum* can cause severe disease (38), However, the actual significance of human infection with this nematode is not known. Among people who visit or live on farms where pigs are raised, *A. suum* may be a significant cause of illness.

Recent molecular studies provide evidence that *A. lumbricoides* and *A. suum* represent a single species (52). Other results suggest the existence of homogenizing gene flow between these two taxa, which appear to be variants of a single polytypic species (53).

Gongylonema pulchrum

The thin nematode *Gongylonema pulchrum* is a common parasite of ruminants and has been diagnosed in bears, hedgehogs, monkeys, pigs, and occasionally humans. Human cases have been reported from Europe, Morocco, the former USSR, China, New Zealand, Sri Lanka, and the United States. Human infection is acquired by accidental ingestion of infected insects. Pathology in human cases is due to maturing and adult worms migrating through the mucosa and submucosa of the buccal cavity and the esophageal mucosa. Worms have been recovered from the lips, gums, hard and soft palate, tonsils, and angle of the jaw. In some cases, blood is present. In a case report from the United States, a 41-year-old woman living in New York City presented with a history of a sensation of a "moving organism" in her mouth for more than a year (54). On two occasions she removed worms from her mouth, once from the lip and once from the gum. The patient also reported a history of reflux-like symptoms that may have been associated with esophageal involvement. The worm extracted from the lip was identified as a mature female *Gongylonema* worm, probably *G. pulchrum*. The anterior was very thin and threadlike, with a diameter of 0.5 mm; it was covered with typical bosses (scutes) arranged in longitudinal rows (Fig. 29.23). The posterior end of the worm was considerably wider. The eggs measured 50 by 28 µm.

In another case, a 48-year-old man complained of itching in various parts of the buccal mucosa over the preceding weeks. The patient lived in a rural region in southern Alsace and had never visited Africa. He worked overseeing the unloading of flour at the port of Basel. The initial clinical examination was negative. However, the patient photographed a filament previously present in his buccal mucosa, and he extracted a worm. The latter was identified at the Strasbourg Institute of Parasitology as *G. pulchrum* (55).

The 13th reported case of human infection with *Gongylonema* spp. in the United States, and the first to be confirmed as *G. pulchrum*, was reported in 2013.The parasite described was isolated from the oral cavity of a resident of Williamsburg, VA. The identity of the parasite was verified through morphological and genetic approaches and provided the first genetic confirmation of a *Gongylonema* sp. in humans (56).

Haycocknema perplexum

A new genus of nematode, *Haycocknema perplexum*, causes polymyositis in humans. Adult male and female nematodes and larvae were recovered from myofibers after biopsy of the right vastus lateralis muscle. This infection in a man in Tasmania, Australia, was associated with a polymyositis (57). Two other potential cases have been reported, one of which was also in a patient from Tasmania (58). A muspiceoid nematode causing polymyositis was involved in these cases. These minute adult worms are very slender (<35 µm) and measure approximately 300 µm (male) and 425 µm (female) in length. The adult worms are very small and may be mistaken for larvae. While treatment with prednisone produced no improvement, subsequent treatment with albendazole led to immediate improvement.

Another case was reported as the sixth case from Australia. A 50-year-old man from Tasmania had a 2-year history of progressive weakness, weight loss of 10 kg, and dysphagia. The muscle biopsy was initially interpreted as polymyositis with eosinophils. He deteriorated after several months of treatment with prednisolone and methotrexate, and subsequent review of the muscle biopsy showed intramyofiber parasites of *H. perplexum*. After 3 months of treatment with albendazole therapy, he recovered, and his creatine kinase decreased to 470 U/liter. This uniquely Australian parasite can mimic polymyositis and leads to significant irreversible morbidity and even mortality, if diagnosed late or after corticosteroids. Diagnosis is based on histopathology of muscle biopsy tissue (59). Muscle weakness, eosinophilia, and biopsy results have been consistent with an active polymyositis.

Cestodes

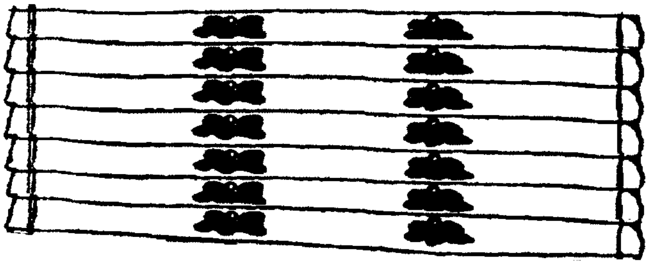
Although *Echinococcus oligarthrus* and *Echinococcus vogeli* were covered in this chapter in previous editions of this book, they have been moved to chapter 17. A new species, *Echinococcus shiquicus*, has been identified from China. Although no human infections have yet been identified, the possibility of infection certainly exists.

Diplogonoporus spp.

Diplogonoporus grandis and *Diplogonoporus balaenopterae* have been identified as tapeworm parasites of humans. This tapeworm is normally found in whales but has been isolated from a number of Japanese patients (38). The adult worm measures 1.4 to 5.9 m long and has gravid proglottids that are very wide (15 to 25 mm) and very short (0.54 mm). There are two sets of genital organs in each proglottid (Fig. 29.24). The eggs are operculated, their morphology is very similar to that of eggs of *Diphyllobothrium latum*, and they measure 63 to 68 μm by 50 μm (Fig. 29.25).

In one case reported from Spain, a 58-year-old man who consumed raw fish passed a short chain of gravid proglottids. After therapy with 50 mg of paromomycin sulfate per kg divided into three doses, all given on the same day, the worm was finally evacuated. The man had not been out of Zaragoza Province in Spain for approximately 20 years, and the infection was probably associated with the importation of fish into Spain. Outside of the Far East, this is the first confirmed case of diplogonoporiasis. The viability of the infective larval stage is evidence of resistance to export/import conditions (60).

Figure 29.24 *Diplogonoporus* tapeworm proglottids. Note the width of the proglottids and their very short length; also note the two genital organs in each proglottid. doi:10.1128/9781555819002.ch29.f24



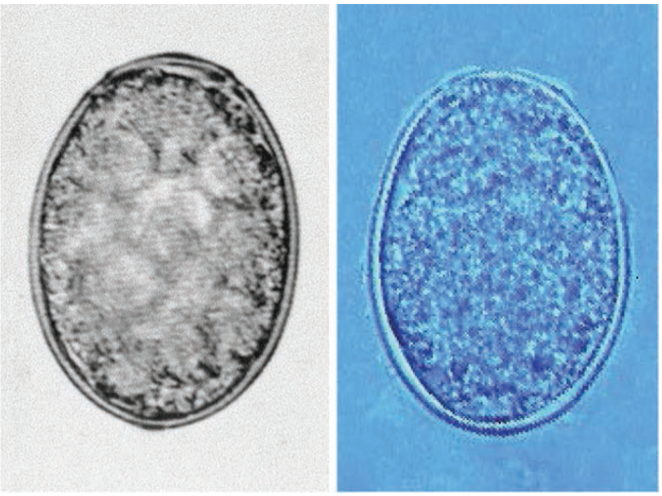


Figure 29.25 *Diplogonoporus* egg. This egg measures 63 to 68 μm by 50 μm; note the resemblance to the *Diphyllobothrium latum* egg. (Left) Drawing; (right) methylene blue preparation direct mount. doi:10.1128/9781555819002.ch29.f25

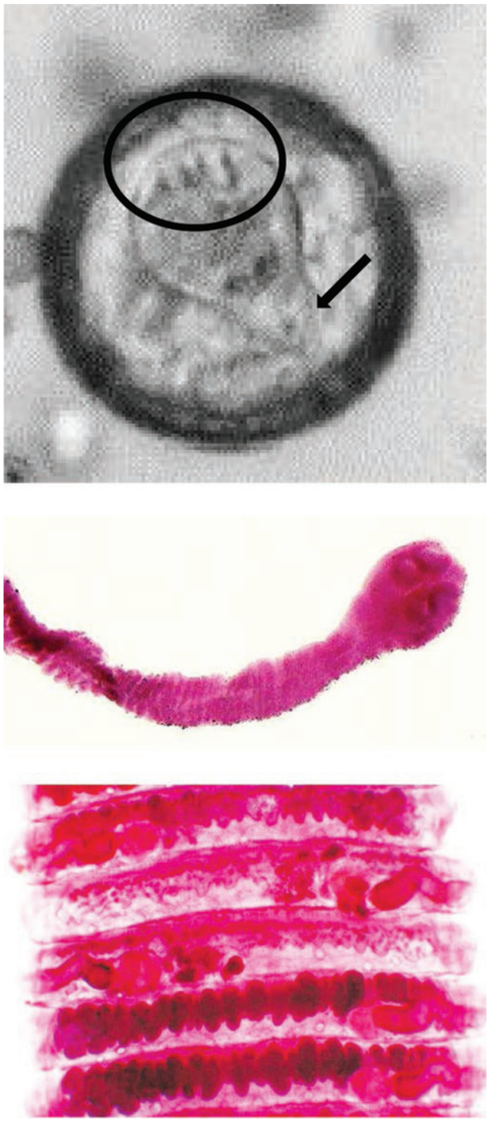
An additional 46 cases were found on the Pacific coast of Central Japan in 1996. The cases were predominantly elderly male patients over 50 years of age. Transmission was probably due to the consumption of raw juvenile Japanese anchovy (*Engraulis japonicus*), which are seasonally caught in the spring months off the Pacific coast. In almost a hundred years after its discovery in 1894, there had been more than 180 cases of human diplogonoporiasis recorded in Japan. The high incidence within a relatively short time frame of this investigation was regarded as unusual (61).

Bertiella studeri

The tapeworm *Bertiella studeri* was originally recovered from an orangutan in Borneo and has been isolated from approximately 30 patients from India, Sri Lanka, Malaysia, Sumatra, Java, Borneo, Vietnam, Singapore, Philippines, East Africa, Yemen, St. Kitts, and British West Indies (62-66). The worm is relatively small, measuring up to 300 mm long and 10 mm wide. The proglottids are shed about 20 at a time; each mature proglottid is approximately 6 mm broad by 0.75 mm long. The eggs have an irregular, oval shape and measure 45 to 46 µm by 49 to 50 µm. There is a delicate middle envelope and an inner shell with a bicornuate protrusion on one side (Fig. 29.26).

Infection is acquired by the accidental ingestion of mites containing the cysticercoid larval stage of the worm. After therapy with niclosamide or other anthelmintics, the worms are evacuated; they may also be passed spontaneously, as seen with other tapeworms. Patients may be asymptomatic or complain of vague intestinal disturbances. Some symptoms include intermittent epigastric pain after meals, accompanied by nausea, diarrhea, and anorexia, with no fever or weight loss (62). The eggs are very characteristic, and identification can be confirmed by finding the eggs or a chain of proglottids in the stool. Most of the confirmed human infections have been found in children. Although both niclosamide (Yomesan) and albendazole have been used for therapy, treatment is not always successful (63).

Figure 29.26 *Bertiella studeri*. (Top) Egg; note the pyriform apparatus (arrow) and hooklets (oval). (Middle) Scolex. (Bottom) Proglottids. (Courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch29.f26



Human infections with *Bertiella mucronata* have also been found; however, fewer than 10 cases have been recorded. One infection has been recorded in a child in Fargo, ND, who may have come in contact with an imported monkey (38). Other cases from Saudi Arabia, India, and China have also been reported (64–66).

Inermicapsifer madagascariensis

The tapeworm *Inermicapsifer madagascariensis* is often seen in humans in Havana, Cuba; in fact, outside of Africa, where it causes a disease of rodents, it may be restricted to humans. Although the life cycle has not been established, an arthropod vector is thought to be involved in human infections, which are most common in children aged 1 to 3 years. Symptoms are vague, but there may be anorexia, weight loss, abdominal pain, or irritability (67). Diagnosis is performed by finding the rice grain-like proglottids; however, these proglottids, eggs, or egg capsules are extremely similar to those of *Raillietina* spp. Specific treatment with praziquantel has been reported to be effective in eliminating the tapeworm (Fig. 29.27) (68).

Raillietina celebensis

The tapeworm *Raillietina celebensis*, common in rats, has also been found in humans, mostly children (Fig. 29.28). The intermediate hosts are various species of ants. Usually, the infection causes no symptoms. The proglottids are small (3 mm or less) and resemble those of *I. madagascariensis*.

The adult worm is approximately 40 cm long; each egg packet contains one to four large eggs measuring 90 by 46 µm. Any symptoms that might be present tend to disappear after treatment with niclosamide.

A number of other species in the genus *Raillietina* have been implicated in human disease, although the number of cases has been small. *Raillietina demerariensis* has been found in approximately 5% of patients in the rural areas near Quito, Ecuador; cases have also been reported from Cuba. The adult worms measure up to 60 cm long by 3 mm wide and have around 5,000 proglottids (38). The individual proglottids resemble rice grains and contain about 200 to 250 egg packets, each measuring about 200 µm in diameter. The oval eggs contain very conspicuous hooklets. *Raillietina asiatica*, *R. garrisoni*, and *R. siriraji* all cause infection in humans, and, again, children rather

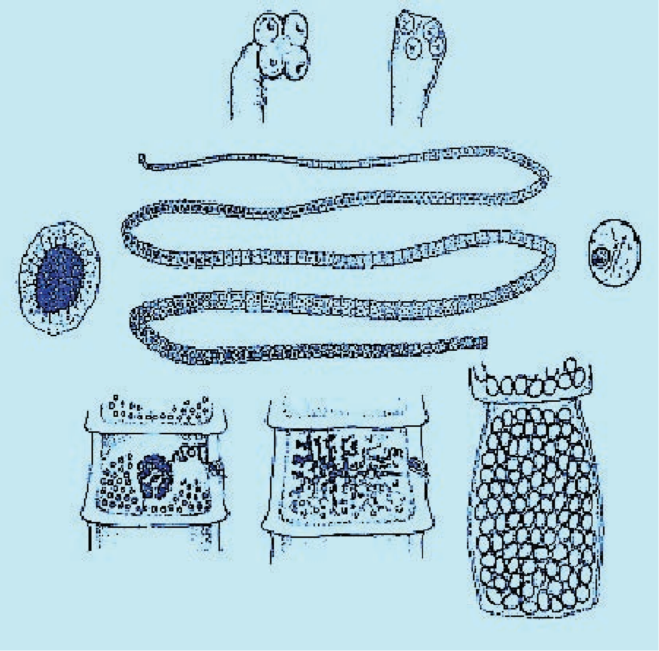


Figure 29.27 *Inermicapsifer madagascariensis*. (Top) Scolex (two views). (Middle, left to right) Egg capsule, strobila, single egg containing a hexacanth larva. Figure 29.29 *Mesocestoides* spp. Tetrathyridium larva contained in meat from animal that serves as the intermediate host and which is ingested by the human. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch29.f29

than adults are affected. Accidental ingestion of arthropod intermediate hosts is implicated in transmission.

Mesocestoides spp.

Approximately 27 cases of human infection have been reported, probably acquired from ingestion of the larval form (tetrathyridium) in inadequately cooked meat from some animal that serves as the intermediate host (Fig. 29.29). The tapeworm in one case measured 40 cm by 2 mm (Fig. 29.30). The infected child was irritable, had a poor appetite and abdominal colic, and was anemic (69). A second case was reported from Korea (70). The patient, who was a farm worker, complained of abdominal pain and passed a number of proglottids in the stool over a period of several months. The proglottids were described as looking like sesame seeds. Adult worms were recovered after therapy with niclosamide and consisted of 32 complete worms. This is probably the heaviest worm burden reported in a human case. The patient had a history of frequently eating raw viscera of chickens. The seventh

CS, cirrus sac; OV, bilobed ovary; TE, numerous testes; VA, vagina. (Bottom) Gravid proglottid. ED, excretory ducts; UT, uterus. (All stained with carmine; courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch29.f30

case was reported in the United States; the patient was a 19-month-old boy from Alexandria, LA. The infection was probably food borne, associated with local dietary customs in the Acadian and Creole communities of Louisiana, including eating sausage containing wild-animal viscera (71). The cases within the United states are probably *Mesocestoides variabilis* (71).

Mesocestoides corti serves as a murine model of human neurocysticercosis caused by *Taenia solium* in terms of the release/secretion of parasite antigens, immune responses elicited within the central nervous system environment, and subsequent pathogenesis. The kinetics of leukocyte subsets infiltrating into the brain have been examined in the context of disruption of the central nervous system barriers at distinct anatomical sites and the mechanisms contributing to these processes. Also, production of various inflammatory mediators and the mechanisms involved in their induction by the Toll-like receptor signaling pathway have been clarified. Overall, the knowledge gained from the mouse model of neurocysticercosis has provided new insights for understanding the events contributing to different stages of this disease and may lead to more effective therapeutic approaches (72).

Taenia crassiceps

Taenia crassiceps is a common tapeworm of the red fox and dogs in the Northern Hemisphere. Larval forms are generally found under the skin and in the body cavities in animals. Human cases are quite rare and appear to depend on the status of the host's immune system. An infection was reported in a 33-year-old patient with AIDS and a history of *Pneumocystis jiroveci* pneumonia and cerebral toxoplasmosis. The patient developed a subcutaneous paravertebral infiltrate that resembled a hematoma. During a period of several weeks, the lesion spread such that almost the entire back was covered. Approximately 3 weeks after admission, the infiltrate ruptured spontaneously, releasing blood and many white spherical masses (2 to 3 mm in diameter). The masses were identified as the larval form of *T. crassiceps*. After therapy with mebendazole and praziquantel, the infiltrate regressed. Praziquantel treatment was continued for 10 weeks, at which time the patient stopped taking the medication. At the end of 4 months, the lesion recurred but was successfully treated with an additional course of mebendazole and praziquantel (73).

A second case in an AIDS patient has been reported from France; this case involved invasion of subcutaneous and muscular tissues by the larval forms of *T. crassiceps* (74). The authors emphasized the problems in differentiating this infection from cysticercosis, coenurosis, sparganosis, and hydatidosis. The proliferative growth of the larvae, recurrence of lesions after surgical removal, and possible invasion of other tissues carry a poor prognosis for this group of immunocompromised patients. The biological properties of *T. crassiceps* cysticerci and the epidemiologic characteristics of pandemic AIDS could indicate the potential for new cases of this disease in humans (75).

Another case illustrates a non-AIDS-associated infection with *T. crassiceps* (76). A healthy 15-year-old girl developed an iridocyclitis in her right eye. A contractible living parasite measuring about 2 mm could be seen in the anterior chamber, while the rest of the eye was not involved

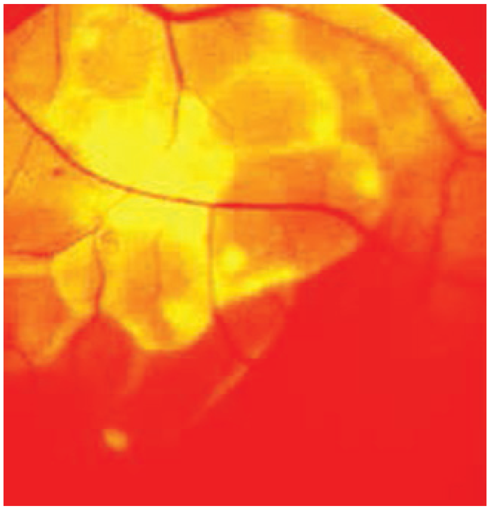

Figure 29.31 *Taenia crassiceps*. Retinal photograph showing budding cysticercus *in situ*. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of Renio Freeman.) doi:10.1128/9781555819002.ch29.f31

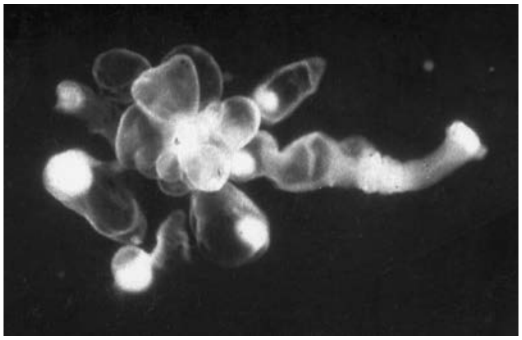
(Fig. 29.31). The patient reported having close contact with a young dog in the family. The larval form was removed alive but was not developed enough to have the characteristic scolex (Fig. 29.32). Western blot results provided sufficient indirect evidence to confirm the identity of the organism as *T. crassiceps*. After follow-up for 2 years, no further evidence of ocular or general infestations with this parasite could be found.

Another case was reported in a patient with malignancy (non-Hodgkin's lymphoma) (77). An 82-year-old woman was hospitalized due to progressive pain and swelling in the left forearm and back of the left hand. The symptoms had started 6 weeks earlier after she had fallen on her hand. She sustained soft tissue injury with lymphedema but without fracture. Despite massage therapy, the symptoms worsened. On examination, the patient was febrile (38°C). The left forearm and back of the hand were swollen, and the skin was tender to palpation. The patient had received the last of six cycles of chemotherapy with fludarabine phosphate and cyclophosphamide 2 months before admission. She had undergone radiotherapy of retrocardiac and iliac lymph nodes. Ultrasonography of the arm showed massive edema of subcutaneous tissue and in between muscles and tendons. Multiple, well-defined, cystic lesions were demonstrated intermuscularly. The findings were confirmed by magnetic resonance imaging tomography (Fig. 29.33). On the fifth day after admission, the patient developed a massive swelling of the forearm and an 8-cm lump on the back of the hand. The patient underwent emergency fasciotomy. Jelly-like tissue containing multiple spherical masses with diameters of up to 2 mm, similar to fish eggs, was discovered and removed from the subcutis, muscles, and tendons by multiple excisions. After therapy with praziquantel, the wounds healed, and there were no signs of recurrence for a period of 9 months follow-up.

Figure 29.32 *Taenia crassiceps* cysticercus after surgical removal from the eye. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of Renio Freeman.) doi:10.1128/9781555819002.ch29.f32



The method for obtaining antigenic extracts from *T. crassiceps* cysticerci and their cross-reactivity with *T. solium* cysticerci antigens have made them an interesting antigen source for diagnostic work. The use of 18- and 14-kDa *T. crassiceps* immunoaffinity-purified proteins for detection of anti-cysticercus antibodies in cerebrospinal fluid and/or serum samples by using an enzyme-linked immunosorbent assay system showed good performance and a high specificity for serum samples, dispensing with the use of confirmatory tests, such as immunoblotting, for checking specificity (78).

Trematodes

Alaria americana

Alaria americana is a trematode that is normally found in the intestines of wild mammalian carnivores such as wolves, foxes, raccoons, bobcats, and skunks. The eggs are passed in the stool, hatch in water, and invade freshwater snails of the genus *Helisoma*. Cercariae then leave the snail and infect frog tadpoles. The first case of disseminated human infection by the mesocercarial stage of this worm was found in a 24-year-old man in Canada who died 8 days after the onset of his illness (79). The infection was probably acquired through ingestion of inadequately cooked frogs, which serve as intermediate hosts for this

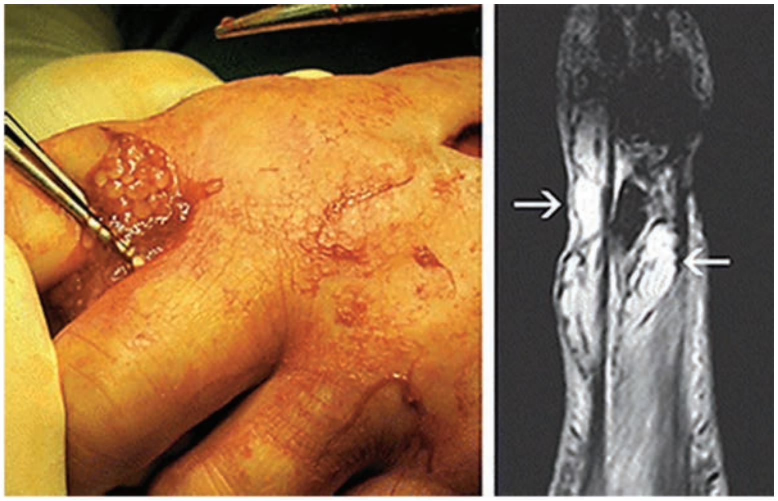


Figure 29.33 *Taenia crassiceps*. (Left) View of the base of the left index finger of the patient during surgery. Numerous fish spawn- or roe-like cysts were found, measuring approximately 3 mm in diameter. At the right upper quadrant a surgical cut in the back of the hand is visible, where further cysticerci were removed. (Right) T2-weighted magnetic resonance imaging tomography of the left forearm. Bright white areas correspond to parasitic infiltration (arrows). (Courtesy of reference 77.) doi:10.1128/9781555819002.ch29.f33

parasite. The infection was diagnosed by lung biopsy, and mesocercariae were found in the stomach wall, lymph nodes, liver, myocardium, pancreas and surrounding adipose tissue, spleen, kidney, lungs, brain, and spinal cord at autopsy (Fig. 29.34 and 29.35). Apparently, there was no host reaction to the parasites. Granulomas were present in the stomach wall, lymph nodes, and liver, but no worms were recovered from these sites.

Two cases of eye infections with mesocercariae of *Alaria* were found in unrelated Asian men who had unilateral decreased vision (80). Both patients had pigmentary tracks in the retina, areas of active and/or healed retinitis, and other signs of diffuse unilateral subacute neuroretinitis (Fig. 29.36). The worms were seen in the retinas and vitreous several years after the original infection was thought to have occurred. The probable source of infection was

Figure 29.34 *Alaria americana*. Living mesocercaria removed from a human liver at autopsy. (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of R. S. Freeman.) doi:10.1128/9781555819002.ch29.f34

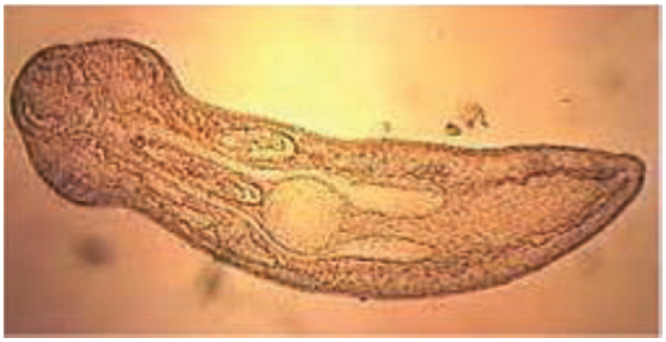

Figure 29.35 *Alaria americana*. (Top left) Mesocercaria in the patient's pons; (Top right) Mesocercaria in lung; (Lower) Magnified image from lung. (From A Pictorial Presentation of Parasites: A cooperative collection prepared and/or edited by H. Zaiman. Photograph courtesy of R. S. Freeman.)
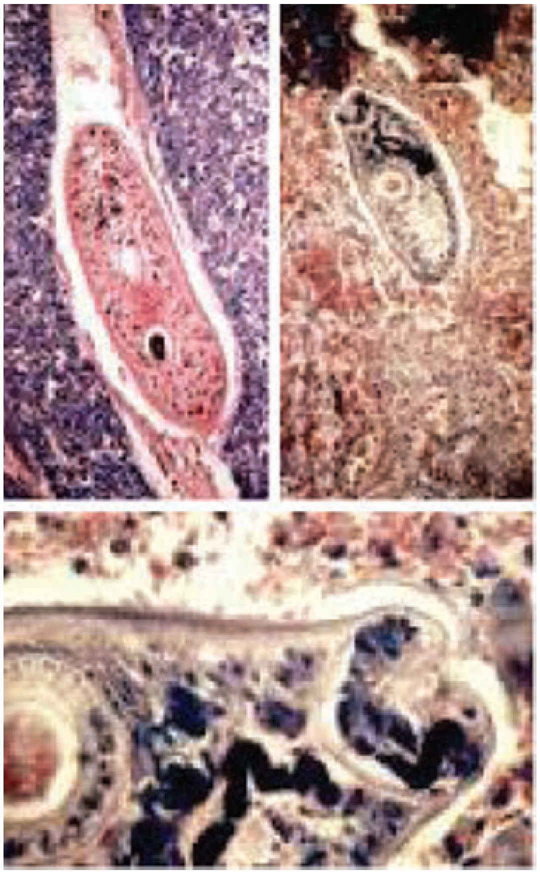
doi:10.1128/9781555819002.ch29.f35



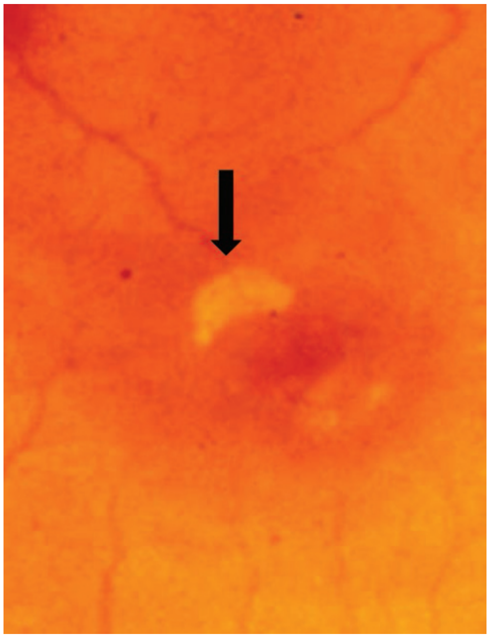


Figure 29.36 *Alaria americana*. Freely moving *Alaria* mesocercaria on the retina of the human eye (arrow). (From *A Pictorial Presentation of Parasites*: a cooperative collection prepared and/or edited by H. Zaiman; photograph courtesy of R. S. Freeman.) doi:10.1128/9781555819002.ch29.f36

ingestion of undercooked frogs' legs containing the infective stage. In addition to the prolonged intraocular infection, the mesocercariae caused diffuse unilateral subacute neuroretinitis, a condition thought to be caused only by intraocular nematode larvae.

Plagiorchis spp.

Plagiorchis spp. cause human intestinal infections that have been confirmed in the Philippines, Indonesia, Korea, Thailand, and Japan. The infection is acquired from the ingestion of grubs of certain insects thought to be the second intermediate host for this fluke. Ingestion of raw or poorly cooked freshwater fish containing the metacercariae was implicated in the case in Korea (Fig. 29.37) (81). Metacercariae obtained by an artificial ingestion technique used on freshwater fish were administered to a Sprague-Dawley rat; on day 8 postinfection, one *Plagiorchis muris* worm was recovered from the small intestine of the rat. Infections with multiple helminths from northeast Thailand have included *Plagiorchis harinasutai* as well as other unusual trematodes (82). Confirmation of these infections may be difficult since the eggs resemble those of *Opisthorchis viverrini* and *Clonorchis sinensis*.

Plagiorchis vespertilionis is generally considered a bat parasite and was reported for the first time in a human in 2007 (83). The patient was a 34-year-old male who lived in a coastal village in the Republic of Korea. Only one worm, 2.6 mm long and 0.7 mm wide, was recovered after praziquantel therapy and purging with magnesium salts. The fluke characteristics were as follows: a large body size, a sucker ratio of 1:1, a straight cirrus organ, a short distance between the ventral sucker and ovary, well-developed vitellaria, a uterus with descending and ascending loops, and fully developed eggs with an average size of 32.5 × 17.5 μm. The patient had frequently eaten the raw flesh of snakehead mullet and gobies that had been caught near his village.

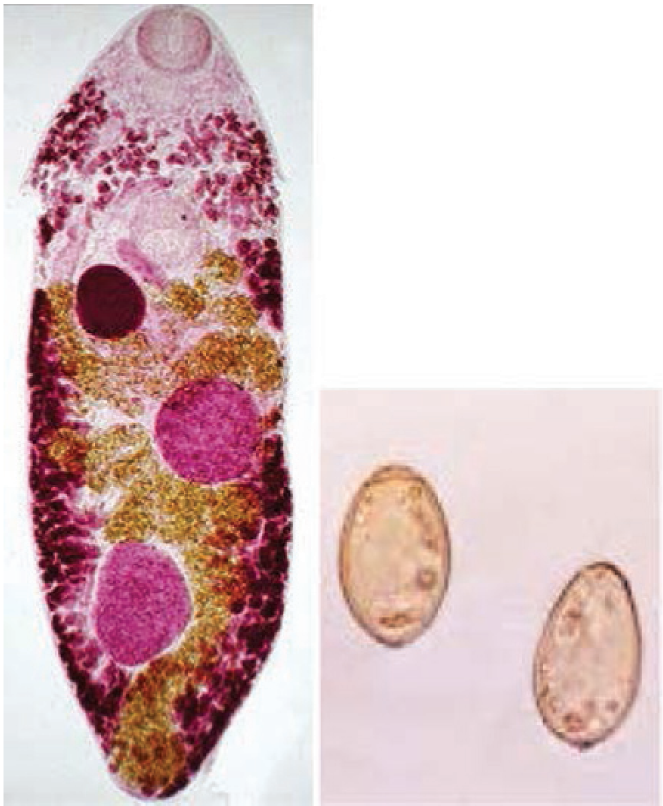

Figure 29.37 *Plagiorchis* spp. (Left) Adult fluke. (Right) Eggs that resemble those of *Opisthorchis viverrini* and *Clonorchis sinensis*. (From reference 81, with permission.) doi:10.1128/9781555819002.ch29.f37

Neodiplostomum seoulense

Neodiplostomum seoulense is known to infect humans in Korea and has been linked to snake consumption. The first human case was found in 1982 in a young man suffering from acute abdominal pain and fever, who had a history of consuming improperly cooked snakes 7 days prior to admission to a hospital (Fig. 29.38) (84). More human

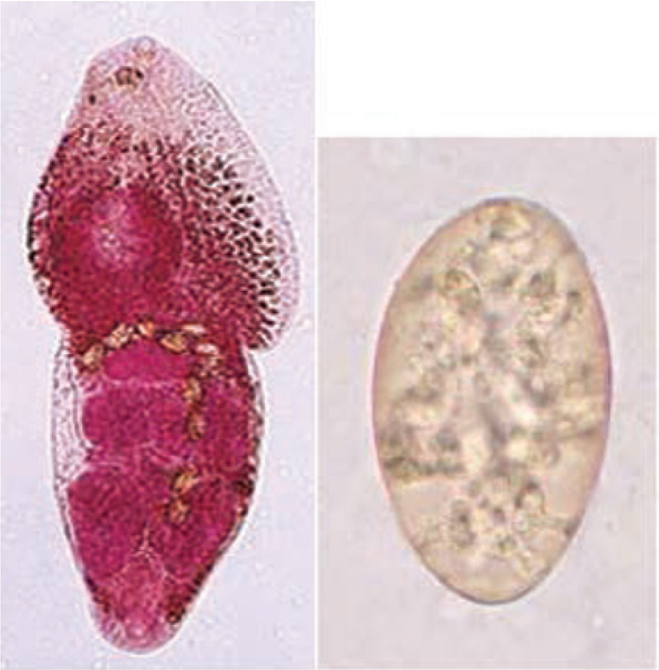

Figure 29.38 *Neodiplostomum seoulense*. (Left) Adult fluke. (Right) Eggs that somewhat resemble those of *Fasciola*, but can be differentiated on the basis of size. (From the Korean Society for Parasitology Web Atlas of Medical Parasitology, http://atlas.or.kr/index.html.) doi:10.1128/9781555819002.ch29.f38

cases were found among soldiers who had eaten raw snakes during their survival training. The parasites can normally be found in house rats, frogs and their tadpoles, and several terrestrial snakes. Symptoms have been noted in human infections and include epigastric pain, diarrhea, fever, and eosinophilia. The eggs can be differentiated from those of *Paragonimus*, *Echinostoma*, and *Fasciola*; they measure 81 to 102 μm long by 51 to 63 μm wide, are golden brown and bilaterally symmetrical, have an oblique opercular margin, and are immature when passed in the stool. In animal studies, this parasite appears to have the potential to kill most strains of mice by causing irreversible damage to their intestine (85). In follow-up studies of intestinal parasitic infections of the Army soldiers in Whachon-gun, Korea, additional cases of infection with *N. seoulense* were identified (86). Additional molluscan intermediate hosts for *N. seoulense* continue to be identified (87).

Spelotrema brevicaeca

Spelotrema brevicaeca has been reported to cause infections in humans in the Philippines. The eggs of these trematodes are suspected of causing lesions in the heart, brain, and spinal cord of patients dying of acute cardiac dilation. Although the complete life cycle is not known, the encysted metacercarial stage has been found in the crab *Cararius maenas*, which is the implicated food source. The adult worms are small, measuring 0.5 to 0.7 mm long by 0.3 to 0.4 mm wide, and have a spinose cuticle. The eggs are quite small (15 to 16 μm long by 9 to 10 μm wide). The infection can be confirmed by finding the eggs in stool or tissues or by finding adult worms in the stool after therapy.

Brachylaima sp.

Two 21-month-old children from the same rural area of South Australia presented 18 months apart with mild abdominal pain and diarrhea; trematode eggs of *Brachylaima* sp. were found in the stool (88). Therapy with praziquantel resulted in cessation of the symptoms and elimination of eggs in the stool. The life cycle involving the common house mouse, poultry, and introduced European helicid snails is well established in South Australia. Both children had been seen eating raw snails; examination of the snails from the environment confirmed that they were infected with metacercariae of this brachylaimid trematode.

In 1998, a 78-year-old woman presented with an 18-month history of intermittent diarrhea. Eggs of a brachylaimid trematode were seen in the stool for a week (Fig. 29.39). After she had been treated with praziquantel, a degenerated adult fluke was recovered from the stool and subsequently identified as *Brachylaima* sp. She lived in South Australia and consumed vegetables grown in her garden, which was infested with helicid snails. These snails, commonly infected with brachylaimid intermediate larval stages, are considered to be the source of human infection (89). This life cycle was established in the laboratory from eggs recovered from human feces in Australia (90). The differential features of *Brachylaima cribbi* n. sp. are the specificity for helicid snails as first and second intermediate hosts; characteristic ventral sucker and body cercarial chaetotaxy; and a long slender adult worm with equal size suckers in the first quarter of the worm, the ventral sucker occupying 41% of the body width, the uterus extending anterior to the ventral sucker, and the vitelline follicles falling short of the posterior margin of the ventral sucker. No other known *Brachylaima* species exhibits all of these features. *B. cribbi* n. sp. is the first brachylaimid known to have infected humans and is probably of European origin, as the intermediate host snails were all introduced into Australia from Europe (91).

Terrestrial edible land snails imported into northeast Spain from Algeria and South Africa and intended for human consumption via sale in public markets were analyzed to assess their contribution to geographic dissemination of *Brachylaima* species. From extensive data analysis, it appears that imported edible *Cornu aspersum* (*Helix*

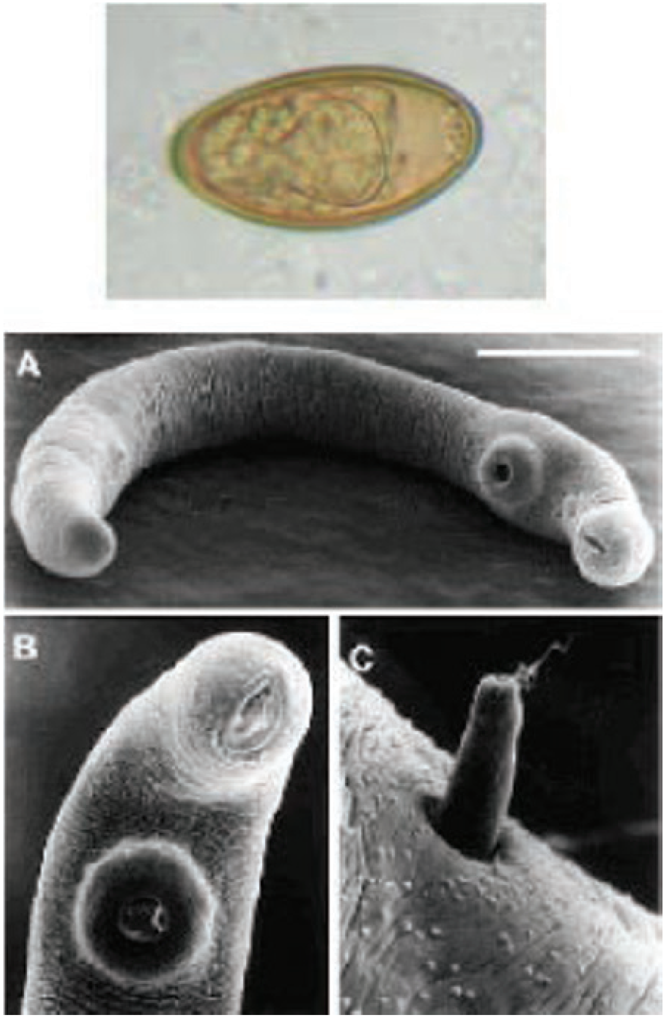

Figure 29.39 *Brachylaima cribbi*. (Upper) Egg; these eggs measure 26 to 32 µm long and 16 to 17.5 µm wide. (Lower) Electron microscopy: (A) Adult *Brachylaima cribbi* trematode (B) has two suckers and a spiny coat and (C) releases sperm from a genital pore. Scale bar, 0.5 mm. (Lower panels from reference 91, with permission.) doi:10.1128/9781555819002.ch29.f39

aspersa) snails could contribute significantly to the geographic spread of *Brachylaima* species by harboring infective metacercariae which could easily infect animals, given their heteroxenous character, and which could be enhanced by commerce in terrestrial snails (92).

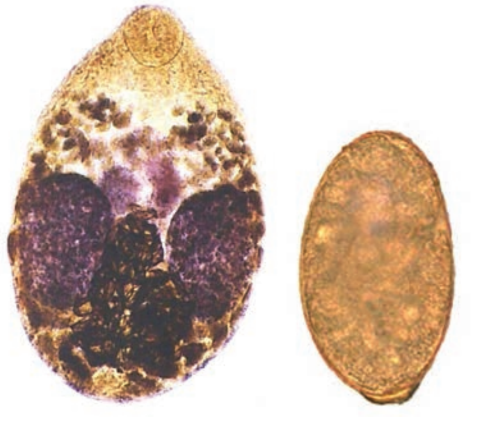
Heliciculture is an excellent alternative to obtain edible snails but its viability is seriously threatened by pathogens, including those involving *Brachylaima* sp. infecting *Cornu aspersum*. Study results confirm the importance of parasites in heliciculture and emphasize the need to prevent the entry of wild reservoirs into the farms and to rapidly remove the carcasses of dead snails from the reproduction units and fattening pens (93).

Nanophyetus (*Troglotrema*) *salmincola*

Human nanophyetiasis is a zoonotic disease recognized in the coastal Pacific Northwest of the United States and is caused by the digenetic trematode *Nanophyetus salmincola*. Ten stool-proven cases from the same geographic area have been identified; five presented with histories of gastrointestinal complaints and five had eosinophilia. Nine of 10 patients had histories of fish ingestion (incompletely cooked or home-smoked salmon or steelhead trout) and were treated with praziquantel. Prompt resolution of symptoms was seen following therapy. In all treated cases, subsequent stool examinations were negative for eggs of *Nanophyetus*. This infection may be most commonly encountered parasitic trematode endemic to North America, and the use of praziquantel in its treatment appears to be efficacious (94).

The trematode *N. salmincola* has been associated with poisoning in dogs eating raw salmon or trout on the Pacific coast of the United States and Canada. Normal hosts would include the coyote, fox, raccoon, mink, and lynx in North America and aborigines of eastern Siberia. The adult worms are quite small, measuring 0.8 to 1.1 mm long by 0.3 to 0.5 mm wide. The eggs are broadly oval, operculated, thick-shelled, and yellow and measure 60 to 80 µm long by 34 to 50 µm wide (Fig. 29.40). When salmon and trout, as well as other fish and the Pacific giant salamander, are eaten raw, metacercariae in their kidneys cause infection in the intestine of the definitive host (the dog). A rickettsia is associated with the fluke infection and has caused severe and fatal symptoms in dogs, coyotes, and foxes; this rickettsia is also possibly a human pathogen.

Figure 29.40 *Nanophyetus (Troglotrema) salmincola*. (Left) Adult fluke, which is quite small and measures 0.8 to 1.1 mm long by 0.3 to 0.5 mm wide. (Right) Egg, which is broadly oval, operculated, thick-shelled, and yellow and measures 60 to 80 µm long by 34 to 50 µm wide. (Courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch29.f40



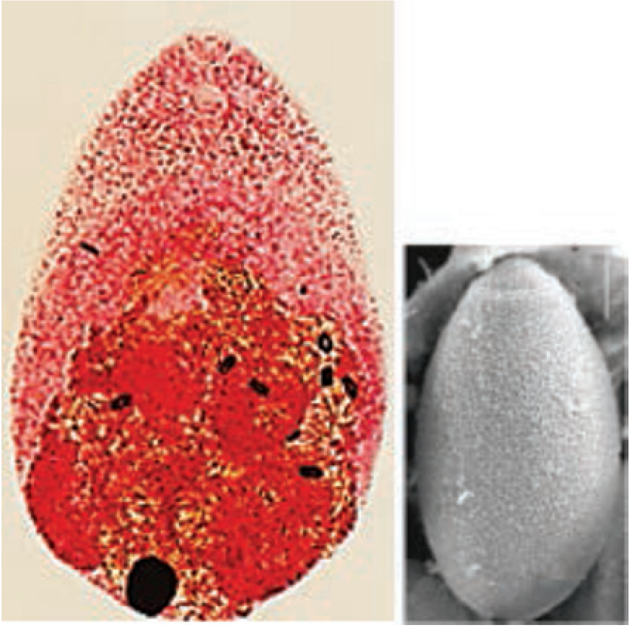
Praziquantel is the recommended therapy for human infection with this trematode.

Stellantchasmus falcatus

Stellantchasmus falcatus infections in two humans have been reported from Korea. Vague abdominal discomfort and hunger pains were reported. In both patients, adult worms were recovered in the stool after treatment with praziquantel (Fig. 29.41) (95–97). Both patients reported eating several kinds of brackish-water fish. Based on these case histories, the total number of human infections remains at 10 to date. This infection has also been documented in a patient eating raw mullet in Hawaii (98). In Thailand, several reports have also shown that *S. falcatus* metacercariae are found in freshwater fish, such as half-beaked fish (*Dermogenus pusillus*) and climbing perch (*Anabas testudineus*), both of which have high infection rates of *S. falcatus* endemic in northern Thailand. Molecular methods of identification have been developed for many of the smaller trematode infections.

Another infection linked to the ingestion of raw mullet is caused by a *Phagicola* sp. A patient in Brazil complained of mild intestinal pain, and examination of the stool specimen revealed trematode eggs in the stool. The patient also had an 8% eosinophilia. After treatment with praziquantel, the symptoms disappeared (99). Another infection linked to the ingestion of raw brackish-water or freshwater fish in Korea is caused by *Heterophyopsis continua*, a trematode whose consumption results in vague abdominal complaints (100).

Figure 29.41 *Stellantchasmus falcatus*. (Left) Adult fluke (courtesy of the CDC Public Health Image Library). (Right) Eggs, SEM view; these eggs measure 26 to 27 µm long and 12 to 13 µm wide with a narrow/small operculum (from reference 95, with permission). doi:10.1128/9781555819002.ch29.f41



Phaneropsolus spinicirrus, *Phaneropsolus bonnei*, and *Prosthodendrium molenkempi*

Members of the *Phaneropsolus* group of trematodes have been found in reptiles, birds, and mammals; however, only *Phaneropsolus bonnei* was reported to have been isolated from humans (Fig. 29.42) (101). Adult worms of *Phaneropsolus spinicirrus* sp. nov. were recovered after treatment with praziquantel followed by a magnesium sulfate purgative 5 h after medication. All stools passed over the next 48 h were preserved in 10% formalin and strained through a 120-mesh screen (200-µm openings), and the strained material was examined with a stereoscopic microscope. The adult worms were stained with Mayer's hemalum, dehydrated, cleared, and mounted for examination. Differences in morphologic characteristics that provided evidence for the identification of *P. spinicirrus* rather than *P. bonnei* included more conspicuous spines on the cirrus, a larger body and internal organs, conical spines on the tegument, an ovoid to bilobed ovary, and a large, V-shaped excretory bladder (102). The structure of the tegumental spines and the characteristic excretory bladder allow the two species to be recognized, even in unstained specimens.

The two small trematodes *Phaneropsolus bonnei* (Fig. 29.43) and *Prosthodendrium molenkempi* have been recovered in large numbers from the intestine of humans; however, there are no well-defined intestinal pathologic or clinical findings. These infections are documented and endemic among rural populations in northeastern Thailand and Laos; in some areas the prevalence is as high as 10 to 40%. Infection occurs after ingestion of raw or poorly cooked small fish contaminated with infected naiads (water nymphs of dragonflies). Diagnosis can be confirmed by finding adult worms or eggs in the stool; however, the eggs may be difficult to differentiate from each other and from those of *O. viverrini*. *O. viverrini* and several species of heterophyid and lecithodendriid flukes, which are endemic in two riverside localities in Laos, suggesting that the intensity of infection and the relative proportion of fluke species vary by locality along the Mekong River basin (103). Staining using a 1% (wt/vol) concentration of potassium permanganate for 1 min is useful in differentiating the egg surface morphology of *O. viverrini*, *Haplorchis taichui*, and *P. bonnei* eggs (104).

(Reprinted from reference 102 with permission.) doi:10.1128/9781555819002.ch29.f42

Haplorchis taichui

Haplorchis taichui is a minute human intestinal trematode that parasitizes the small intestine of humans and other mammals (Fig. 29.44). It is the smallest trematode reported from the Republic of Korea. Pathologic changes seen in three patients from Thailand include mucosal ulceration, mucosal and submucosal hemorrhages, fusion and shortening of the villi, chronic inflammation, and fibrosis of the submucosa (105).

An exceptionally high rate of infection (36%) has been identified in human populations on Mindanao Island, southern Philippines, and Lao PDR. The source of infection has been linked to consumption of raw or undercooked freshwater fish containing infective metacercariae. Clinical symptoms include upper abdominal discomfort or pain and loud gurgling noises produced by the movement of gas, fluid, or both in the alimentary canal, sounds which are audible at a distance. Other reported symptoms were nausea, chronic diarrhea, and weight loss. Symptoms rapidly resolved after treatment with praziquantel (106). The adult fluke is pyriform; eggs and the ventral sucker can generally be seen (106). Molecular testing has made detection of these small trematodes much easier.

Gymnophalloides seoi

Gymnophalloides seoi is a new human intestinal trematode that was first found in a Korean woman who complained of epigastric discomfort. This trematode is highly prevalent among the inhabitants of a seashore village on a southwestern island of the Republic of Korea. Normally, it is a parasite of shorebirds and is thought to be the only known species in the family *Gymnophallidae* that can infect humans. Various bivalves (clams) are known to serve as the first or second intermediate hosts for some of these trematodes. Symptoms are generally somewhat nonspecific and include abdominal pain, diarrhea, indigestion, anorexia, easy fatigability, and weakness. On the basis of fecal examinations, 70 (71.4%) of 98 patients were found to be infected with various intestinal parasites. *G. seoi* eggs were found in 48 (49.0%) of 98 patients. Individual worm burdens, as measured by collection of adult flukes after treatment and purgation, ranged from 106 to 26,373 specimens. The average number of worms per patient was 3,326. There were no sex- or age-related differences. This study indicates that *G. seoi* is a human intestinal trematode under natural conditions and does not represent just an accidental infection (107, 108). The eggs of *G. seoi* mea-

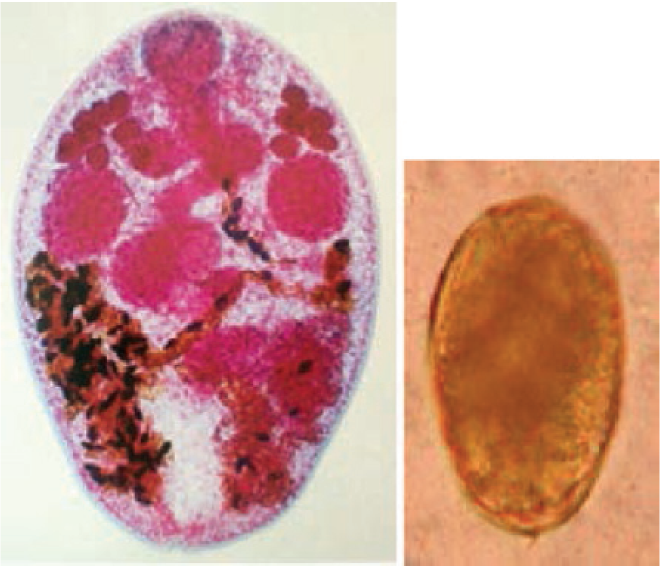


Figure 29.43 *Phaneropsolus bonnei*. (Left) Adult fluke, (Right) Eggs, which are quite small and measure 23 to 33 µm long by 12 to 18 µm wide. Figure 29.45 *Gymnophalloides seoi*. (Left) Adult fluke, which measures 0.4 to 0.5 mm by 0.2 to 0.3 mm—the smallest of all human trematodes reported in the Republic of Korea (courtesy of the CDC Public Health Image Library). (Right) Egg, which measures from 20 to 25 µm to 11 to 15 µm (from reference 107, with permission). doi:10.1128/9781555819002.ch29.f45

sure 19 to 25 µm in length (smaller than *C. sinensis*) and have a thin, transparent shell (Fig. 29.45). The adult worm measures approximately 0.4 mm long and 0.25 mm wide (Fig. 29.45).

Metorchis conjunctus (North American Liver Fluke)

A common-source outbreak of acute clinical illness among 19 people who ate raw fish (sashimi) prepared from the white sucker has been reported from Canada. The sashimi contained infective metacercariae of *Metorchis conjunctus* (Opisthorchiidae). The adult fluke lives within the biliary tree of the definitive host (Fig. 29.46). Symptoms included persistent upper abdominal pain, low-grade fever, high eosinophil counts, and increased liver enzyme levels with an obstructive pattern. After 15 days, trematode eggs were recovered in the stool specimens; morphologically they were identical to those of *O. viverrini*. The symptoms lasted several weeks, but the patients responded rapidly to therapy with praziquantel. Necropsy of golden hamsters that had been fed metacercariae from the fish revealed adult flukes identified as *M. conjunctus*. Apparently, this is a newly emerging human disease and represents the first report of a common-source outbreak of an acute illness

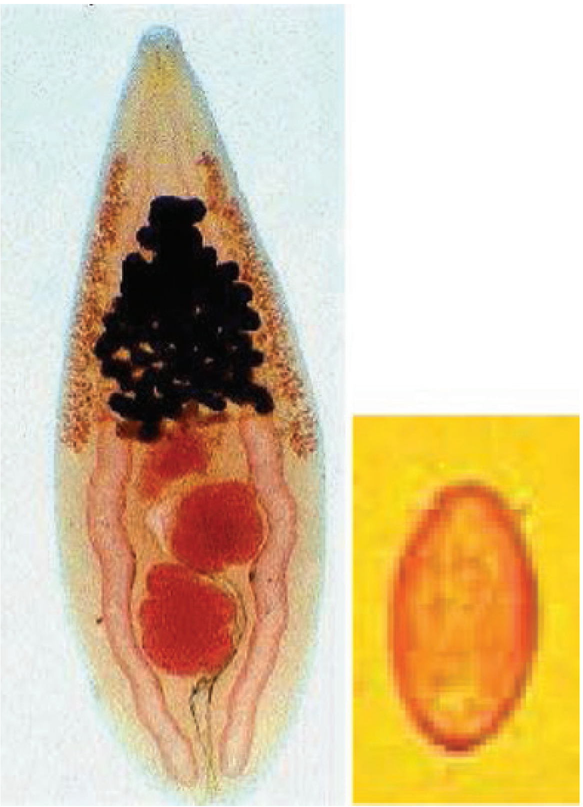

Figure 29.46 *Metorchis conjunctus*. (Left) Adult fluke (courtesy of University of Sydney, Centre for Veterinary Education, http://vetbook.org/wiki/dog/index.php/Metorchis_spp). (Right) Egg with very similar morphology to many of the other small trematodes (courtesy of McGill University/Canada, on Stanford's site, http://www.stanford.edu/group/parasites/ParaSites2006/Metorchiasis/diagnostics_management&therapy.html). doi:10.1128/9781555819002.ch29.f46

caused by these North American liver flukes (109). Although some patients remain asymptomatic, the prevalence in some isolated communities within Canada reaches 20% (110). Because fish parasites infecting humans within the United States and Canada are becoming more important and prevalent, a composite list has been provided (Table 29.2).

It is important to remember not only that opisthorchiid and heterophyid eggs are similar, but that great variability is present among eggs from the same species. Without evidence of the adult fluke or molecular diagnostic options, confirmation to genus/species can be difficult.

TABLE 29.2 Human parasites acquired from the ingestion of raw or poorly cooked fish[a,b]

Parasite	Fish host(s)
Nematodes	
Anisakis simplex	Salmonids, tuna, herring, mackerel, squid
Pseudoterranova decipiens	Cod, pollack, haddock
Eustrongylides spp.	Killifish, estuarine species
Dioctophyma renale	Freshwater fish, estuarine species
Cestodes	
Diphyllobothriurn latum	Salmonids, pike, perch, burbot
Diphyllobothrium dendriticum	Salmonids
Diphyllobothrium ursi	Salmonids
Diphyllobothrium spp.[c]	Salmonids
Schistocephalus solidus	Sticklebacks
Trematodes	
Troglotrema (*Nanophyetus*) *salmincola*	Salmonids
Metorchis conjunctus	White sucker
Haplorchis taichui	Freshwater fish
Plagiorchis spp.	Freshwater fish
Cryptocotyle lingua	Flounder
Amphimerus pseudofelineus	Freshwater fish

[a] Adapted from reference 110.

[b] Not every parasite mentioned in this table has been included in this chapter on unusual parasites; often case reports are very limited. Parasites listed in this table are geographically relevant to the United States and Canada, and the table does not include all parasites discussed in the chapter.

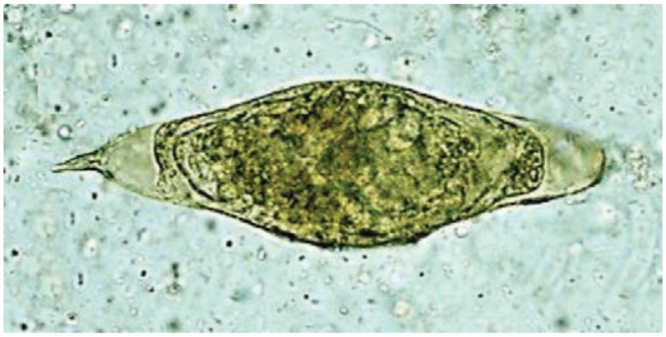
[c] The taxonomy of the genus *Diphyllobothrium* remains unclear.

Schistosoma mattheei

Schistosoma mattheei causes infections in sheep, cattle, and horses; human infections, which caused mild disease, have also been reported from South Africa. The eggs resemble those of *Schistosoma intercalatum*, have a terminal spine, and measure 120 to 180 µm in length (Fig. 29.47). Clinical specimens include urine and stool; eggs can be recovered in both. Although human infections tend to be mild, the effect of this infection on animals is more serious.

The pathology of human disease is similar to that seen in other schistosome diseases and can include egg granulomas in the large intestine and liver, mild hepatosplenomegaly, and granulomatous bowel disease. There tends to be coinfection with either *Schistosoma haemato-*

Figure 29.47 *Schistosoma mattheei*. Image of *Schistosoma intercalatum* egg (very similar to *S. mattheei*). doi:10.1128/9781555819002.ch29.f47



bium or *Schistosoma mansoni*. Patients may present with mild mucoid diarrhea in which blood is present, crampy abdominal pain, and general nonspecific complaints; many patients remain asymptomatic. Praziquantel is recommended for therapy.

Enzyme electrophoresis indicates that most, if not all, *S. mattheei* eggs passed in the urine in human infections derive from *S. mattheei* females *in copulo* with *S. haematobium* males. It appears that *S. mattheei* males do not reach sexual maturity in humans; however, the *S. haematobium* × *S. mattheei* males possibly do (111). Studies indicate that it is highly unlikely that *S. mattheei* and *S. haematobium* will evolve into a single species; it does not seem likely that the virulence of the parental species will be influenced (112).

Philophthalmus lacrimosus

Philophthalmus lacrimosus is an avian eye trematode, found primarily in the eyes of wild and domestic birds. A number of mammals, including humans, can serve as the intermediate as well as the definitive host; however, human cases are quite rare. In cases of conjunctivitis, one of the symptoms is the feeling of having a foreign body in the eye. In one patient from Mexico, a small live parasite was found in the connective tissue of the conjunctiva and was removed surgically (Fig. 29.48) (113). Another case has been reported from Thailand (114).

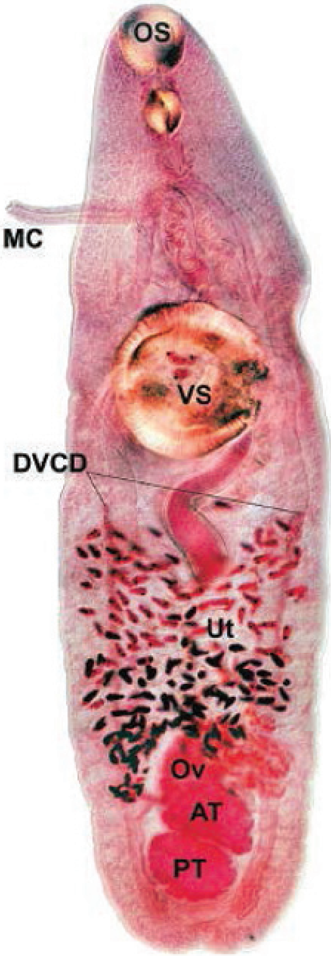


Figure 29.48 Adult *Philophthalmus lacrimosus* trematode. OS, oral sucker; MC, muscular cirrus; VS, ventral sucker; DVCD, distal vitellaria collecting duct; Ut, uterus; Ov, ovary; AT, anterior testis; PT, posterior testis. (Courtesy of Pinto RM et al, *Mem Inst Oswaldo Cruz* **100**:579–583, 2005.)
doi:10.1128/9781555819002.ch29.f48

Achillurbainia spp.

Achillurbainia spp. are trematodes (similar to *Paragonimus* spp.) that are normally found in the maxillary sinuses of the opossum. They have been isolated from humans. In one case of surgical inguinal hernia repair, massive numbers of small granulomata on the omentum and other peritoneal surfaces were found to contain trematode eggs like those of *Achillurbainia recondita* (115). *Achillurbainia* eggs and/or adult worms have been found in retroauricular cysts or abscesses in individuals in West Africa and Southeast Asia. Another case was reported from the United Kingdom in a 29-year-old Nigerian student (116). Trematode eggs were found in a neck lump aspirate that resembled *Paragonimus uterobilateralis* or *Achillurbainia*; based on clinical findings, *Achillurbainia* was chosen for the diagnosis.

Pentastomids

Armillifer spp., *Linguatula serrata*, and *Sebekia* spp.

The organisms are found in a separate phylum, Pentastomida, and are called tongue worms. Human infections have been reported from Africa, Europe, Asia, and the Americas (117). A representative life cycle is seen in Fig. 29.49. The pentastomids are a group of parasites classified between the arthropods and annelids (118).

When humans serve as the intermediate hosts, the infective larvae die *in situ*. However, when mature larvae (often encysted) are ingested, they may migrate from the stomach, attach themselves to nasopharyngeal tissues, develop into adult pentastomids, and produce symptoms of the halzoun syndrome. Symptoms include throat discomfort, paroxysmal coughing, sneezing, and occasionally dysphagia and vomiting (119).

Occasionally, pentastomid larvae infect the eye. Inflammation is minimal, and infection is probably the result of direct eye contact with water containing pentastomid eggs (120). In one case report, a 34-year-old woman in

Guayaquil, Ecuador, presented with a 2-month history of ocular pain on the right side, with conjunctivitis and visual difficulties due to the presence of a shadow (121). Apparently, when she lay down on her right side, her vision became clear. Examination revealed a mobile body in the anterior chamber of the eye; the body was removed, fixed, stained, and mounted for more detailed microscopic examination. The parasite was identified as a third-stage instar larval form of *Linguatula serrata*. This case represents the first report in Ecuador and South America.

A case of dermatitis in a 31-year-old Costa Rican woman was reported to be caused by a pentastomid larva belonging to the genus *Sebekia*, apparently the first reported case of infection of a human by this genus. The adult worms are parasites found in the respiratory tract of reptiles, and the larval forms are found in the viscera and muscles and along the spinal cord of freshwater fish. The patient, who was pregnant, presented with a "strong itch" in the lower right quadrant of her abdomen and a "biting sensation," particularly at night. She had a serpiginous burrow surrounded by an intense erythematous zone on her lower abdomen and a 30% eosinophilia. A white, active larva approximately 1 cm long was removed from the burrow. On the basis of morphologic features, including spines on the hooks and other details, the larva was identified as being in the genus *Sebekia*. Although there is no way to determine how the patient became infected or why the larva migrated to the skin as does larva migrans, the possibility of ingesting water containing eggs of the parasites or ingesting raw or improperly cooked fish could explain the infection (122).

Diagnosis is made by identifying the pentastomid in a biopsy specimen or at autopsy (Fig. 29.50 and 29.51). Treatment is usually not necessary; however, surgical removal of the parasite is recommended if the patient is symptomatic.

Acanthocephalans

Macracanthorhynchus hirudinaceus and *Moniliformis moniliformis*

The acanthocephalans (thorny-headed worms) were formerly included in the same phylum as the nematodes. These worms get their name from the proboscis, which is covered with spines. The life cycle is seen in Fig. 29.52 and adult worms are seen in Fig. 29.53.

Very few cases have been reported in the literature; however, reported symptoms include abdominal pain and tenderness, anorexia, and nausea. In some cases, adult worms were passed in the stool (Fig. 29.54) (123, 124).

In the past few years, a number of human infections with *Macracanthorhynchus hirudinaceus* have been reported from China. The infections have been primarily in children, probably acquired from the ingestion of raw beetles. Clinical manifestations include intestinal obstruction and perforation, with perforation occurring in over 200 cases. No eggs were found in the stool specimens of these patients. In many cases, the worms were recovered at surgery or autopsy. Signs and symptoms of infection with *Moniliformis moniliformis* include serious gastrointestinal pain, diarrhea, exhaustion, somnolence, and tinnitus; vomiting, jaundice, cough, and a protuberant abdomen have also been reported (125). In children, the infection has resulted in retarded development and irritability (38).

In some areas of China, eggs have been recovered in 16 to 60% of pigs examined (38); in pigs, this worm can be found worldwide. In Fig. 29.55, the proboscis of *M. hirudinaceus* is seen attached to the pig bowel wall. The

Parasitic Infections in the Compromised Host

Entamoeba histolytica
Free-living amebae
Blastocystis spp.
Giardia lamblia
Toxoplasma gondii
Cryptosporidium spp.
Cyclospora cayetanensis
Cystoisospora (*Isospora*) *belli*
Sarcocystis spp.
Microsporidia
Leishmania spp.
Strongyloides stercoralis
Plasmodium spp.
Babesia spp.
American trypanosomiasis
Crusted scabies

This chapter discusses some of the representative opportunistic organisms that can cause disease in immunocompromised patients. Any parasitic infection in the immunocompromised host may cause more severe symptoms; however, the organisms presented in this chapter have been identified as causing severe disease in this population.

The body has three types of host defense mechanisms: surface and mechanical factors, the humoral immune system, and the cellular immune system. Within these three groups, further distinction can be made between first-line (nonspecific) innate immunity and second-line (specific) adaptive immunity. By definition, a compromised host is one in whom normal defense mechanisms are impaired (e.g., AIDS), absent (e.g., congenital deficiencies), or bypassed (e.g., penetration of the skin barrier). These patients are becoming more common in most medical facilities and represent a growing problem in terms of diagnosis and subsequent therapy.

As seen in Table 30.1, first-line surface and mechanical factors include the skin, the cough reflex, ciliary motion (respiratory epithelium), and flushing action (urine); secondary defense mechanisms include immunoglobulins such as IgA. In the humoral portion of the immune system, first-line defenses include complement, lysozyme, fibronectin, and interferon; secondary defense mechanisms include antibodies such as IgM and IgG. The cellular portion of the immune system includes first-line defenses such as phagocytes (polymorphonuclear leukocytes [neutrophils and eosinophils] and monocytes) and natural killer cells (T cells); the second line of defense is defined as cell-mediated immunity. Specific problems and potential causes that can arise include penetration of the skin barrier (needle penetrations, burns); splenectomy (impaired IgM antibody production); aspiration of stomach contents, impaired cough reflex, impaired microbicidal clearance by alveolar macrophages, defects in complement activity, etc. (alcoholism); neutropenia (use of immunosuppressive drugs); problems with inhibited phagocytosis (rheumatic diseases); neutropenia, cell-mediated immunity defects, and antibody response defects (renal failure); skin and mucous membrane defects due to poor protein production as well as diminished IgA levels in the gut (malnutrition); and diminished humoral and cellular immunity defenses (AIDS, other underlying infectious diseases). To determine possible host defense defects, a number of procedures can be used (Table 30.2).

doi:10.1128/9781555819002.ch30

TABLE 30.1 Host defense mechanisms

Immunity type	Factor		
	Surface and mechanical	**Humoral (antibody dependent)**	**Cellular (antibody independent)**
Nonspecific	Skin (intact) (intravenous lines, obstruction of ureters, bronchi) Cough reflex Ciliary motion in respiratory epithelium Flushing action (urine)	Complement Lysozyme Fibronectin Interferon	Phagocytes (neutrophils) Chemotaxis Phagocytosis (monocytes, eosinophils) Natural killer cells
Specific	Immunoglobulins (IgA) (antibody found in secretions)	Antibodies B cells (IgG, IgM) (found in serum and extravascular spaces) IgE (affinity for mast cells, basophils, and eosinophils)	Cell-mediated immunity Sensitized cells (cytotoxic T cells, activated macrophages, natural killer cells)
Additional comments		IgG and IgM fix complement; initiate complement-mediated lysis of the target cell. IgG and IgE bind to macrophages, eosinophils, and mast cells via the Fc portion and to the target cell via the Fab portion	Macrophage functions include detection of organism invasion; restriction of organism spread; recruitment of immune cells; action as accessory cells in lymphocyte activation and as effector cells in cell-mediated immunity

Humans have very effective defense mechanisms to protect themselves against foreign invaders. One system consists of surface and mechanical barriers, pH, temperature, phagocytosis, and nonspecific inflammation (innate resistance). The other system is induced and includes specific products that recognize foreign invaders (adaptive immunity). The two major components of the adaptive immune response are humoral (antibody) and cellular (sensitized cells); B lymphocytes (B cells) are responsible for the humoral response, and T lymphocytes (T cells) are responsible for the cellular response. The human immune system is very complex, with different classes of antibody and various subsets of T cells that have different functions as immune effectors. Unfortunately, the immune system is not always protective and under certain circumstances can be directed toward the human body itself, not the foreign invader.

Within the context of this background information on the immune system, various parasitic infections are discussed, with emphasis on infections in the immunocompromised patient. With the continued increase in the number of these patients, every institution will eventually provide medical care for someone in this category and

TABLE 30.2 Selected procedures for determination of host defense defects[a]

Defect	Procedure	
	Screening	**Diagnostic**
Inflammation	White blood cell count and differential C_{50} hemolytic complement	Complement levels Inhibitor levels Complement-fixing immune complexes
Phagocytosis	White blood cell count and morphology Immunophenotyping	Phagocytic index Bactericidal tests Nitroblue tetrazolium test Cell surface glyproteins Lymph node biopsy
Humoral antibody	Immunoelectrophoresis Immunoglobulin levels in serum	IgE levels in serum Secretory IgA B-cell levels, subsets Isohemagglutinins Purine-metabolizing enzymes
Cellular sensitivity	Skin tests Quantitation of T cells and T-cell subsets	Sheep erythrocyte rosettes Mitogen responses Lymph node biopsy CT, MRI of thymus

[a] Adapted from Sell S, *Immunology, Immunopathology, and Immunity*, 6th ed, ASM Press, Washington, DC, 2001.

laboratories will continue to perform more procedures for the diagnosis of opportunistic infections.

Routine diagnostic procedures for the diagnosis of parasitic infections in the compromised host are presented in Table 30.3, and clinical findings in normal and compromised hosts are described in Table 30.4. Molecular methods for diagnosis continue to be developed, including some newer gastrointestinal panels. A 19-plex laboratory-developed gastrointestinal pathogen panel (GPP) using Luminex xTAG analyte-specific reagents (ASRs) has been validated (xTAG Gastrointestinal Pathogen Panel; Luminex, Inc., Austin, TX), which simultaneously screens directly in fecal specimens for diarrhea-causing pathogens, including bacteria, viruses, and parasites (*Giardia lamblia*, *Cryptosporidium* spp., and *Entamoeba histolytica*). The BioFire FilmArray Gastrointestinal Panel is another FDA-approved multiplex PCR test that can simultaneously detect 22 gastrointestinal pathogens in about an hour (BioFire FilmArray Gastrointestinal Panel; BioFire Diagnostics, Salt Lake City, UT). The panel includes *Cryptosporidium*, *Cyclospora cayetanensis*, *Entamoeba histolytica*, and *Giardia lamblia*, along with a number of bacteria and viruses.

Parasitic infections in individuals with a normal immune system are not uncommon. Not only are they unpleasant and debilitating, but they can be fatal. However, individuals with immune system defects have an abnormally high susceptibility to infections with nonvirulent and minimally pathogenic organisms. Many of these individuals contract parasitic infections in addition to suffering numerous infectious episodes with bacterial, viral, and fungal organisms. Immune system deficiencies can be attributed to congenital absence, abnormal development, malignancy, therapy with cytotoxic drugs, irradiation, or infections, such as with HIV. Of particular interest are patients with AIDS.

Although any parasitic infection may be more severe in the immunosuppressed host, certain organisms tend to produce greater pathologic sequelae in these patients, while other organisms occur with a higher frequency in individuals with certain immune system deficiencies. It is important for the laboratorian and clinician to be aware of problems that these organisms can cause in compromised patients and to be aware of the proper diagnostic techniques and their clinical relevance.

Entamoeba histolytica

Entamoeba histolytica is the cause of amebiasis (Tables 30.3 and 30.4; Fig. 30.1). Two types of disease, reviewed here, are particularly helpful when one is discussing serologic test results. "Intestinal disease" indicates that the organisms are confined to the gastrointestinal tract, with no gross or microscopic invasion through the mucosal lining. "Extraintestinal disease" denotes invasion of the mucosal lining of the gastrointestinal tract, the organisms having passed through the mucosal lining, entered the bloodstream, and been carried to other body tissues, particularly the liver. In patients in whom the organisms have begun to invade the mucosal lining, interpretation of serologic tests may be difficult. In this situation, the terms "intestinal" and "extraintestinal" do not strictly apply. These differences should be understood when one is discussing the clinical interpretation of serologic tests for amebiasis.

Although a large number of people throughout the world are infected with this organism, only a small percentage develop clinical symptoms. Morbidity and mortality due to *E. histolytica* vary depending on the geographic area, organism strain, and patient immune status. Recognition of *Entamoeba dispar*, *Entamoeba moshkovskii*, and *Entamoeba bangladeshi* in humans has further complicated the diagnosis of *E. histolytica*. since these species are morphologically indistinguishable unless ingested red blood cells (RBCs) are found within the trophozoite cytoplasm (true pathogen, *E. histolytica*).

Research emphasis has been on the molecular differences between pathogenic *E. histolytica* and nonpathogenic *E. dispar*. However, the molecules considered the most important for host tissue destruction (amebapore, galactose/*N*-acetylgalactosamine-inhibitable lectin, and cysteine proteases) can be found in both organisms. Pathogenicity differences may be related to the composition and properties of the surface coat components (or pathogen-associated molecular patterns) and the ability of the innate immune response to recognize these components, thus eliminating the organisms. Targets of the host immune system modulation appear to be both neutrophils and macrophages, which are unable to abort the infection even when present at the site of the lesion. The total body of evidence supports the classification of the pathogenic *E. histolytica* and the nonpathogenic *E. dispar* as two distinct species.

Intestinal Disease

In patients with intestinal disease, symptoms range from none to acute or chronic amebic colitis, both of which can mimic inflammatory bowel disease. A number of factors influence the outcome of an amebic infection, including the host immune system response. At one time, it was thought that invasive strains were found only in tropical areas of the world; however, it is now apparent that there are strains within the United States that cause hepatic abscess in patients who have no history of travel outside the United States. Groups at highest risk of having serious sequelae are children, the elderly, the malnourished, and patients receiving corticosteroid therapy. The ascending

TABLE 30.3 Diagnosing parasitic infection in the compromised host[a]

Organism	Size	Specimen	Procedure[b]	Method of examination	Laboratory findings	Comments[c]
Entamoeba histolytica Intestinal disease Note: Pathogenic *E. histolytica* can now be differentiated from nonpathogenic *E. dispar* using immunoassays; morphologic characteristics are identical, *E. histolytica* containing RBCs in the trophozoite could be identified as pathogenic true *E. histolytica*.	Trophozoite: usual range, 15–20 µm; range, 10–60 µm. Cyst: usual range, 12–15 µm; range, 8.5–20 µm. Note: These sizes refer to organisms seen on the permanent stained smear. There may be as much as 1–1.5 µm of shrinkage of organisms as a result of reagents	Stool	O&P examination (minimum of concentration and permanent stained smear) IAs	Concentration (high dry, ×400) IA depends on format	Trophozoites or cysts Presence or absence of antigen	A series of 3 stools (collected every other day) is recommended for the O&P examination Can detect *Entamoeba histolytica* or the *E. histolytica*/*E. dispar* group
		Sigmoidoscopic biopsy or scrapings	Permanent stained smear and routine histologic test	Permanent stain (oil immersion, ×1,000)	Trophozoites	The permanent stained smear is mandatory for a complete O&P examination
		Serum	Amebic serologic tests	IHA, IFA, CIE, ID, ELISA	Not recommended for intestinal disease; negative or possible low titer, indicating present or past exposure	At least 2 different serologic tests (methods) should be performed so results can be compared
				Radiographic studies	Barium	Intestinal abnormalities (may also be normal)
Extraintestinal disease	Trophozoite stage only	Stool	O&P examination	See above	No organisms recovered in about 50% of cases	There may be no evidence of GI disease before or during extraintestinal invasion
		Sigmoidoscopic biopsy or scrapings	Permanent stained smear and routine histologic test	See above	No organisms recovered in about 50% of cases	
		Serum	Amebic serologic tests (antibody); IHA, EIA reagents available	See above	Positive titers may be lower in compromised patients	At least 2 serologic tests (methods) should be performed so that results can be compared
			Scans		Evidence of space-occupying lesion	
Free-living amebae						
Naegleria fowleri	Biphasic (amebic and flagellate forms). Trophozoite: usual range, 8–15 µm, amebic form, lobate pseudopodia. Cyst: not present in tissue, small, smooth, rounded	CSF	Centrifugation, wet or stained preparation; agar plates with bacterial overlay (culture)	Wet: low (×100) and high dry (×400); stained: oil immersion (×500, ×600, or×1,000); culture: low (×100) and high dry (×400) on material from culture plate surface	Trophozoites in specimens; trophozoites and cysts in culture	Since all these organisms are normally free-living, they will survive shipment via mail to any laboratory for subsequent examination and/or culture; various culture temperatures are recommended in different situations

Acanthamoeba spp.	Trophozoite: large, 15–25 µm, amebic form, spiky pseudopodia. Cyst: present in tissue, large with wrinkled double wall.	CSF, eye specimens, cutaneous biopsy	Centrifugation, wet or stained preparation; agar plates with bacterial overlay (culture); histology	As above, histology and routine microscopic exam	Trophozoites and/or cysts in specimens and culture	Agar plates with bacterial overlay (culture) more sensitive than wet preparations
Balamuthia mandrillaris	Trophozoite: large, 12–60 µm, amebic form, fingerlike pseudopodia. Cyst: large, 6–30 µm, with wrinkled double wall.	CSF, eye specimens, cutaneous biopsy	Centrifugation, wet or stained preparation; cell culture only, will not grow on routine agar culture with bacterial overlay; histology	All of the above, including cell culture if available	Trophozoites and/or cysts in specimens and cell culture	Becoming more widely recognized as causing same types of disease as *Acanthamoeba* spp.
Sappinia sp.	Trophozoite: 40–80 µm, oblong or ovoid; flattened with wrinkles on the surface. Cyst: 15–30 µm.	CSF, biopsy, MRI, PCR	Centrifugation, wet or stained preparation; agar plates with bacterial overlay (culture); histology	As above, histology and routine microscopic exam	Trophozoites and/or cysts in specimens and culture	Can be distinguished from other amebae by the presence of a distinctive double nucleus in which the 2 nuclei are closely apposed with a central flattening; 2 nucleoli
Blastocystis spp.	Vacuolar forms usual range, 3–120 µm. Human (5–15 µm)	Stool	O&P examination (minimum of concentration and permanent stained smear)	Concentration (high dry, ×400); permanent stain (oil immersion, ×1,000)	Central body form (vacuolar); other forms may be present, but they are difficult to identify	Central vacuole fills 70–90% of cell; giant cells with multiple nuclei occasionally seen; cytoplasm and organelles limited to thin peripheral rim (may be difficult to see in wet mounts); most common form seen in microscopy of fecal specimens
Giardia lamblia	Trophozoite: usual range, 10–12 µm long by 5–10 µm wide. Cyst: usual range, 11–14 µm long by 7–10 µm wide	Stool	O&P examination Immunoassays	Concentration (high dry, ×400); permanent stain (oil immersion, ×1,000) Depends on format	Trophozoites or cysts (may not always be detected) Presence or absence of antigen or actual organisms	The parasite may not be recovered from stool even after 4 or 5 examinations on different specimens. This does not mean that the diagnostic techniques are inadequate or that the organisms are missed by inexperienced personnel. Additional diagnostic techniques (including biopsy) may have to be used. IAs available and now being used as orderable tests (FA, EIA, rapid cartridge formats).
		Duodenal aspirate	Wet preparations, permanent stained smears	See above	Trophozoites	

(continued)

TABLE 30.3 Diagnosing parasitic infection in the compromised host[a] *(continued)*

Organism	Size	Specimen	Procedure[b]	Method of examination	Laboratory findings	Comments[c]
		Entero-Test capsule	Wet preparations, permanent stained smears	See above	Trophozoites	
		Biopsy	Routine histologic tests and special stains		Possible upper GI tract changes and/or trophozoites	
		Serum	Serologic tests	Experimental (not generally available)		
Toxoplasma gondii	Tachyzoite: 4–6 µm long by 2–3 µm wide. Bradyzoite: individual tissue cysts may contain many hundreds of organisms. Cyst: may range up to 50–75 µm.	Serum	Serologies	IHA, IFA, ELISA, Sabin-Feldman dye test	Results are often sufficient to confirm diagnosis	Patients with positive IgM serologic test results may have Epstein-Barr virus infections. There may be nonspecific stimulation of other antibody-producing cells. Although organism isolation techniques with animals and/or tissue culture may be used, these results must be evaluated within the context of the total clinical picture.
		Biopsy	Routine histologic test		Possible recovery of bradyzoites	Organism may not be etiologic agent of disease
			Tissue culture or animal isolation		Possible recovery of tachyzoites	Organism may not be etiologic agent of disease
		Spinal fluid	Organism isolation (direct, tissue culture, or animal isolation)		Presence of tachyzoites	Considered confirmatory
			Serologic tests		Confirmatory if higher in CSF than in serum	Rare finding
Cryptosporidium spp.	Developmental stages within brush border of intestine. Cells: 1–2 µm. Oocysts in stool: 4–6 µm	Stool	Acid-fast stains (may need modified KOH digestions)	Permanent stain (high dry, ×400; confirm on oil immersion ×1,000)	Oocysts visible	Regardless of staining technique used on stool, the more normal the stool specimen (formed), the greater the chances that artifacts will present problems in identifying organisms and fewer organisms will be present. Specimens representing classic diarrhea will allow easier recovery and ID of organisms. Numbers of organisms will vary from day to day.

			IAs	Depends on format	Presence or absence of antigen or actual oocysts	ELISA, FA, or rapid cartridge format
		Intestinal mucosal biopsy	Routine histology	H&E stain	Developmental stages (1 μm) along brush border, other organs	
			Electron microscopy	Routine EM	May see developmental stages or possibly oocysts	Very specific, but not very sensitive
		Serologies		Experimental only (not generally available)		Used for epidemiologic studies
Cyclospora cayetanensis	Oocyst: 8–10 μm	Stool	Acid-fast stains (modified)	Permanent stain (high dry, ×400; confirm on oil immersion, ×1,000)	Oocysts visible	Owing to morphologic similarities to *Cryptosporidium* spp., it is important to measure the oocysts. There is tremendous staining variability of the oocysts with acid-fast stains (from clear to deep purple). Oocysts appear wrinkled. Oocysts in stool are unsporulated and do not contain any internal definition or structure.
			Wet preparation examinations; oocysts will autofluoresce	Green with 450–490 DM excitation filter, blue with 365 DM excitation filter. Wet preparation (high dry, ×400).	Oocysts visible as green or blue circles (interior of oocyst does not fluoresce) (1+ to 3+)	Used as a screening method
		Intestinal mucosal biopsy	Routine histologic test	H&E stain	Organisms resembling coccidia found in jejunal enterocytes	Developmental location will differentiate from *Cryptosporidium* spp.
			EM	Routine EM	May see developmental stages or possibly oocysts

TABLE 30.3 Diagnosing parasitic infection in the compromised host[a] *(continued)*

Organism	Size	Specimen	Procedure[b]	Method of examination	Laboratory findings	Comments[c]
Cystoisospora (*Isospora*) *belli*	Oocyst: 30 by 20 µm, development within the intestinal mucosal cells; oocysts in stool range from undivided mass of protoplasm to those containing fully developed sporocysts and sporozoites	Stool	O&P examination (concentration is important; PVA distorts morphology)	Concentration (low, ×100, and high dry, ×400)	Oocysts (may be in various stages of development)	Although these organisms are thought to be rare, some workers speculate that oocysts are occasionally missed during a stool examination. There is also the possibility that a biopsy specimen is positive while the stool examination is negative.
			Permanent stained smear	Acid-fast stains	Oocysts (as above). High dry, ×400.	
		Intestinal mucosal biopsy	Routine histologic test	H&E stain, high dry (×400)	Developmental stages within the mucosal cells	
Sarcocystis suihominis, *S. bovihominis*	Oocyst thin walled, contains 2 mature sporocysts, each with 4 sporozoites; sporocysts are 9–16 µm long by 7.5–12 µm wide	Stool	O&P examination (concentration important; PVA may distort morphology)	Concentration (low, ×100, and high dry, ×400)	Oocysts or sporocysts	Not commonly seen; size can overlap that of *C. belli*
Other *Sarcocystis* spp.	Shapes and sizes of skeletal and cardiac muscle sarcocysts vary	Tissue biopsy	Routine histology	H&E stain (high dry, ×400)	Developmental stages within tissue cells	Sarcocysts contain several hundred to thousands of trophozoites, each measuring 4–9 µm wide by 12–16 µm long; sarcocysts may be divided into compartments by septa (not seen in *Toxoplasma* cysts)
Microsporidia[d] (*Anncaliia*, *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, *Trachipleistophora*, *Microsporidium* spp., *Vittaforma*, *Tubulinosema*)	Spore, 1–4 µm; dividing forms within epithelial cells	Tissue biopsy	Routine histologic test	Methenamine silver, acid-fast, PAS-positive granule, Giemsa, H&E	Spores, dividing forms	It is sometimes difficult to find and identify the organisms by routine histologic techniques. Because of the difficulties in identification at the light microscopy level, EM methods have been recommended. Organisms have been identified in stool, although current procedures may be somewhat difficult to interpret
			EM	Routine EM	Spores, dividing forms	Specific but insensitive
		Stool	Permanent stained smear	Modified trichrome	Spores	Artifacts confusing
			EM Direct detection methods	Routine EM IFA; not yet available commercially	Spores	Specific but insensitive

		Serologic sample	IFA, CF, microagglutination	Experimental (not generally available)	Titers	
Leishmania spp.	Amastigotes in tissue measure 1–3 µm; tend to appear larger when released from cells, such as a touch or squash preparation; will appear as dots within the cells in routine histology preparations	Blood specimen (looking at buffy coat cells); tissue biopsy (bone marrow most common)	Buffy coat preparations, centrifugation, smear preparation; smears, culture (Novy-MacNeal-Nicolle medium) of bone marrow aspirates	Microscopic examination (high dry, ×400 power and ×1,000 oil immersion)	Presence of amastigotes in macrophages and/or tissues; presence of promastigotes (motile, flagellated) in culture	Multiple specimens may be required; cultures must not become contaminated or results may represent a false negative; controls must accompany all patient cultures
Strongyloides stercoralis	Larval stage: 180–380 by 14–20 µm, in feces; larvae (rhabditiform) have a short buccal cavity and a prominent genital primordium; both noninfective and infective larvae, adults, and eggs may be found in duodenal specimens	Stool	O&P examination (concentration important)	Direct smears and concentration (low, ×100; confirm on high dry, ×400)	Rhabditiform larvae (infective filariform larvae may also be found)	Caution should be used when working with fresh specimens that may contain infective filariform larvae. *Strongyloides* infections may be difficult to diagnose from stool specimens. Examination of material from the duodenum may be necessary, and concentrations or cultures can also be used.
		Duodenal aspirate	Baermann concentrate, Harada-Mori and petri dish cultures	As above	As above	
			Wet preparations (direct smears)	As above	Larvae (usually rhabditiform)	
		Entero-Test	Wet preparations (direct smears)	As above	Larvae (as above)	
Plasmodium spp.	Young rings may be missed without use of the 100× oil immersion objective	Blood	Thick and thin stained blood films	1,000× objective for minimum of 300 fields, each blood film	Various stages of the life cycle	Parasitemias may be higher than normal in HIV coinfections; do not tend to see rings outside of the RBCs
Babesia spp.	Ring forms may be missed without use of the 100× oil immersion objective; may mimic *P. falciparum* ring forms	Blood	Thick and thin stained blood films	100× objective for minimum of 300 fields, each blood film	Ring forms, may or may not see Maltese cross configuration	Parasitemias may be higher than those seen in malaria infections; may see rings outside of the RBCs
Trypanosoma cruzi	Trypomastigotes require 40× or 100× objectives	Blood, CSF	Thick and thin stained blood films; buffy coat films	100× objective for minimum of 300 fields, each blood film	Trypomastigotes	May also find organisms in histologic preparations (cardiac myopathy, GI tract myopathy)

(continued)

TABLE 30.3 Diagnosing parasitic infection in the compromised host[a] *(continued)*

Organism	Size	Specimen	Procedure[b]	Method of examination	Laboratory findings	Comments[c]
Crusted scabies (*Sarcoptes scabiei*)	Mites are microscopic; live in cutaneous burrows where female deposits eggs; mites range from 215 to 390 µm in length; eggs are 170 µm long by 92 µm wide; fecal pellets are yellow-brown	Skin scrapings	Use skin-scraping technique (see chapter 9)	Prepare slides of skin-scraping material and examine microscopically using low power (×100) and high power (×400)	Mites, eggs, or scybala (fecal pellets) may be present	Highly infectious; most common skin sites are interdigital spaces, backs of the hands, elbows, axillae, groin, breasts, umbilicus, penis, shoulder blades, small of the back, buttocks; may see kerotic excrescences on the body; itching may be absent.

[a] CF, complement fixation; CIE, counterimmunoelectrophoresis; EIA, enzyme immunoassay; ELISA, enzyme-linked immunosorbent assay; EM, electron microscopy; FA, fluorescence assay; GI, gastrointestinal; H&E, hematoxylin and eosin; IA, immunoassay; ID, immunodiffusion; IFA, immunofluorescent assay; IHA, indirect hemagglutination assay; MRI, magnetic resonance imagery; O&P, ova and parasite; PVA, polyvinyl alcohol; RBCs, red blood cells.

[b] Some parasites (*Giardia, Entamoeba histolytica, Cryptosporidium, Cyclospora*) are now being detected with molecular PCR panels (automated); additional organism targets are currently being developed.

[c] The use of immunoassays for the direct and indirect detection of some of these parasites has become much more common. Reagents are available for *Entamoeba histolytica/E. dispar*, *Entamoeba histolytica*, *Giardia lamblia*, *Cryptosporidium* spp., and the microsporidia (not currently available within the United States).

[d] This genus has been reported in humans; organisms that have not yet been classified to genus have been placed in the genus *Microsporidium*, which has now been accepted as a genus name rather than a "catchall" term.

colon is the most affected region of the large intestine. Severe colitis presents with severe dysentery, abdominal pain, and, rarely, fever. The extensive necrotizing colitis is often fatal.

The diagnosis of amebiasis begins with an ova and parasite examination. This procedure includes the following: the direct saline mount, which is designed to allow the mobility of the organisms to be seen; the concentration procedure, which provides a method to recover helminth eggs and larvae and protozoan cysts; and the permanent stained smear, which is the most important technique for diagnosis of the intestinal protozoa. Although motility can be seen on direct wet preparations, the material must be fresh, and a diagnosis of amebic infection should *never* be made solely from this type of examination. At the very least, the concentration procedure and permanent stained smear should be performed on every stool sample that is submitted to the laboratory for an ova and parasite examination (1). Many clinical laboratories now receive stool submitted in fecal fixatives; thus, the ova and parasite examination would consist of the concentration and permanent stained smear. This eliminates the lag time between stool passage and fixation, thus removing the problem of organism disintegration and false-negative reports.

Stools should normally be submitted to the laboratory on an every-other-day basis for a period of no more than 10 days. Although for many years the recommended minimum number of stools to be examined has been three, some laboratories are accepting two specimens. When intestinal amebiasis is suspected, six specimens may be submitted over a 15-day period. Multiple specimens are recommended because populations of intestinal protozoa tend to be cyclic. That is, the specimen may be negative on collection day 1 but positive by collection day 3. It is also possible for only a nonpathogen to be found on collection day 1 but pathogenic organisms to be recovered from the second or third specimen. If nonpathogenic protozoa are found, there is always the possibility of finding pathogenic organisms on subsequent examinations.

Presumptive identification of the organism as *Entamoeba histolytica/E. dispar* is based on the typical nuclear morphology (evenly arranged chromatin on the membrane and the presence of a small, central karyosome). The presence of RBCs within the trophozoite cytoplasm would provide definitive identification as true *E. histolytica* (rather than nonpathogenic *E. dispar*); however, RBCs must also be present in the background of the smear if they are reported to be inside the cytoplasm of the organism. In general, if the patient is symptomatic, one assumes that the causative agent is pathogenic *E. histolytica* (assuming that the cause is related to the presence of intestinal protozoa).

TABLE 30.4 Parasitic infections: clinical findings in normal and compromised hosts

Organism	Normal host	Compromised host
Entamoeba histolytica	Asymptomatic to chronic or acute colitis; extraintestinal disease may also occur (primary site: right upper lobe of liver)	Diminished immune system capacity may lead to extraintestinal disease
Free-living amebae	Primary amebic meningoencephalitis (PAM); patients tend to have eye infections with *Acanthamoeba* spp.; linked to poor lens care	PAM; granulomatous amebic encephalitis (GAE)
Blastocystis spp.	Asymptomatic to diarrhea; most common protozoan found in gastrointestinal tract throughout the world	Has been associated with infections in immunocompromised patients; 9/13 subtypes seen in humans; some pathogenic, some not; implicated in extraintestinal disease, as well
Giardia lamblia	Asymptomatic to malabsorption syndrome	Certain immunodeficiencies tend to predispose an individual to infection
Toxoplasma gondii	Approximately 50% of individuals have antibody and organisms in tissue but are asymptomatic	Disease in compromised host tends to involve the central nervous system with various neurological symptoms; *Toxoplasma* encephalitis (TE)
Cryptosporidium spp.	Self-limiting infection with diarrhea and abdominal pain	Owing to autoinfective nature of life cycle, is not self-limiting, may produce fluid loss of over 10 liters/day, and there may be multisystem involvement; no known totally effective therapy
Cyclospora cayetanensis	Self-limiting infection with diarrhea (3–4 days), with relapses common	Diarrhea may persist for 12 wk or more; biliary disease has also been reported in this group, particularly in those with AIDS
Cystoisospora (*Isospora*) *belli*	Self-limiting infection with mild diarrhea or no symptoms	May lead to severe diarrhea, abdominal pain, and possible death (rare case reports); diagnosis is occasionally missed because of nonrecognition of the oocyst stage; is not seen when concentrated from polyvinyl alcohol fixative
Sarcocystis spp.	Self-limiting infection with diarrhea, or mild symptoms	Symptoms may be more severe and last longer
Microsporidia (*Anncaliia*, *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, *Trachipleistophora*, *Tubulinosema*, *Microsporidium*)	Little known about these infections in the normal host; serologic evidence suggests infections may be more common than recognized	Can infect various parts of the body; diagnosis often depends on histologic examination of tissues; routine examination of clinical specimens (stool, urine, etc.) becoming more common; can probably cause death
Leishmania spp.	Asymptomatic to mild disease	More serious manifestations of visceral leishmaniasis; some cutaneous species will manifest visceral disease; difficult to treat and manage; definite coinfection with AIDS
Strongyloides stercoralis	Asymptomatic to mild abdominal complaints; can remain latent for many years owing to low-level infection maintained by internal autoinfective life cycle	Can result in disseminated disease (hyperinfection syndrome due to autoinfective nature of life cycle); abdominal pain, pneumonitis, sepsis-meningitis with Gram-negative bacilli, eosinophilia; distinct link to some leukemias and lymphomas; can be fatal
Plasmodium spp.	Asymptomatic to severe symptoms, depending on immune status of patient	Parasitemias tend to be higher, particularly with HIV coinfections
Babesia spp.	Asymptomatic, self-cure in immunocompetent patient (*B. microti*); may be more severe in patients with *B. divergens* or *B. duncani*	May cause severe symptoms, even death, in patients who have been splenectomized or who are immunocompromised for other reasons
Trypanosoma cruzi, American trypanosomiasis	In children younger than 5 years, the disease is seen in its severest form, whereas in older children and adults, the disease is milder and is commonly diagnosed in the subacute or chronic form rather than in the acute form; acute-stage symptoms only occur in about 1% of patients; recovery may occur without therapy	Individuals who were previously infected with *T. cruzi* and later become positive for HIV are at risk of reactivation of their Chagas' disease; these patients develop a severe multifocal or diffuse meningoencephalitis with numerous tissue parasites; associated with high mortality
Crusted scabies (*Sarcoptes scabiei*)	Infections can range from asymptomatic to moderate itching	Severe infection with reduced itching response; hundreds or thousands of mites on body; infection very easily transferred to others; secondary infection very common

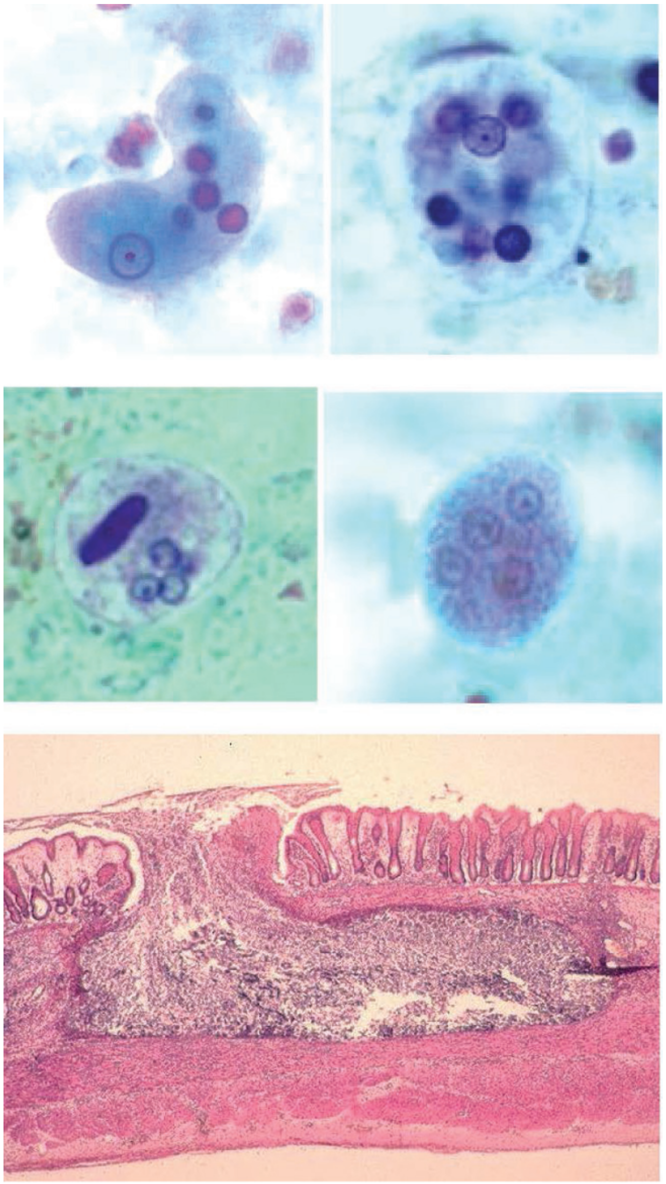

Figure 30.1 (Top) *Entamoeba histolytica* trophozoites containing ingested RBCs. (Middle) *Entamoeba histolytica/E. dispar* cysts. (Bottom) Amebic liver abscess in section; note the "flask-shaped" ulcer. doi:10.1128/9781555819002.ch30.f1

The cyst of *E. histolytica/E. dispar* may contain chromatoidal bars with smooth, rounded edges. Even though the mature cyst contains four nuclei, these are not always visible, and the cyst can often be identified from the chromatoidal bars alone.

In a wet preparation, such as the direct smear or concentration sediment, the trophozoites and cysts of *E. histolytica* measure >12 and >10 µm, respectively. Because of artificial shrinkage during the preparation of permanent stained smears, the sizes are diminished somewhat, with the trophozoites measuring at least 10.5 to 11 µm and the cysts measuring at least 8.5 to 9 µm. Organisms measuring less than these limits and containing morphologic characteristics similar to those of *E. histolytica* would be identified as *E. hartmanni*, a nonpathogenic ameba.

One of the most important things to remember is that some human cells found in the stool can mimic *E. histolytica*. Macrophages or monocytes can look like the trophozoite form of *E. histolytica*, and polymorphonuclear leukocytes, when they have been in the stool for a while, can mimic the four-nucleus *E. histolytica* mature cyst. However, if the patient has diarrhea or dysentery, it is very unusual to find cysts in the stool; the gut motility is so rapid, there is not time for cyst formation.

Other tests include sigmoidoscopy, in which both scrapings and smears can be submitted for permanent stains. Biopsy specimens should also be submitted for histopathologic studies. Radiographic examination with barium is helpful; however, the presence of barium in the stool makes the ova and parasite examination very difficult to perform. Ova and parasite examinations should be done before barium studies or at least 1 week to 10 days afterward. The sensitivity of serologic tests for antibody in patients with intestinal amebiasis varies, and a negative serologic test does not necessarily rule out the presence of amebic infection. Serologic tests for antibody are not recommended for the diagnosis of intestinal amebiasis.

Tests for antigen detection in the stool are much more relevant for intestinal disease. Reagents are currently available for antigen detection of the *E. histolytica/E. dispar* group and specifically for *E. histolytica*. Fresh, frozen, or stool submitted in Cary-Blair medium is required for the procedure (confirm with the package insert); PCR, isoenzyme analysis, and antigen detection are available for confirmation of *E. histolytica* infection. However, the antigen detection method is both rapid and technically simple.

If *E. histolytica* organisms are not seen in the stool and the final diagnosis is inflammatory bowel disease, the patient may receive corticosteroid therapy. Immunosuppression may predispose the patient to more severe disease if the true pathogen, *E. histolytica*, is present and not detected.

Extraintestinal Disease

When organisms invade the mucosal lining and are carried via the bloodstream to the liver via the portal vein (extraintestinal or hepatic disease), a somewhat different approach to diagnosis is necessary. Both fecal and sigmoidoscopic examinations for organisms are negative in approximately half of the patients with extraintestinal amebiasis. Both radioactive and computed tomographic (CT) scans are available to assist the clinician in defining the presence of an abscess.

Lesions in the liver may range from less than a few centimeters to several inches in diameter. In either case, if the patient has a normal humoral immune system, serologic tests for antibody are generally positive.

Serologic tests for extraintestinal amebiasis are generally very specific and quite sensitive. However, in some parts of the country, sensitivity may present a problem in patients previously exposed to *E. histolytica*. In these individuals, a low to moderate titer may represent past infection rather than current disease. Also, patients with diminished immunoglobulin levels may present with low or negative serologic titers (Table 30.3). Various serologic techniques include complement fixation, indirect hemagglutination assay (IHA), counterimmunoelectrophoresis, latex agglutination, indirect fluorescent-antibody (IFA) assay, and enzyme-linked immunosorbent assay (ELISA), as well as tests for the detection of antigen in the stool. It is generally recommended that two different procedures be used so that the results can be compared. One approach is to use both qualitative screen and quantitative titer procedures. Commercial suppliers of kits are limited, and few laboratories routinely provide this type of testing. Serum for serologic tests should be sent to the state and local public health laboratories if the test is not routinely available.

AIDS Patients. Invasive amebiasis appears to be an emerging parasitic disease in patients infected with HIV in areas where amebic infection is endemic. Medical, microbiological, and histopathologic records of 296 HIV-infected patients and serologic data from IHAs of samples from 126 HIV-infected patients were reviewed to identify cases of invasive amebiasis. An IHA titer of 1:128 was considered positive. Of these 296 HIV-infected patients, 18 (6.1%) were diagnosed with invasive amebiasis. Clinical manifestations included amebic colitis (13 patients), amebic liver abscess (9 patients), both colitis and abscess (4 patients), and pleural effusion (2 patients). Invasive amebiasis was the initial presentation of HIV infection in nine patients. Of the 18 patients diagnosed with invasive amebiasis, 13 had an IHA titer of ≥1:128. The sensitivity of the IHA in the diagnosis of invasive amebiasis was 72.2%, and the specificity was 99.1%. The positive predictive value of IHA for invasive amebiasis in this patient population was 92.9% and the negative predictive value was 95.5% (2). It appears that invasive amebiasis is becoming more important as one of the opportunistic parasitic infections in patients with HIV infection in areas of amebiasis endemicity. In this type of area of endemicity, the IHA should be considered a relevant diagnostic approach.

In a study from Mexico, the prevalence estimated with PCR data showed that *E. histolytica* infection was more common in the HIV-positive/AIDS group (25.32%) than in HIV-negative contacts (18.46%). *E. histolytica/E. dispar* infection was more frequent in HIV-positive/AIDS patients (13.3%) than in HIV-negative contacts (0.7%). However, *E. histolytica* and/or *E. histolytica/E. dispar* infection was highly prevalent in HIV-positive/AIDS patients (34.1%) without evidence of recent or current invasive disease. Contacts of HIV-positive/AIDS patients who were infected with *E. histolytica/E. dispar* were asymptomatic cyst passers. These data indicate that *E. histolytica* strains prevalent in the studied community appear to be of low pathogenic potential within the compromised patient, and infection with HIV-1 does not appear to be a risk factor for amebiasis (3).

However, in another study, 49 (5.2%) of 951 HIV-infected persons had 51 episodes of invasive amebiasis. A high IHA titer was detected in 39 (6.2%) of 634 HIV-infected persons compared with 10 (2.3%) of 429 uninfected controls with gastrointestinal symptoms and 0 of 178 uninfected healthy controls. Stool specimens from 40 (12.1%) of 332 HIV-infected persons and 2 (1.4%) of 144 uninfected healthy controls were positive for *E. histolytica* or *E. dispar* antigen. Of the 40 antigen-positive stool specimens from HIV-infected persons, 10 (25.0%) contained *E. histolytica*. Therefore, persons infected with HIV in Taiwan are at increased risk for invasive amebiasis and exhibit a relatively high frequency of elevated antibody titers and intestinal colonization with *E. histolytica* (2).

High-risk areas for acquiring amebiasis include Mexico, the western portion of South America, western Africa, South Africa, parts of the Middle East, and South and Southeast Asia. Invasive disease is much more common in these areas of the world.

Free-Living Amebae

Small, free-living amebae are becoming recognized clinically as important parasitic pathogens causing infections, particularly in immunocompromised patients (Table 30.5) (4). Primary amebic meningoencephalitis (PAM) caused by *Naegleria fowleri* and granulomatous amebic encephalitis (GAE) caused by *Acanthamoeba* spp. and *Balamuthia mandrillaris* (including cases in patients with AIDS) are now well recognized (see Fig. 30.2 and 30.3). Another identified group of infections caused by these organisms is *Acanthamoeba* keratitis, which is related primarily to poor lens care in those who wear contact lenses. When free-living, these organisms feed on bacteria and nutrients in moist soil and in fresh and marine waters.

Although it is well known that both free-living and pathogenic protozoa harbor a variety of endosymbiotic bacteria, it is unclear what role these organisms play in

TABLE 30.5 Comparison of diseases caused by the most common free-living amebae

Determinant	*Naegleria fowleri*	*Acanthamoeba* sp., *Balamuthia mandrillaris*
Stages	Trophozoites: 10–15 µm, with broad, rounded pseudopods. Cyst: 7–10 µm, round, thick double wall	Trophozoites: 25–40 µm with slender, pointed/spiky pseudopods. Cyst hexagonal with double wall, spherical
Disease	Primary amebic meningoencephalitis (PAM)	Granulomatous amebic encephalitis (GAE); *Acanthamoeba* keratitis
Epidemiology	Good health, recent history of swimming in lake or other warm water natural sources, including nontreated swimming pools; use of neti pots for nasal irrigation with contaminated water; also inhalation via dust	Immunocompromised (e.g., AIDS); other causes such as various diseases and/or transplantation
Predisposing conditions	None	Alcoholism, pregnancy, systemic lupus erythematosus, hematologic disorders, AIDS, chemotherapy, radiation therapy, transplantation, and steroid treatment
Incubation	3–7 days	Probably >10 days
Portal of entry	Olfactory neuroepithelium	Skin, lungs, olfactory neuroepithelium
Onset	Very rapid	Slow, insidious
CNS spread	Direct	Probably hematogenous
Organs affected	Brain only	Brain, skin, eyes, lungs
Clinical course	Acute, fulminant; fatal within 10 days or less	Subacute (8–30 days) or chronic (>32 days)
Signs and symptoms	Severe headache, anorexia, nausea, vomiting, fever, mental abnormalities, stuffy/blocked nose	Mental abnormalities, seizures, fever, hemiparesis, headache, visual abnormalities
Ocular involvement	None	Keratitis
CSF	Similar to bacterial meningitis (clear to purulent); neutrophilic pleocytosis, high protein, low glucose	CSF similar to those in viral encephalitides
Laboratory diagnosis	Direct examination of fresh CSF shows active trophozoites (recommended: slide with coverslip, not counting chamber); culture, nonnutrient agar plate with bacterial overlay; calcofluor white for cysts	Culture, nonnutrient agar plate with bacterial overlay; calcofluor white for cysts
Potential diagnostic problems	Bacterial meningitis diagnosed on the basis of false-positive Gram stain for bacteria; antibiotics not effective for PAM; false-positive Gram stain, BUT negative routine bacterial cultures; amebae in CSF in counting chamber may be confused with PMNs and/or monocytes	Specimens diluted on too many agar plates (temperature options), resulting in a false-negative culture; amebae in CSF in counting chamber may be confused with PMNs and/or monocytes.
Host response	Purulent leptomeningitis, hemorrhagic necrotizing meningoencephalitis, brain edema, perivascular collection of amebas	Granulomatous encephalitis with focal necrosis and multinucleated giant cells, necrotizing angitis
CNS amebic forms	Trophozoites	Trophozoites and cysts
Differential diagnosis	Acute pyogenic (bacterial) leptomeningitis	Tuberculous, viral, or fungal encephalitis; brain tumors, brain abscess; ocular herpes; fungal keratitis
Therapy	Amphotericin B + miconazole + rifampin	A topical biguanide, 0.02% chlorhexidine or polyhexamethylene biguanide (PHMB, 0.02%), either alone or combined with a diamidine, propamidine isethionate (Brolene) or hexamidine (Desomodine)

terms of host survival, infectivity, and invasiveness. *Legionella pneumophila* can infect, multiply within, and kill both *Naegleria* and *Acanthamoeba* amebae. These amebae may be natural hosts for *Legionella*, as well as for other bacteria such as *Listeria monocytogenes*, *Vibrio cholerae*, *Mycobacterium leprae*, and *Pseudomonas aeruginosa*. Because of their well-known resistance to chlorine, the amebic cysts are considered to be vectors for these intracellular bacteria. This can have tremendous significance for any hospital where the water source is contaminated with free-living amebae. There is also evidence to suggest that the presence of amebae in domestic water supplies may provide growth conditions that enhance the pathogenicity of the organism for the human host. These amebae are also acceptable hosts for echoviruses and polioviruses. The epidemiology, immunology, protozoology, pathology, and clinical features of the infections produced by these free-living protozoa differ considerably.

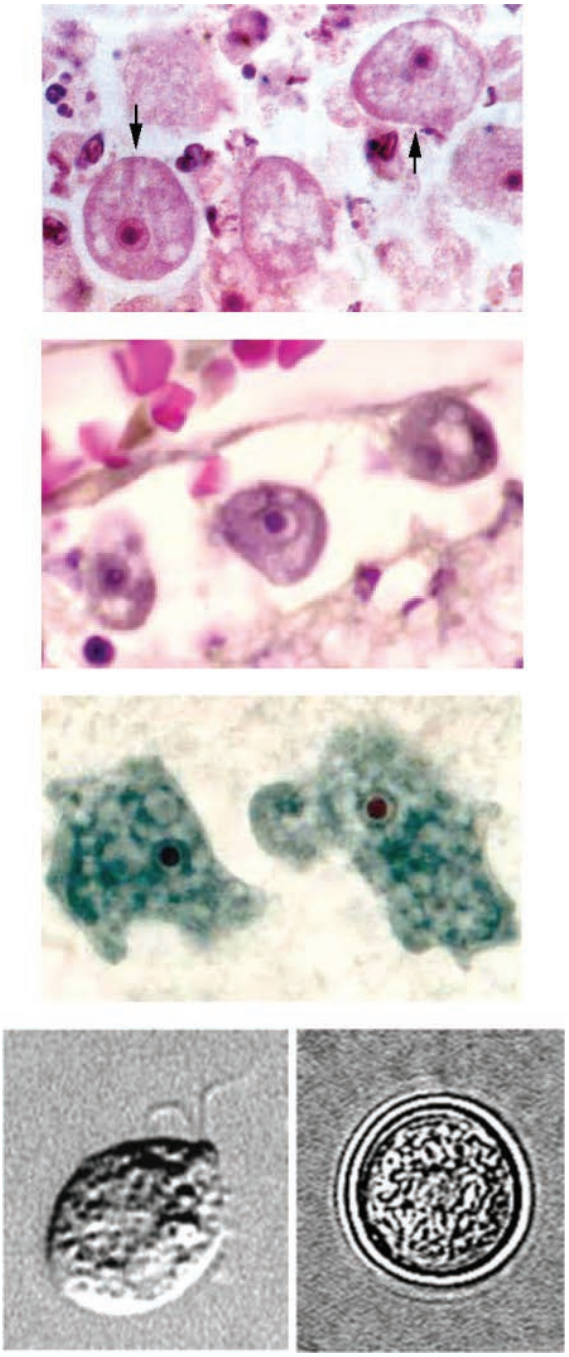

Figure 30.2 (Top) *Naegleria fowleri* trophozoite (note the large karyosome within the nucleus). (Row 2) *N. fowleri* trophozoites within brain tissue. (Row 3) *N. fowleri* trophozoites; note "globby/rounded" pseudopods. (Bottom, left) Flagellated form of *Naegleria*; (right) cyst of *Naegleria*, not seen in human tissue. (Bottom images courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch30.f2

Naegleria fowleri

Central nervous system (CNS) infections caused by free-living amebae have been recognized only since the mid-1960s. *N. fowleri* causes PAM, a fulminant and rapidly fatal disease that affects mainly children and young adults (Fig. 30.2). The disease closely resembles bacterial meningitis but is caused by this free-living ameba, an organism found in moist soil and freshwater habitats. Although PAM is usually associated with healthy, young individuals with a history of recent water-related sport activities, it is an important infection to consider in both immunocompetent and immunocompromised individuals. However, almost all infections have been seen in otherwise healthy individuals. Close to 200 cases of PAM have occurred worldwide, and approximately 90 of those cases have been reported from the United States.

Life Cycle. There are both trophozoite and cyst stages in the life cycle, and the stage depends primarily on environmental conditions. Trophozoites can be found in water or moist soil and can be maintained in tissue culture or other artificial media. The trophozoites can occur in two forms, ameboid and flagellate. Motility can be observed in hanging-drop preparations from cultures of cerebrospinal fluid (CSF); the ameboid form (the only form recognized in humans) is elongate with a broad anterior end and a tapered posterior end. The size ranges from 7 to 20 µm. The diameter of the rounded forms is usually 15 µm. There is a large central karyosome and no peripheral nuclear chromatin. The cytoplasm is somewhat granular and contains vacuoles. The ameboid-form organisms change to the flagellate form when they are transferred from culture or teased from tissue into water and maintained at a temperature of 27 to 37°C. The flagellate form is pear shaped, with two flagella at the broad end. Motility is typical, with either spinning or jerky movements. These flagellate forms do not divide, but when the flagella are lost, the ameboid forms resume reproduction. Cysts from nature and from agar cultures look the same and have a single nucleus almost identical to that seen in the trophozoite. The cysts are generally round, measuring 7 to 10 µm in diameter, with a thick double wall.

Amebic Meningoencephalitis. PAM caused by *N. fowleri* is an acute, suppurative infection of the brain and meninges. In humans, with extremely rare exceptions, the disease is rapidly fatal. The period between contact with the organism and onset of clinical symptoms such as fever, headache, and rhinitis may vary from 2 to 3 days to as long as 7 to 15 days.

The amebae may enter the nasal cavity by inhalation or aspiration of water, dust, or aerosols containing the trophozoites or cysts. The organisms then penetrate the nasal mucosa, probably through phagocytosis of the olfactory epithelial cells, and migrate via the olfactory nerves to the brain. Early symptoms include vague upper respiratory distress, headache, lethargy, and occasionally olfactory problems. Cysts of *N. fowleri* are generally not seen in brain tissue. The acute phase includes sore throat; stuffy, blocked, or discharging nose; and severe headache. Progressive symptoms include pyrexia, vomiting, and stiffness of the neck. Mental confusion and coma usually occur approximately 3 to 5 days prior to death. The cause of death is usually cardiorespiratory arrest and pulmonary edema.

Organ Transplantation, Other Immunocompromised Conditions. The first case of organ transplantation from a donor who had died of undiagnosed *N. fowleri* infection was reported in 1997 (5, 6). While no subsequent amebic infections occurred in the three organ recipients, this report emphasizes the need for adequate evaluation of the benefits and risks of transplanting tissues from persons whose illness might have been caused by an infectious agent. Apparently, the Centers for Disease Control and Prevention (CDC) is also aware of another instance in which kidneys were transplanted prior to determination that the donor was infected with *N. fowleri* (5, 6). At present, the risk of transmission of *N. fowleri* by donor organs has not been clarified, and no practical test is available to ensure that donor organs are organism free. Also, no prophylactic drug regimen to treat transplant recipients has been established.

Another case was reported in a patient with systemic lupus erythematosus. Although treatment was undertaken with intravenous amphotericin B, the patient suffered a fatal relapse while still on therapy (7).

Diagnosis. PAM can resemble acute purulent bacterial meningitis and may be difficult to differentiate, particularly in the early stages. The CSF may have the predominantly polymorphonuclear leukocytosis, increased protein concentration, and decreased glucose concentration that are seen with bacterial meningitis. Unfortunately, if the CSF Gram stain is interpreted incorrectly (identification of bacteria as a false-positive result), the antibacterial therapy will have no effect on the amebae and the patient will usually die within several days. Extensive tissue damage occurs along the path of amebic invasion; the nasopharyngeal mucosa shows ulceration, and the olfactory nerves are inflamed and necrotic. Hemorrhagic necrosis is concentrated in the region of the olfactory bulbs and the base of the brain. Organisms can be found in the meninges, perivascular spaces, and sanguinopurulent exudates.

Clinical and laboratory data usually cannot be used to differentiate pyogenic meningitis from PAM, and so the diagnosis may have to be reached by a process of elimination. A high index of suspicion is often mandatory for early diagnosis. Although most cases are associated with exposure to contaminated water through swimming or bathing, this is not always the case. The rapidly fatal course of 4 to 6 days after the beginning of symptoms (with an incubation period of 1 day to 2 weeks) requires early diagnosis and immediate chemotherapy if the patient is to survive.

Analysis of the CSF shows decreased glucose and increased protein concentrations. Leukocyte counts may range from several hundred to >20,000 cells/mm^3. Gram stains and bacterial cultures of CSF are negative. A definite diagnosis could be made by demonstration of the amebae in the CSF or in biopsy specimens. Either CSF or sedimented CSF should be placed on a slide under a coverslip and observed for motile trophozoites; smears can also be stained with Wright's or Giemsa stain. CSF, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to mistake leukocytes for actual organisms or vice versa. It is very easy to confuse leukocytes and amebae, particularly when one is examining CSF by using a counting chamber, hence the recommendation to use just a regular slide and coverslip. Motility may vary, so that the main differential characteristic is the spherical nucleus with a large karyosome.

Unfortunately, most cases are diagnosed at autopsy; confirmation of these tissue findings must include culture and/or special staining using monoclonal reagents in IFA procedures. Organisms can also be cultured on nonnutrient agar plated with *Escherichia coli*. In cases of presumptive pyogenic meningitis in which no bacteria are identified in the CSF, the CT appearance of basal arachnoiditis (obliteration of basal cisterns in the precontrast scan with marked enhancement after the administration of intravenous contrast medium) should indicate the possibility of acute PAM.

The amebae can be identified in histology preparations by using indirect immunofluorescence and immunoperoxidase techniques. The organism in tissue sections looks very much like an *Iodamoeba bütschlii* trophozoite, with a very large karyosome and no peripheral nuclear chromatin; the organisms can also be seen with use of routine histologic stains. In general, serologic tests have not been helpful in the diagnosis of this infection. The disease progresses so rapidly that the patient is unable to mount an immune response.

Acanthamoeba spp.

Granulomatous Amebic Encephalitis. Another type of meningoencephalitis, GAE, caused by freshwater amebae may occur as a subacute or chronic disease with focal granulomatous lesions in the brain (Fig. 30.3) (8, 9). Several species of *Acanthamoeba* belonging to several different genotypes cause this insidious and chronic disease,, principally in immunocompromised hosts including persons infected with HIV/AIDS. The route of CNS invasion is thought to be hematogenous, with the primary site being the skin or lungs. In this infection, both trophozoites and cysts can be found in the CNS lesions. A case involving acute onset of fever, headache, and pain in the neck preceded by 2 days of lethargy has been described. Conditions associated with GAE include skin ulcers, liver disease, pneumonitis, diabetes mellitus, renal failure, rhinitis, pharyngitis, systemic lupus erythematosus, and tuberculosis. Predisposing factors include alcoholism, pregnancy, systemic lupus erythematosus, hematologic disorders, AIDS, chemotherapy, radiation therapy, and steroid treatment. This infection has become more widely recognized in AIDS patients, particularly those with a low $CD4^+$ cell count (10). Although *Acanthamoeba* infections stimulate a granulomatous response, the response in AIDS patients is minimal or absent, consistent with the poor immune response in these patients. Examples of specific infections seen in immunocompromised patients are listed in Table 30.6.

The *Acanthamoeba* group also causes keratitis and corneal ulceration. There are a number of published cases, which emphasizes the need for clinicians to consider acanthamoebic infection in the differential diagnosis of eye infections that fail to respond to bacterial, fungal, or viral therapy. These infections are often due to direct eye exposure to contaminated materials or solutions.

Unlike *N. fowleri*, *Acanthamoeba* spp. do not have a flagellate stage in the life cycle, only the trophozoite and cyst (Fig. 30.3). Motile organisms have spinelike pseudopods; however, progressive movement is usually not very evident. There is a wide range in size, with the average diameter of the trophozoites being 30 μm. The nucleus has the typical large karyosome, like that seen in *N. fowleri*. This morphology can be seen on a wet preparation. The cysts are usually round with a single nucleus and also have the large karyosome seen in the trophozoite nucleus. The double wall is usually visible, with the slightly wrinkled outer cyst wall and what has been described as a polyhedral inner cyst wall. This cyst morphology can be seen in organisms cultured on agar plates.

Laboratory examinations similar to those for *N. fowleri* can be used to recover and identify these organisms; the one exception is recovery by culture, which has not proven to be as effective with GAE cases. The most effective approach uses nonnutrient agar plates with Page's saline and an overlay growth of *E. coli* on which the amebae

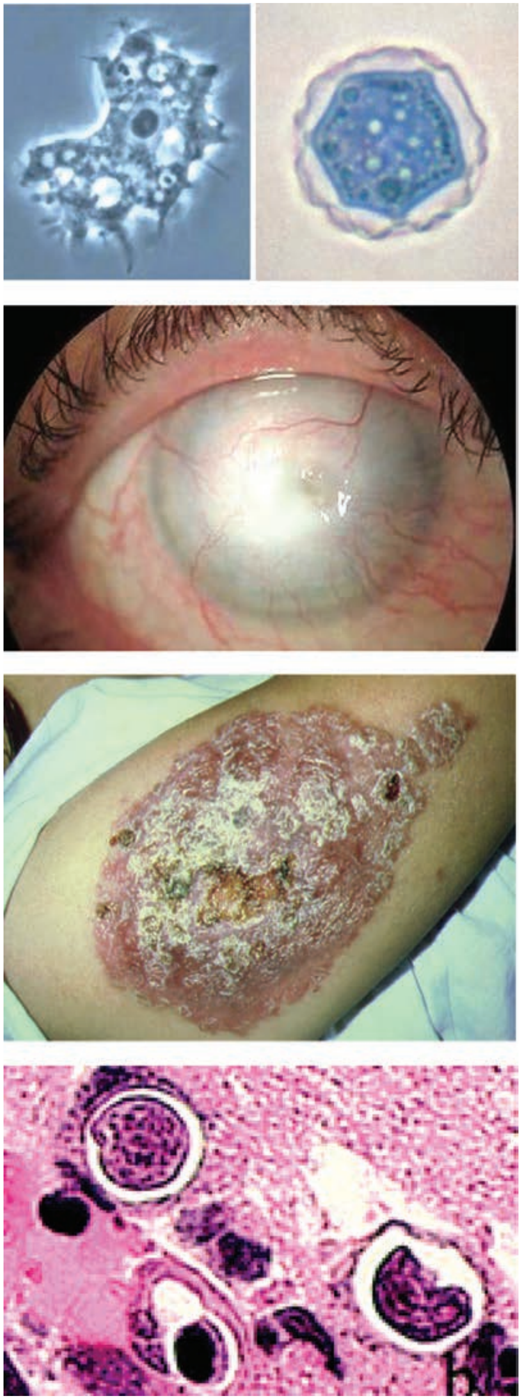

Figure 30.3 (Top, left) *Acanthamoeba* trophozoite (note the sharp, spiky pseudopodia); (right) *Acanthamoeba* cyst (note the hexagonal double wall). (Row 2) *Acanthamoeba* keratitis. (Row 3) Cutaneous *Acanthamoeba* infection. (Bottom) *Acanthamoeba* cysts in brain: case of GAE. Note that cysts are present in tissue, unlike *Naegleria* infections, where only trophozoites are seen in tissue. TABLE 30.6 *Toxoplasma gondii* infections in immunocompromised patients[a]

Underlying condition	Disease manifestation and complication	Comments
AIDS and lymphoma	Cerebral toxoplasmosis	Regional CBV (rCBV) determined by perfusion MRI; rCBV reduced throughout toxoplasmosis lesions; all active lymphomas had increased rCBV results; differences were significant; perfusion MRI is a rapid, noninvasive tool that may allow differentiation between cerebral lymphoma and toxoplasmosis
AIDS and lymphoma	Cerebral toxoplasmosis	Knowledge of patient's serostatus does not aid discrimination between lymphoma and toxoplasmosis; single lesions on MRI with focal accumulation of thallium-201 strongly suggest lymphoma; multiple lesions on MRI with uptake ratios of ≥2.9 also suggest lymphoma; uptake ratios of <2.1 do not aid in discrimination
AIDS	CNS disease	Diagnosis of CNS toxoplasmosis often incorrect; another diagnosis is most likely in patients who are anti-*Toxoplasma* seronegative or who are receiving prophylactic TMP-SMX
AIDS	CNS disease and intracranial mass lesions	Neurologic disease is first indication of AIDS in 10–20% of HIV-seropositive individuals; over half will present with intracranial mass lesion; toxoplasmosis is the most common cause in developed countries; data indicate that it is also the most common cause in underdeveloped countries
AIDS	CNS disease and gastrointestinal mastocytosis	Simultaneous occurrence of both conditions and regression after treatment for toxoplasmosis; may suggest a possible relationship between mast cell proliferation and parasitic infection
AIDS	Chorea	Chorea not unusual in AIDS; however, its causes are variable; AIDS-related disease should be considered in young patients presenting with chorea with no family history of movement disorders
AIDS	Risk factors	While risk factors are still somewhat unclear, specific prophylaxis for patients with low CD4 cell counts and high *Toxoplasma* Ab titers is recommended
AIDS	Emerging disease in India (TE)	Management protocol in AIDS patients critical to the diagnosis of TE in patients with CNS symptoms; increasing numbers of AIDS patients require constant consideration of opportunistic infections
AIDS	Immunoblot profiles (TE)	In patients with *Toxoplasma* Ab (ELISA), IgG 27 band or IgG 31 band on Western blot is highly indicative of TE, independent of each other; Western blot positivity provides useful data for improving diagnosis of presumptive TE in HIV-infected patients with suspected TE and positive *Toxoplasma* serology
AIDS	Long-term outcome (TE)	Cerebral infections like TE may negatively influence HIV-1 activity so far latent in the brain
AIDS	Sulfadiazine and obstructive nephropathy	Patients receiving sulfadiazine for cerebral toxoplasmosis can develop obstructive nephropathy; will resolve with alkalic hydration and discontinuation of sulfadiazine
AIDS	High or low doses of TMP-SMX	High doses of TMP-SMX appear to be more effective than low doses for decreased risk for toxoplasmosis in HIV-infected patients; rifampin may reduce the efficacy of TMP-SMX
Immunosuppressive drugs for BMT	Cerebral toxoplasmosis	Clinical diagnosis confirmed by PCR on CSF and blood leukocytes; retrospective testing indicated PCR was positive 52 days prior to onset of clinical symptoms; results highlight value of PCR in early detection of cerebral toxoplasmosis
Immunosuppressive drugs for BMT	TE	In group of 27 BMT patients (allogeneic only) who developed CNS infections, the most common (74%) was TE; one group showed edema but no enhancement, while one group showed the typical MRI pattern with the exception of frequent hemorrhagic transformation
Immunosuppressive drugs for BMT	Cerebral toxoplasmosis reactivation	*T. gondii* infection reactivation occurs predominantly in patients after allogeneic BMT; tends to occur within 3 mo after transplantation; late cerebral toxoplasmosis reactivation may be triggered by a course of corticosteroids (administered for graft-versus-host disease); risk factors should signal reinstitution of prophylactic treatment with TMP-SMX
Immunosuppressive drugs for BMT	MRI problems	In patients with low leukocyte count (poor immunologic response) and/or high doses of immunosuppressive therapy, typical contrast enhancement may be absent (poor visualization of cerebral lesions)
SLE therapy	Cerebral toxoplasmosis	Symptoms of fever, confused state, convulsions consistent with lupus cerebritis; patient died of cerebral toxoplasmosis, which was confused with lupus cerebritis
Non-Hodgkin's lymphoma	TE	Involvement of mediastinum, para-aortic lymph nodes, pleura, peritoneum, bone marrow; patient deteriorated; CSF smear revealed tachyzoites; TE should be considered a potential cause of consciousness disturbance in patients with malignant lymphoma

[a] Adapted from references 26–29. Ab, antibody; BMT, bone marrow transplantation; CBV, cerebral blood volume; MRI, magnetic resonance imaging; SLE, systemic lupus erythematosus; TE, *Toxoplasma* encephalitis; TMP-SMX, trimethoprim-sulfamethoxazole.

feed. There is also evidence to indicate that phosphate-buffered saline can be used. Specimens transported in ameba saline (5.0 ml) and filtered through 13-mm-diameter, 0.22-µm-pore-size cellulose acetate and nitrate filters (Millipore Corp., Bedford, MA) have also been acceptable for organism recovery. The filter is then placed in the center of the nonnutrient agar plate seeded with *E. coli*. Tissue stains are also effective, and cysts can be stained with Gomori's methenamine silver, periodic acid-Schiff (PAS), and calcofluor white.

Although detection of antibodies to *Acanthamoeba* spp. has been confirmed, the usefulness of serologic tests for the diagnosis of these infections has not been proven. Also, these procedures are not generally available. Further work related to the issue of false-positive and false-negative results and interpretive guidelines regarding past exposure or present infection need to be pursued before these diagnostic procedures can be routinely used.

Balamuthia mandrillaris

The leptomyxid ameba *Balamuthia mandrillaris* is relatively uncommon and was originally thought to be another harmless soil organism, unlikely or unable to infect mammals. However, in studies from the CDC, antisera to the leptomyxid amebae have been shown to react in indirect immunofluorescence assays with tissues from both animals and humans with GAE. There have been over 70 cases worldwide, some of which have occurred in AIDS patients (5, 6, 11, 12). The disease is very similar to GAE caused by *Acanthamoeba* spp. and has an unknown incubation period. The clinical course tends to be subacute or chronic and is usually not associated with swimming in freshwater. No characteristic clinical symptoms, laboratory findings, or radiologic indicators have been found to be diagnostic for GAE. The neuroimaging findings show heterogeneous, hyperdense, nonenhancing, space-occupying lesions (Fig. 30.4). Whether single or multiple, they involve mainly the cerebral cortex and subcortical white matter. These findings suggest a CNS neoplasm, tuberculoma, or septic infarcts. Patients complain of headaches, nausea, vomiting, fever, visual disturbances, dysphagias, seizures, and hemiparesis. There may also be a wide range in terms of the clinical course, from a few days to several months. Death can occur from a week to several months after the onset of stroke-like symptoms that can mimic other conditions. Both trophozoites and cysts of *B. mandrillaris* are found in many of the same CNS tissues as are *Acanthamoeba* organisms. Although differentiation of these two organisms in tissue by light microscopy is difficult, in some tissue sections *B. mandrillaris* appears to have more than one nucleolus in the nucleus. Generally, electron microscopy

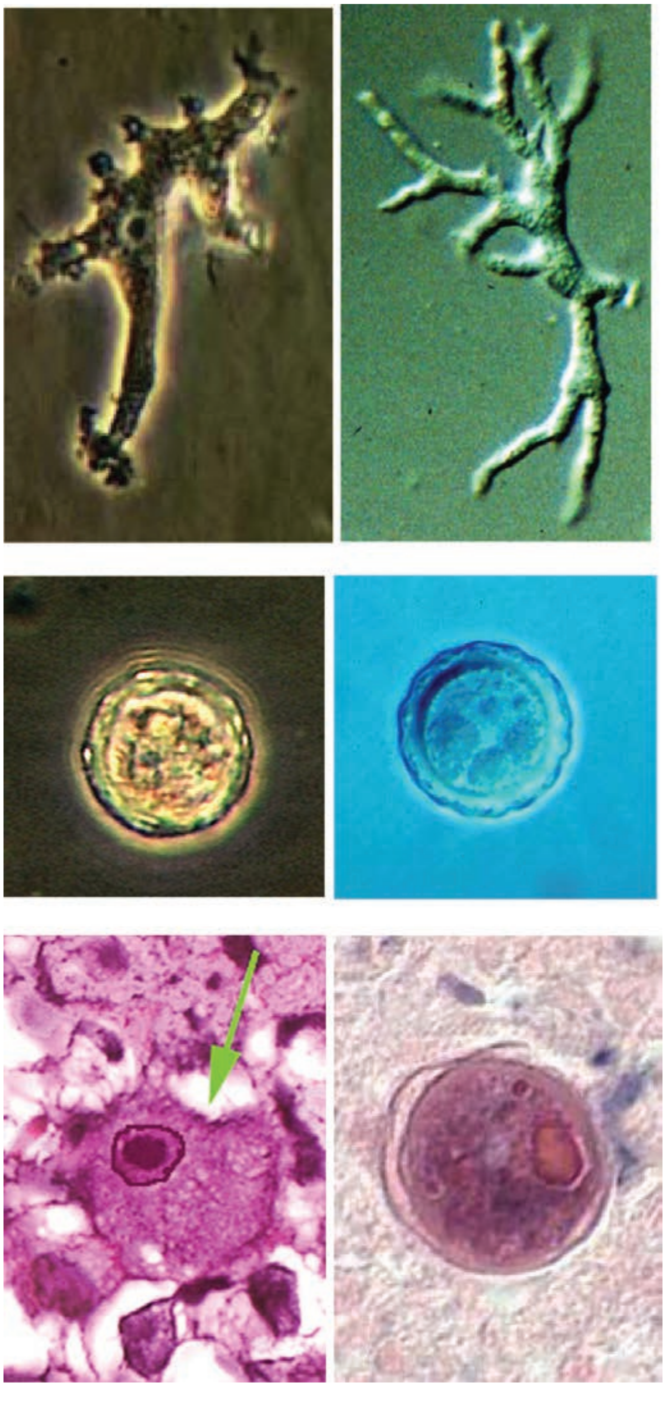

Figure 30.4 *Balamuthia mandrillaris*. (Top) Trophozoites. (Middle) Cysts. (Bottom, left) Trophozoite in brain tissue; (right) cyst in brain tissue (courtesy of the CDC Public Health Image Library; lower right from the University of Kentucky Hospital, Lexington, KY). doi:10.1128/9781555819002.ch30.f4

and histochemical methods are required for definitive identification of *B. mandrillaris*.

Attempts to isolate the organisms from some humans with GAE have not been successful, and leptomyxid amebae do not grow well on *E. coli*-seeded nonnutrient agar plates. In the diagnostic laboratory, these organisms can be cultured using mammalian cell cultures; some success has been obtained with monkey kidney cells and with MRC, HEp-2, and diploid macrophage cell lines. The trophozoites have extensive branching and a single nucleus (occasionally binucleate forms are seen) with a central karyosome, and they measure 15 to 60 µm. Occasionally, a few elongated forms with several contractile vacuoles are seen. The cysts have a single nucleus (occasionally binucleate forms are seen), have the typical double wall with the outer wall being thick and irregular, and measure 15 to 30 µm. Using primary cultures of human brain microvascular endothelial cells, amebae have been isolated from the brain and CSF (13). Serum antibodies to *B. mandrillaris* have been found in both adults and children; however, testing is generally limited to the CDC, where PCR has also been used for the detection of mitochondrial 16S rRNA gene DNA from the amebae in clinical specimens (14).

From the information presented above, it is clear that *B. mandrillaris*, formerly regarded as having no pathogenic potential, will continue to be identified as the etiologic agent of fatal meningoencephalitis in humans as well as animals. This opportunistic infection may also continue to cause disease in individuals with AIDS.

Sappinia sp.

Sappinia pedata and *Sappinia diploidea* are newly discovered human pathogens of the CNS which can cause amoebic encephalitis in humans. *Sappinia* has a worldwide distribution and has been isolated from elk and buffalo feces, soil contaminated with bovine feces, decaying ground plant litter, and freshwater. The life cycle of *Sappinia* consists of two stages, a trophozoite and a cyst (Fig. 30.5). The first case of amoebic encephalitis caused by *Sappinia* sp. occurred in a previously healthy immune-competent adult male who survived the infection. The route of infection is thought to be by inhalation through the nasopharynx or by hematogenous spread to the brain.

In the first case reported, a sinus infection occurred prior to the onset of symptoms. The patient developed nausea, vomiting, bifrontal headache, photophobia, and blurry vision. A loss of consciousness occurred for a brief period (6). Brain images revealed a solitary mass in the posterior left temporal lobe that was made up of necrotizing hemorrhagic

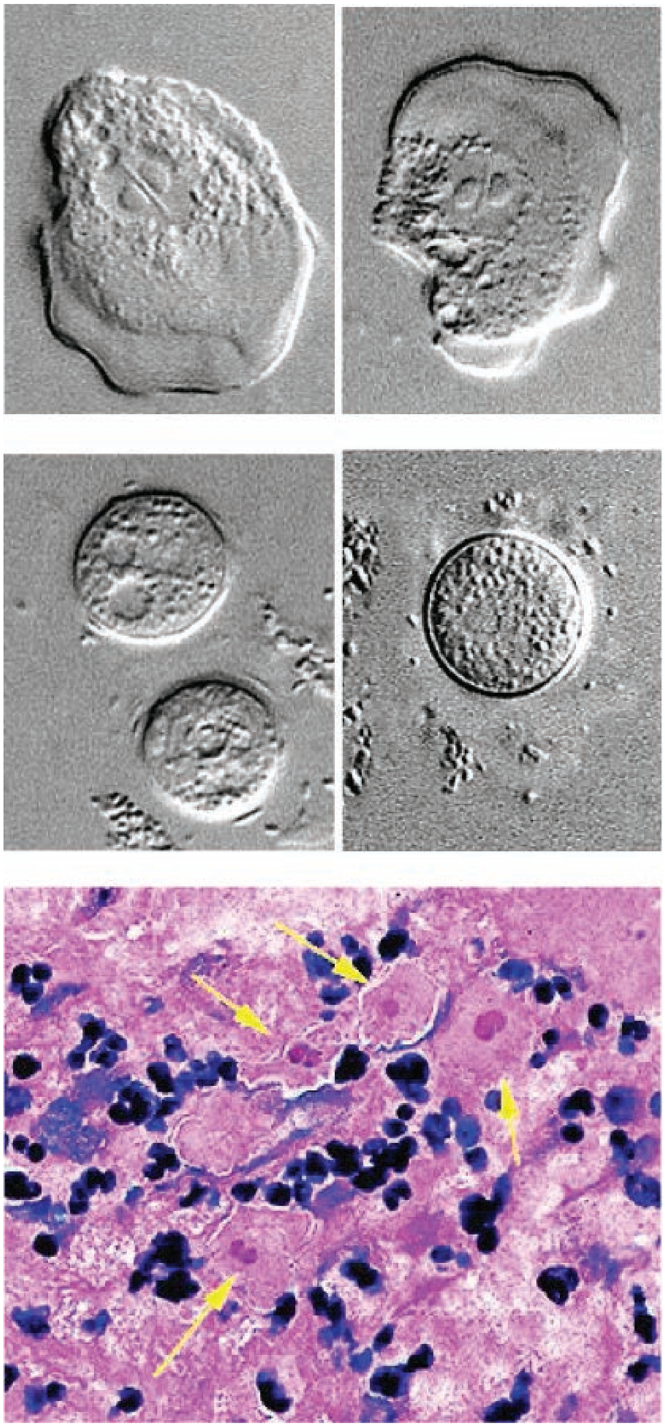

Figure 30.5 *Sappinia* sp. (Top) Trophozoites viewed under differential interference contrast (DIC); note there are two nuclei. (Middle) Cysts viewed under DIC. (Bottom) Four trophozoites (yellow arrows) of *S. pedata* in brain tissue, H&E stain; in three of the amebae, two nuclei are visible (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch30.f5

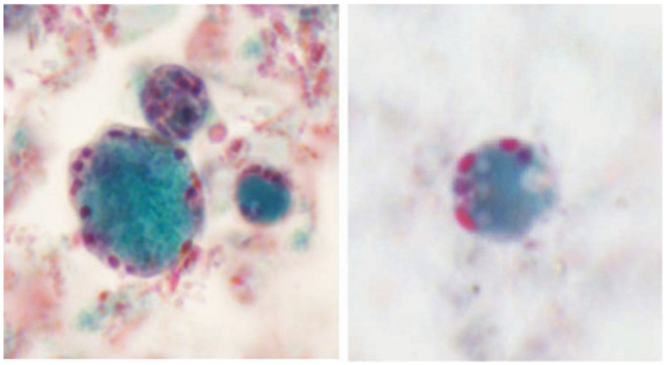
inflammation containing free-living amebae. Immunofluorescence microscopy showed that the organism was not one of the known species of ameba causing encephalitis. Trophozoites had a double nucleus, and transmission electron microscopy confirmed that they contained two nuclei closely apposed along a flattened surface. The nuclear structure and other unique structural features led to the diagnosis of *S. diploidea* encephalitis (15). The patient survived after surgical excision of the tumor-like mass in the brain and treatment using azithromycin, intravenous pentamidine, itraconazole, and flucytosine (15). However, the amoeba that caused this encephalitis was originally identified as *S. diploidea* but has now been identified as *S. pedata* by molecular techniques. The assay specific for *Sappinia* can be incorporated into the multiplex PCR assay that distinguishes *Acanthamoeba*, *B. mandrillaris*, and *N. fowleri* for simultaneous detection of the four genera of free-living amebae that cause infections in humans (16). This assay was able to detect one single ameba per sample, as determined with CSF spiked with diluted cultured amebas. *Sappinia* can be cultured on nonnutrient agar plates with a bacterial overlay, as well as tissue culture cells.

Blastocystis spp.

Intestinal protozoa are becoming increasingly recognized as significant pathogens in immunocompromised hosts. Microsporidia and *Blastocystis* have also emerged as important players, due in part to improved molecular diagnostic assays. *Blastocystis* spp. are among the most common intestinal protozoan parasites found in humans (Fig. 30.6). The prevalence of *Blastocystis* ranges from approximately 10% in developed countries to 60% in developing countries.

Blastocystis has been traditionally named *Blastocystis hominis* when isolated from human fecal materials. However, recent phylogenetic analyses suggest limiting its name to "*Blastocystis* species" because of their genetic diversity. This parasite has been considered as a species complex comprising 13 subtypes, of which at least 9 have been found in humans (17). Furthermore, they exhibit wide genetic diversity that may result in the assignment of different species to the subtypes. The confirmation of their species status and determination of virulence and pathogenic profiles might explain why some patients remain asymptomatic while others have clinical symptoms.

Figure 30.6 *Blastocystis* sp. Central body forms, Wheatley's trichrome stain. doi:10.1128/9781555819002.ch30.f6



Disagreements regarding its pathogenicity led to remarkable findings on both phenotypic and genotypic characteristics of asymptomatic and symptomatic human-derived *B. hominis* isolates (18). Certain subtypes of this organism are associated with intestinal disorders including irritable bowel syndrome. Cases of invasive intestinal infections and skin rashes have been attributed to infection by *Blastocystis* sp. in immunocompetent individuals, suggesting that it is an emerging parasite with pathogenic potential. In a recent case, a 22-year-old female patient complained of pain in the left hypochondrium. Ultrasonography and abdominal CT scans revealed two splenic cysts. The cyst fluid analysis demonstrated numerous *Blastocystis* sp.; PCR and DNA sequencing analyses confirmed the presence of *Blastocystis* subtype 3 (19).

The genome of *Blastocystis* subtype 7 encodes proteases, hexose digestion enzymes, lectins, protease inhibitors, and glycosyltransferases besides several proteins that are predicted to be secreted. The roles of some of these proteins are known in other parasites with direct connections to their pathogenicity in processes such as host cell invasion, excystation, metabolism, cytoadherence, and other virulence functions (20). Cysteine proteases from *Blastocystis* can increase epithelial permeability, and cysteine proteases are important enzymes for host invasion and infection and are well recognized as virulence factors in pathogenic protozoa (20).

Giardia lamblia

Giardia lamblia (*duodenalis*, *intestinalis*) is a flagellate commonly found in many parts of the world (Tables 30.3 and 30.4; Fig. 30.7). Although a number of papers on the nomenclature of *Giardia duodenalis* replacing *G. lamblia* or *G. intestinalis* have been published, apparently this change has not been formally recognized by the International Code of Zoological Nomenclature. Therefore, we will maintain the name *G. lamblia* for this edition. An infection with this organism can be transmitted via the cyst form in both water and food contaminated with fecal material, as can *E. histolytica* infections. Various conditions that have been associated with giardiasis in the compromised patient include hypogammaglobulinemia, protein or caloric malnutrition, previous gastrectomy, histocompatibility antigen HLA YB-12, gastric achlorhydria, blood group A, differences in mucolytic proteins in immunoglobulin deficiencies, and reduced secretory IgA levels in the gut (Table 30.2). Generally, adults and children are mentioned in relation to giardiasis; however, it is important to remember that the elderly, in both tropical and temperate zones, are also susceptible. These patients tend to be somewhat immunodepressed due to age and may be overlooked as having giardiasis.

Although patients with HIV infection have also been found to have giardiasis, the infection does not appear to be more severe among this group, regardless of the $CD4^+$ cell count (21). In some groups, the prevalence of *G. lamblia* is greater for HIV-infected subjects (22, 23). Both humoral and cellular immune responses play a role in acquired immunity, and the mechanisms involved remain somewhat unclear. However, the immune response to intestinal parasites, including *G. lamblia*, might be a risk factor for HIV/AIDS and tuberculosis (24). It is well known that diagnosing intestinal parasites in HIV/AIDS patients is necessary, especially in those who are chronic alcoholics or are not receiving antiretroviral treatment. With progressive immunosuppression following reduced $CD4^+$ counts, the risk of symptomatic *Giardia* infections is increased. However, giardiasis is not considered a major cause of enteritis in HIV-infected patients.

Multiple infections tend to be more common among renal transplant recipients. This highlights the importance of testing for intestinal parasites among this group. Routine examinations of stool samples for parasites would significantly benefit renal transplant recipients by helping to reduce severe infections. Symptomatic giardiasis has been observed in X-linked infantile congenital hypogammaglobulinemia (Bruton's syndrome) and also in the common variable (late-onset) acquired hypogammaglobulinemia. Immunocompromised patients such as nephrotic syndrome children receiving corticosteroids, protein-calorie malnutrition patients, patients with cases of marasmic kwashiorkor, and lymphoma patients have been found to be significantly more at risk for *Giardia* infection (25).

Symptoms of giardiasis may range from none to the malabsorption syndrome, which is characterized by gas,

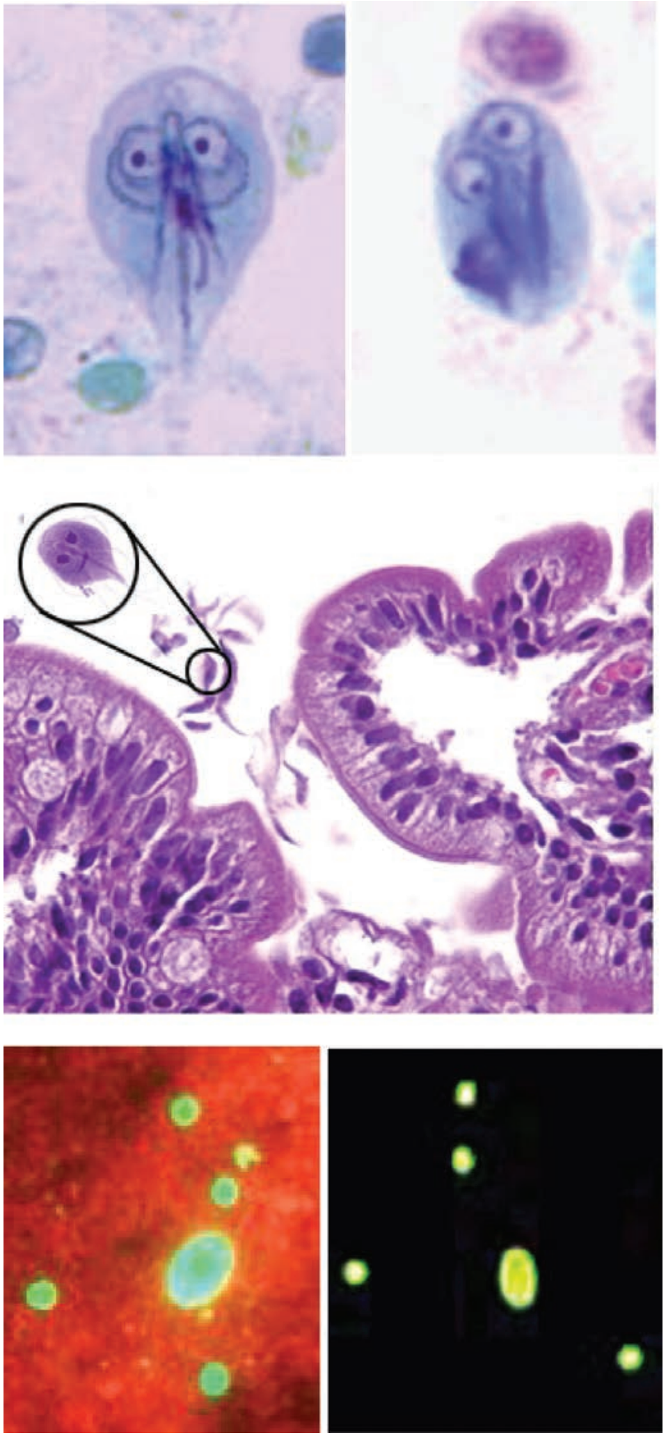


Figure 30.7 (Top, left) *Giardia lamblia* trophozoite (note two nuclei, curved median bodies, and linear axonemes); (right) *G. lamblia* cyst. (Middle) Multiple *Giardia* trophozoites seen in gastrointestinal tract; note the enlargement (courtesy of Medical Sciences, Indiana University, http://medsci.indiana.edu/c602web/602/c602web/nutrit/docs/cas4_giard.htm). (Bottom) *G. lamblia* cyst (large) and *Cryptosporidium* spp. oocysts (small) demonstrating fluorescence in the fecal FA immunoassay. Note in the left image that the background demonstrates use of the counterstain, while in the right image no counterstain was used.
doi:10.1128/9781555819002.ch30.f7

bloating, frothy green foul-smelling stools, and abdominal pain. The organism is reasonably easy to identify. The trophozoite form is teardrop shaped, and the flagella and sucking disk are easily visible. On side view, the trophozoite often looks somewhat like the curved end of a spoon. Trophozoites tend to stain pale, while the cysts usually stain darker and are easier to identify. Cysts are round to oval, with long axonemes and curved median bodies being visible. Normally, cysts can be seen and identified on wet mount preparations from concentrated material and confirmed by using the permanent stained smear.

In contrast to *E. histolytica*, *G. lamblia* inhabits the duodenal area of the intestine, tends to adhere very tightly to the mucosa, and can be very difficult to recover, even after a series of five or six stool examinations. For this reason, other techniques, such as the Entero-Test string capsule, duodenal aspirate, or biopsy, may have to be used. Fecal immunoassays are also recommended for the diagnosis of giardiasis; they are more sensitive than the routine ova and parasite examination.

Toxoplasma gondii

Toxoplasma gondii is worldwide in distribution, and serologic data indicate that human infections are common, although most infections are benign or cause no symptoms (Tables 30.3 and 30.4). Serologic evidence from throughout the United States indicates that anywhere from 20 to 70% of the population are serologically positive for *T. gondii*. The percentage of serologically positive patients tends to be higher in the tropical areas of the world.

Toxoplasmosis can vary from an asymptomatic, self-limiting infection to a fatal disease, as seen in patients with congenital infections or in debilitated patients in whom underlying conditions may influence the final outcome of the infection (Table 30.7). In immunocompromised patients, the infection most often involves the nervous system, with diffuse encephalopathy, meningoencephalitis, or cerebral mass lesions (Fig. 30.8). In one study, multiplex nested PCR analysis was used to determine the genotypes of parasites in CSF; 8 of 10 human HIV-positive patients had infections with type I strains, even though this lineage is normally uncommon in humans and animals (26). Although gastric toxoplasmosis is rare, in some patients with AIDS it is the primary manifestation (27).

Underlying conditions associated with toxoplasmosis in the compromised host include various types of malignancies, such as Hodgkin's disease; non-Hodgkin's lymphomas, leukemias, or solid tumors; collagen vascular disease; and organ transplantation. We must also add to this category patients with AIDS. Over 50% of such patients with toxoplasmosis have alterations of mental status, motor impairments, seizures, abnormal reflexes, and other neurologic symptoms. Studies have shown that even among compromised patients, 80% of those receiving chemotherapy for toxoplasmosis experienced significant clinical improvement or complete remission; however, in those with AIDS, therapy must be continued for long periods to maintain a clinical response.

Toxoplasma encephalitis has been reported as a life-threatening opportunistic infection among patients with AIDS. The overall prognosis can be poor, with the median survival following initiation of therapy being 4 months. A clinical relapse of *Toxoplasma* encephalitis has been reported to occur in 50% of patients discharged from hospital. In AIDS patients who may not receive prophylaxis for *Pneumocystis jiroveci* pneumonia, almost half of the *Toxoplasma*-seropositive patients can develop CNS toxoplasmosis. This figure is considerably higher than previously thought for the development of CNS involvement. Statistics indicate that, overall, approximately 2.5% of AIDS patients have been diagnosed with cerebral toxoplasmosis. Information on toxoplasmosis and the immunocompromised host can be seen in Table 30.7.

In seropositive allogeneic hematopoietic stem cell transplant recipients, the hazard of *T. gondii* reactivation is generally high. The donor's seronegative status seems to contribute to this risk, as approximately 80% of all reported events of toxoplasmosis are observed in cases of donor/recipient serological mismatch. Clinical symptoms of reactivation are usually observed within 2 to 4 months posttransplant. Additional factors that may contribute to early and heavy *T. gondii* dissemination and rapid clinical deterioration include the lack of posttransplantation prophylaxis in an immunosuppressed seropositive recipient. Other contributing factors may involve receipt of a graft from an atypical genotype of *T. gondii* (28).

Humans usually become infected with *T. gondii* by ingesting raw or poorly cooked meats. Another means of transmission is ingestion of infected oocysts found in cat feces. It has been recommended that litter boxes be cleaned daily, with feces disposed of in the toilet and the pans disinfected with boiling water. Since we know that transplacental transmission can occur during an acute but perhaps undiagnosed maternal infection, pregnant women, unless they have serologic evidence of previous infection, should avoid contact with cats whose source of food is not controlled and should not empty litter boxes. Uterine or neonatal infections can give rise to a number of serious sequelae, including microcephaly and hydrocephalus.

In humans, *T. gondii* is found in two different stages. The actively proliferating intracellular forms are called trophozoites or tachyzoites and are crescent shaped. Many different tissues may be parasitized by these organisms,

TABLE 30.7 *Cryptosporidium* infections in immunocompromised patients[a]

Underlying condition	Disease manifestation	Comments
AIDS	Diarrhea and possible dissemination	Parasites associated with 14% of acute diarrheal episodes (<28 days) and 35% of chronic episodes (>28 days); parasite associated with diarrhea in 14% of patients when CD4$^+$ counts are ≥200 cells/µl and in 27% when counts are <200 cells/µl; *Cryptosporidium* associated with 5% of acute episodes and 13% of chronic episodes of diarrhea; *Cryptosporidium* likely to be associated with diarrhea as immunosuppression worsens and with chronic rather than acute diarrhea
AIDS	Diarrhea	Attack rate 14% among HIV-negative individuals and 31% among HIV-positive individuals (varies due to CD4 cell count); chronic symptoms in 15% (<150 CD4 cells/µl at onset); 14% had antibody before outbreak, 51% developed specific antibodies during outbreak; clinical manifestations of cryptosporidiosis strongly influenced by level of HIV-induced immunosuppression
AIDS	Pancreatitis	Acute or chronic pancreatitis associated with *Cryptosporidium* infection; abdominal pain resistant to analgesics, increased amylase level in serum; abnormalities on both sonography and CT; papillary stenosis in all patients; oocysts found in both bile and stool; viral cultures negative; several antibiotic protocols ineffective
AIDS	Gastric involvement	Of 24 individuals, 34% positive for *Cryptosporidium*, 16 (89%) of these had parasites in gastric epithelium; most patients did not show specific symptoms indicating presence in stomach; gastric involvement probably more frequent than expected; no clear correlation between gastric location and related clinical or pathologic features
AIDS	Diarrhea	22 *Cryptosporidium* isolates (Kenya, Switzerland, United States); 4 distinct genotypes identified (*C. parvum*, human genotype; *C. parvum*, cattle genotype; *C. felis*; and *C. meleagridis*, turkey); immunocompromised individuals susceptible to wide range of *Cryptosporidium* spp. and genotypes; full public health ramifications not known
AIDS	Diarrhea	*C. parvum* genotype subgroupings correlate to some extent with infectivity and suggest that additional heterogeneity is present within the subgroups
AIDS	Diarrhea	Treatment of HIV-1-associated microsporidiosis and cryptosporidiosis with combination antiretroviral therapy; combination therapy that includes protease inhibitors can restore immunity to both organisms and result in clinical, microbiological, and histologic responses; persistent CD8 cell and macrophage infiltrate and short time to relapse with declining CD4 lymphocyte counts suggest that neither infection was eradicated
AIDS	Diarrhea due to contaminated tap water	Risk assessment model applied to New York City population; calculated number of tap water-related cases per year was 6 (non-AIDS subgroups) or 34 (AIDS subgroups)
AIDS, pediatrics	Diarrhea	Some 81% of HIV-infected children with persistent diarrhea excreted *Cryptosporidium*, microsporidia, or both organisms, compared with only 10% of children with persistent diarrhea testing negative for HIV; 74% of isolates were *C. hominis*, 17% were *C. parvum*, and 8% were a mixture of the 2 or others
All causes	Diarrhea due to zoonotic transmission	Presence of *Cryptosporidium* in cats (5%) (in addition to other organisms such as *Giardia* spp., *Toxocara cati*, *Salmonella*, *Campylobacter*); enteric zoonotic organisms detected in total of 13% of cats studied; cats in homes of immunocompromised humans should be evaluated for zoonotic organisms
Hodgkin's lymphoma	Diarrhea	Immunocompromised prevalence of 14.3%; control group had 5.6%
Immunosuppressive therapy for pediatric oncology	Diarrhea	In contrast to studies of adult oncology patients, pediatric oncology patients in some areas appear to be at low risk for cryptosporidiosis
Immunosuppressive drugs for kidney transplantation, chronic renal insufficiency	Diarrhea	*Cryptosporidium* found in 35% (renal transplant group), 25% (patients on hemodialysis), and 17% (control group with systemic arterial hypertension) of patients; when number of positive fecal samples is taken into account, there is a significantly higher frequency in renal transplant patients
Immunosuppressive drugs for kidney transplantation	Diarrhea	*Cryptosporidium* present in 19% of patients, *Blastocystis hominis* in 39%; symptomatic infections with *Cryptosporidium* significantly higher in transplant patients than controls
Immunosuppressive drugs for liver transplantation	Diarrhea	Primary hypogammaglobulinemia, chronic hepatitis C, hepatic failure; 14 mo posttransplantation, *Cryptosporidium* diarrhea; no response to therapy; patient died
Immunosuppressive drugs for solid-organ transplantation[b]	Diarrhea	Included 3 liver transplants and 1 small bowel transplant; all 4 patients resolved cryptosporidiosis; while cryptosporidiosis is a nonlethal complication, it allows physician to monitor degree of immunosuppression and relationship to infection

[a] Adapted from references 25 and 31. CT, computed tomography.
[b] Excludes kidney transplantation.

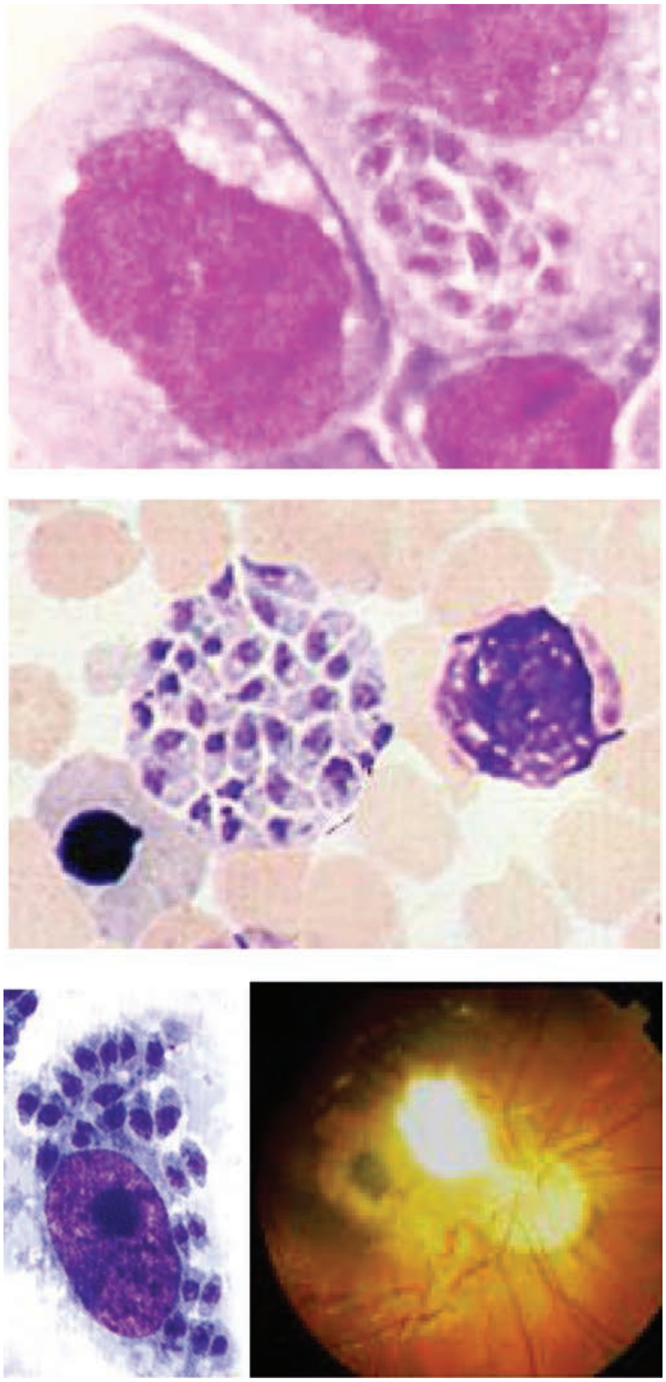

Figure 30.8 *Toxoplasma gondii*. (Top) Tissue cyst containing 8 to 20 parasites. (Middle) Organisms in bone marrow. (Bottom, left) Tachyzoites in tissue culture; (right) granuloma in eye. doi:10.1128/9781555819002.ch30.f8

particularly lung, heart, lymphoid organ, and CNS tissues. The resting forms or cyst stages are found in the tissues and contain the more slowly developing bradyzoites.

Toxoplasmosis can be diagnosed by using various serologic procedures, histologic findings from the examination of biopsy specimens, and isolation of the organism, either in a tissue culture system or by animal inoculation. Individuals with positive serologic tests have been exposed to *Toxoplasma* organisms and may have the resting stages within their tissues. This is why histologic identification of the organism and its recovery either in a tissue culture system or by animal inoculation may be misleading, since the organisms could be isolated yet might not be the etiologic agent of disease. Thus, serologic tests have been recommended as the diagnostic tests of choice. One of the first serologic tests was the Sabin-Feldman dye test, a reaction based on the fact that serum antibodies to *T. gondii* will affect the organisms so that they become refractory to staining with methylene blue. However, since this test requires the use of living *Toxoplasma* trophozoites, most laboratories do not provide it for clinical use.

In an immunodeficient or immunosuppressed patient, a presumptive diagnosis of toxoplasmosis can be made by observing an elevated serologic titer and the presence of the clinical syndrome, which would include neurologic symptoms. However, in certain patients with monoclonal gammopathies, titers to *T. gondii* may be extremely high but may not reflect the cause of the clinical condition. One of the most common diagnostic tests used for toxoplasmosis is the IFA procedure. Definitive diagnosis is usually made when there is a rising titer, an IgM-IFA titer of at least 1:64, or an IgM-ELISA titer of 1:256. A finding that the Sabin-Feldman dye reaction is higher in CSF than in serum is also significant but not that common. An elevated serologic titer in conjunction with demonstration of the actual trophozoites or isolation of the organisms from cerebrospinal fluid is very significant.

A new possibility in *T. gondii* serodiagnosis is the selection and use of molecular markers, which are proteins characteristic of the parasite's tachyzoite or bradyzoite stage that are able to recognize the specific antibodies from acute or chronic human sera. Promising results show that the use of a specific recombinant protein identifies the phase of the disease during the testing of a single serum sample (29).

Cryptosporidium spp.

Although it has been recognized as an animal parasite for many years, one of the newer parasitic organisms infecting humans, particularly compromised patients, is *Cryptosporidium*, a cause of diarrhea (Tables 30.3 and 30.4; Fig. 30.9) (25, 30, 31). *Cryptosporidium* differs from other coccidia that infect warm-blooded vertebrates in that the developmental stages do not occur deep within host cells but are confined to an intracellular, extracytoplasmic loca-

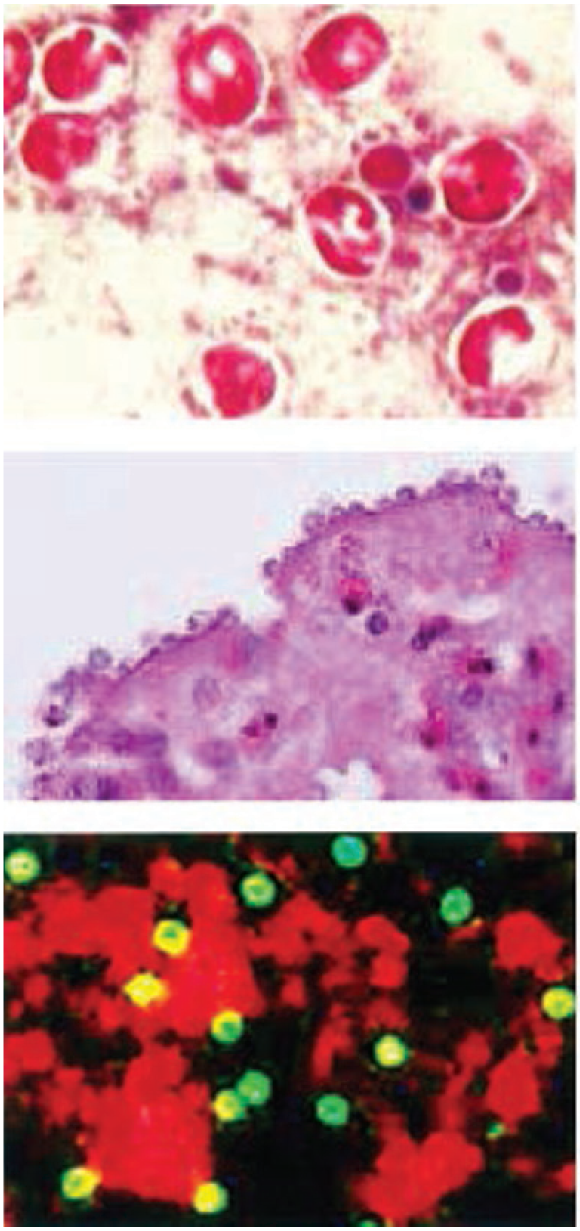

Figure 30.9 *Cryptosporidium.* (Top) Oocysts stained using the modified acid-fast stain; note the spherical shape. Oocysts measure 4 to 6 µm and some contain sporozoites that are visible. (Middle) Organisms visible along the brush border of intestinal mucosa. (Bottom) FA procedure showing fluorescent apple-green oocysts; counterstain present.
doi:10.1128/9781555819002.ch30.f9

tion. Each stage is within a parasitophorous vacuole of host cell origin. What was previously called *C. parvum* and was thought to be the primary *Cryptosporidium* species infecting humans is now classified as two separate species, *C. parvum* (mammals, including humans) and *C. hominis* (primarily humans). Differentiation of these two species based on oocyst morphology is not possible.

Studies have shown that calves and perhaps other animals may serve as potential sources of human infections. Kittens, puppies, and rodents are possible reservoir hosts, since they are easily infected with human *Cryptosporidium*. Person-to-person transmission is also likely and may occur through direct or indirect contact with stool material in the environment and the hospital setting.

This organism is worldwide in distribution, and although the first cases in the literature indicated that the patients were immunosuppressed or immunodeficient, current literature reports numerous infections and outbreaks in patients with a normal immune system capability. In patients with a normal immune system capability, cryptosporidiosis is self-limiting. However, in certain compromised patients, the diarrhea is very severe and prolonged, with death being the eventual outcome (Tables 30.4 and 30.7). Clinical symptoms include nausea, low-grade fever, abdominal cramps, anorexia, and 5 to 10 watery stools per day. Fluid loss in these patients is significant and has been reported to be as great as 17 liters/day.

Although many therapeutic regimens have been tried, there is no completely satisfactory therapy for cryptosporidiosis in humans. Paromomycin, clarithromycin, nitazoxanide, and hyperimmune bovine colostrum are among the drugs being tried in different regimens; the current recommendation is nitazoxanide (30). However, no drug has proven efficacy in cryptosporidiosis in immunosuppressed patients. For HIV-infected patients, potent antiretroviral therapy is the mainstay of treatment. Nitazoxanide (treatment duration of 5 to 21 days), paromomycin, or a combination of paromomycin and azithromycin may be tried to decrease diarrhea and recalcitrant malabsorption of antimicrobial drugs, which can occur with chronic cryptosporidiosis (30). Specific recommendations for immunocompromised patients in avoiding potential risk situations for acquiring infection with *Cryptosporidium* spp. can be found in Table 30.8.

Since the organisms live in the microvillous surface of the mucosal epithelial cells of the intestine, diagnostic techniques have included histologic examination of intestinal biopsy material, scanning and transmission electron microscopic examination of duodenal aspirates and biopsy specimens, and the examination of stool specimens for oocysts.

Although biopsy techniques have been used to recover and identify the organisms in tissue, one problem with a tissue specimen is that the specific area where the organisms reside may not be subjected to biopsy. The examination of stool material for oocysts by using an acid-fast technique or immunoassays allows one to screen a sample from the entire intestinal tract. It is considerably cheaper to examine

TABLE 30.8 Prevention of cryptosporidiosis in immunocompromised patients[a]

Preventive measure	Comments
Hand washing	Prior to eating and food preparation; after touching children in diapers; after touching clothing, bedding, toilets, or bed pans from anyone with diarrhea; after gardening; after touching pets or other animals; after touching or coming in contact with anything contaminated with human or animal stools (includes dirt); after removing gloves to perform any of the above activities
Safe sex	Always wash hands after touching partner's anal or rectal area
Avoidance of farm animals	Particularly important for contact with young animals (especially lambs and calves); wash hands thoroughly; avoid touching stools of any animal; after potential exposure, clean shoes (avoid having someone who is HIV infected perform this task)
Avoidance of pet stools	If HIV infected, avoid cleaning litter boxes or cages and disposing of stools; very important to avoid if animals are less than 6 months old; have puppies or kittens (if less than 6 months old) tested for *Cryptosporidium* before bringing them home; adult cats have also been found to be positive; have any pet tested that develops diarrhea
Precautions while swimming	Avoid swallowing water when in lakes, rivers, pools, or hot tubs; organisms not killed by routine chlorination; oocysts can also survive several days in salt water, so avoid swimming in polluted ocean water
Washing and cooking food	Wash well all fruits and vegetables if eating uncooked; use safe water for washing food; peel fruit; avoid unpasteurized milk or dairy products; cooking kills *Cryptosporidium*; cooked or packaged food is safe unless handled by someone infected with the organism
Water for drinking	Do not drink directly from lakes, rivers, streams, or springs; may want to avoid unboiled tap water (includes water and/or refrigerator ice-maker ice); boil water (rolling boil for 1 min sufficient to kill organisms), filter with appropriate filters (look for "reverse osmosis," "absolute 1 micron," "Standard 53," and the words "cyst reduction" or "cyst removal"); home distiller can be used; store water as for boiled water
Bottled water	Bottled water labels reading "well water," "artesian well water," "spring water," or "mineral water" do not guarantee that the water does not contain *Cryptosporidium*; however, water that comes from protected well or spring water sources is less likely to be contaminated than bottled water from rivers and lakes
Drinks	Canned or bottled soda, seltzer, fruit drinks, and steaming hot tea and coffee are safe; fountain drinks, fruit drinks mixed with tap water from concentrate, and iced tea or coffee may not be safe

[a] Adapted from information prepared by the interagency Working Group on Waterborne Cryptosporidiosis.

a stool specimen than to perform endoscopy or histologic testing. *Cryptosporidium* oocysts in the stool range from 4 to 6 µm in diameter and can be difficult to identify. One must also remember that even in patients with typical watery diarrhea, the numbers of organisms passed can be quite variable.

Respiratory cryptosporidiosis has also been detected in AIDS patients. Sputum specimens should be submitted in 10% formalin or as a fresh specimen and can be examined by the same techniques as used for stool samples.

Some techniques have included sugar flotation, formalin sedimentation, Giemsa stain, trichrome, PAS, methenamine silver, acridine orange, auramine-rhodamine, iodine, modified acid-fast, Kinyoun and Ziehl-Neelsen acid-fast, and immunoassay techniques. The most widely used techniques are modified acid-fast stains, Kinyoun's methods, and fecal immunoassays. Specimens preserved in polyvinyl alcohol do not stain well in the acid-fast techniques.

Because other organisms may also fluoresce when auramine or the auramine-rhodamine combination is used, presumptive positive specimens should be confirmed by using one of the acid-fast methods. *Cryptosporidium*, *Cyclospora*, and *Cystoisospora* fluoresce with auramine-rhodamine and are acid-fast positive. *Cryptosporidium* oocysts are fully mature and infective at the time they are passed in the stool. One can occasionally see the four sporozoites with the dark-staining residual body in the fully developed oocyst.

Immunoassay procedures for the direct detection of *Cryptosporidium* antigen or oocysts in fecal specimens have proven to be much more sensitive than the routine acid-fast stains. Since acid-fast stains do not always consistently stain all oocysts, the increased sensitivity and specificity of these immunoassays provide excellent testing methods. Enzyme immunoassay, solid-phase immunochromatographic assay in cartridge format, and fluorescent antibody methods are currently available. The choice of method depends on a number of variables and differs among diagnostic laboratories. All of the fecal immunoassays are comparable in terms of specificity and sensitivity. Molecular tests are becoming more widely available, including some gastrointestinal panels.

Since *Cryptosporidium* has been recovered from patients with AIDS, it has been recommended that stool specimens be submitted in 5 or 10% formalin, sodium acetate-acetic acid-formalin, or the newer single-vial collection systems for processing. However, each laboratory must confirm that the fixatives selected are compatible with diagnostic procedures performed, including the ova and parasite examination and immunoassays; not all single-vial systems are compatible with diagnostic immunoassay reagents. Laboratories should use standard precautions when working with these stool specimens. When specimens are centrifuged, capped centrifuge tubes should be used to prevent the formation of aerosols. Also, if possible, specimen processing should be performed in a biological safety cabinet.

Cyclospora cayetanensis

Cyclospora cayetanensis organisms are acid-fast-variable coccidia and have been found in the feces of immunocompetent travelers to developing countries, immunocompetent subjects with no travel history, and patients with AIDS (Fig. 30.10) (32–36). The life cycle has been confirmed, but information on potential reservoir hosts has yet to be defined; however, it appears that in some areas the human is the only host (Table 30.9). Outbreaks linked to contaminated water and various types of fresh produce (raspberries, basil, baby lettuce leaves, and snow peas) have been reported.

Oocyst maturation takes approximately 7 to 15 days, so the mature stage may not have been seen in human specimens. The oocyst contains two sporocysts, each containing two sporozoites, a pattern which places these organisms in the coccidian genus *Cyclospora*. Unsporulated oocysts are passed in the stool, and sporulation occurs within approximately 1 to 2 weeks. In patients who have *Cyclospora* oocysts in their stool specimens, two types of meronts and sexual stages have been found within the jejunal enterocytes.

There is generally 1 day of malaise and low-grade fever, with rapid onset of diarrhea of up to seven stools per day. There may also be fatigue, anorexia, vomiting, myalgia, and weight loss, with remission of self-limiting diarrhea in 3 to 4 days, followed by relapses lasting from 4 to 7 weeks. In patients with AIDS, symptoms may persist for as long as 12 weeks. Biliary disease has also been found in this group; acalculous cholecystitis was reported for HIV-positive and AIDS patients and resolved after initiation of treatment (35). These patients presented with right

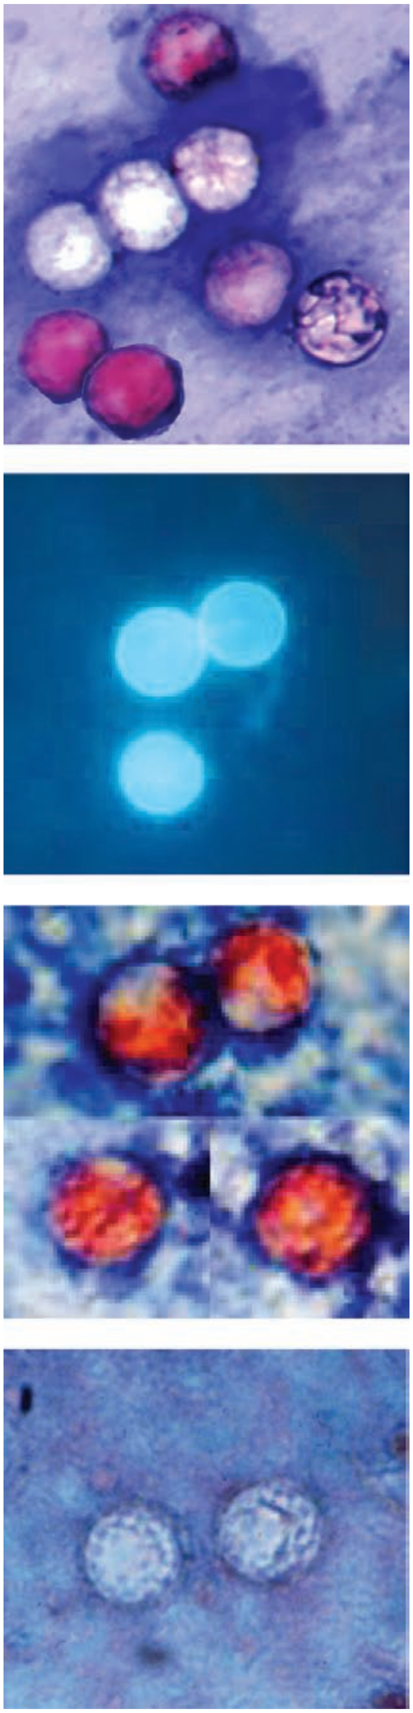

Figure 30.10 *Cyclospora cayetanensis*. (Top) Oocysts stained using the modified acid-fast stain (note the spherical shape; oocysts measure 8 to 10 µm; some oocysts do not stain, thus the organisms are said to be "modified acid-fast variable"). (Row 2) Autofluorescent oocysts using the appropriate filters for calcofluor white. (Row 3) Oocysts stained using the hot safranin method. (Bottom) Oocysts stained using the routine Wheatley's trichrome stain; note the oocysts do not stain well, but appear to be "ghost" cells. doi:10.1128/9781555819002.ch30.f10

TABLE 30.9 *Cyclospora cayetanensis*[a]

Information	Comments
Disease	
Haiti	Fewer infections in winter; summer temperatures may influence seasonality of infection; 34% in AIDS patients; exposure to water is a significant variable associated with infection
Guatemala	Children 5 times more likely to be infected than adults; more common in warmer months; high levels of contamination in rivers May–July; 18% in children 1 month to 1.5 yr old—most likely exposed from foods
Peru	2% in children 2 to 4 yr old; summer peak; 13% 1 to 9 yr old
Nepal	Oocysts identified in sewage water, vegetable washings; 11% in symptomatic travelers; 5% in children 6 to 60 months with diarrhea
Turkey	1.9% in hospital; higher in summer, 4.2% in another hospital study; 24.5% in immunocompromised patients with severe diarrhea (14.3% with *Cryptosporidium* as well)
Egypt	HIV-negative patient with weight loss, cough with purulent sputum, and dyspnea; suggested tuberculosis, *Cyclospora* confirmed by nested PCR; 2 cases on record; organism must be considered a new respiratory system pathogen; 5.6% with diarrhea, 2.3% without diarrhea
India	Important to test for intestinal parasites in HIV-positive patients
Reservoir hosts	
Worldwide	Pigs, cattle, horses, goats, dogs, cats, guinea pigs, chickens, ducks, turkeys, pigeons negative; humans may be the only natural host; controlled laboratory studies with freshwater clams (*Corbicula fluminea*) showed that 48 to 100% of the clams retained *Cyclospora* oocysts for up to 13 days
Disease risk factors	
Guatemala	U.S. infections linked to importation of Guatemalan raspberries; risk factors for workers include drinking water source, sewage drainage, proximity to chickens/other fowl; risk factors for children include contact with soil; drinking untreated water
Egypt	Sporulated and unsporulated oocysts found in tap water and lettuce heads; patients with Hodgkin's lymphoma on chemotherapy are at risk
Peru	Oocysts found in wastewater; may be link to oocysts on vegetables
North America	Linked to raspberries, mesclun, basil, snow peas; over 3,600 cases since 1995; tap water

[a]Adapted from references 32–35.

upper quadrant abdominal pain and elevated alkaline phosphatase levels. Diarrhea alternating with constipation has also been reported; this is not uncommon in a number of protozoal gastrointestinal infections. Clinical clues include unexplained prolonged diarrheal illness during the summer in any patient and in persons returning from tropical areas. The clinical presentation of patients infected with this organism is similar to that of patients infected with *Cryptosporidium* spp.

In clean wet mounts, the organisms are seen as nonrefractile spheres and are acid-fast variable with the modified acid-fast stain; those that are unstained appear as glassy, wrinkled spheres. Modified acid-fast stains stain the oocysts from light pink to deep red, and some contain granules or have a bubbly appearance. It is very important to be aware of these organisms when the modified acid-fast stain is used for *Cryptosporidium* spp. and other similar but larger structures (approximately twice the size of *Cryptosporidium* oocysts) are seen in the stained smear. It is important for laboratories to measure all acid-fast oocysts, particularly if they appear to be somewhat larger than those of *Cryptosporidium* spp. The oocysts autofluoresce green (1+ to 3+) (450 to 490 DM excitation filter) or blue (1+ to 3+) (365 DM excitation filter) under UV epifluorescence. It is strongly recommended that, during concentration (formalin/ethyl acetate) of stool specimens, the centrifugation time and speed should be 10 min at 500 × *g*. Molecular tests are becoming more widely available, as well.

Apparently, patients with *Cyclospora* infection do not respond to conventional antimicrobial therapies. Some patients have been treated symptomatically with antidiarrheal preparations and have obtained some relief; however, the disease appears to be self-limiting within a few weeks. Trimethoprim-sulfamethoxazole is currently the drug of choice; relief of symptoms has been seen in 1 to 3 days posttreatment. However, symptoms recur within 1 to 3 months posttreatment in over 40% of the patients. Although prophylaxis with trimethoprim-sulfamethoxazole is not generally recommended, it might be worth considering for an HIV-positive person visiting an area of endemic infection like Nepal during the summer, when the risk of infection tends to be the highest.

Published reports indicate that individuals of all ages, including immunocompetent and immunosuppressed individuals, can become infected. In Peru, infections with this organism have shown some seasonal variation, with peaks during April to June. This pattern is similar to that seen for *Cryptosporidium* infections in Peru. Preliminary data and extrapolation from what we currently know about cryptosporidiosis suggest that modes of transmission may be similar, particularly considering waterborne transmission.

Cystoisospora (*Isospora*) *belli*

An organism similar to *Cryptosporidium* that causes diarrhea in the compromised host is *Cystoisospora belli* (Tables 30.3 and 30.4; Fig. 30.11 and 30.12). Although *Cystoisospora* infections have been found in many areas of the world, certain tropical areas in South America appear to contain some well-defined locations of endemic infections. These organisms can infect both adults and children. Intestinal tract involvement and symptoms are generally transient unless the patient is immunocompromised (Tables 30.4 and 30.10). In a group of AIDS patients in Brazil, 2% were found to be positive for *C. belli* infection. In reviewing prevalence data for this and other parasites in this group, there did not appear to be any association between $CD4^+$ cell counts and any particular parasite. However, the data supported the value of using standard fecal examinations with this group of infected patients, even in the absence of diarrhea, since examinations can be easily performed, have a low cost, and can disclose treatable conditions (36). Since the introduction of highly active antiretroviral therapy (HAART), the prevalence of opportunistic infections has decreased dramatically; however, studies indicate that, unlike microsporidiosis and cryptosporidiosis, *Cystoisospora* prevalence has increased from 0.4 per 1,000 patients in the pre-HAART era to 4.4 per 1,000 patients in the HAART era (37).

Relapse tends to be common in both immunocompetent and immunosuppressed patients and is thought to be associated with extraintestinal stages (38). These unizoite tissue cysts in extraintestinal sites have been confirmed to be present in the liver, spleen, and mesenteric lymphoid tissues in AIDS patients (38, 39).

Cystoisospora infection is frequent in patients with AIDS in tropical areas. It has also been reported to occur in transplant recipients and in patients with other immunosuppressive diseases, such as lymphoblastic leukemia, adult T-cell leukemia, and Hodgkin's disease. Non-Hodgkin's lymphoma with chronic diarrhea due to *C. belli* has also been reported (40). *C. belli* can cause severe chronic diarrhea in patients with malignancies whose country of origin is in an area of endemic infection. Isosporiasis should be suspected in HIV-infected patients from tropical countries

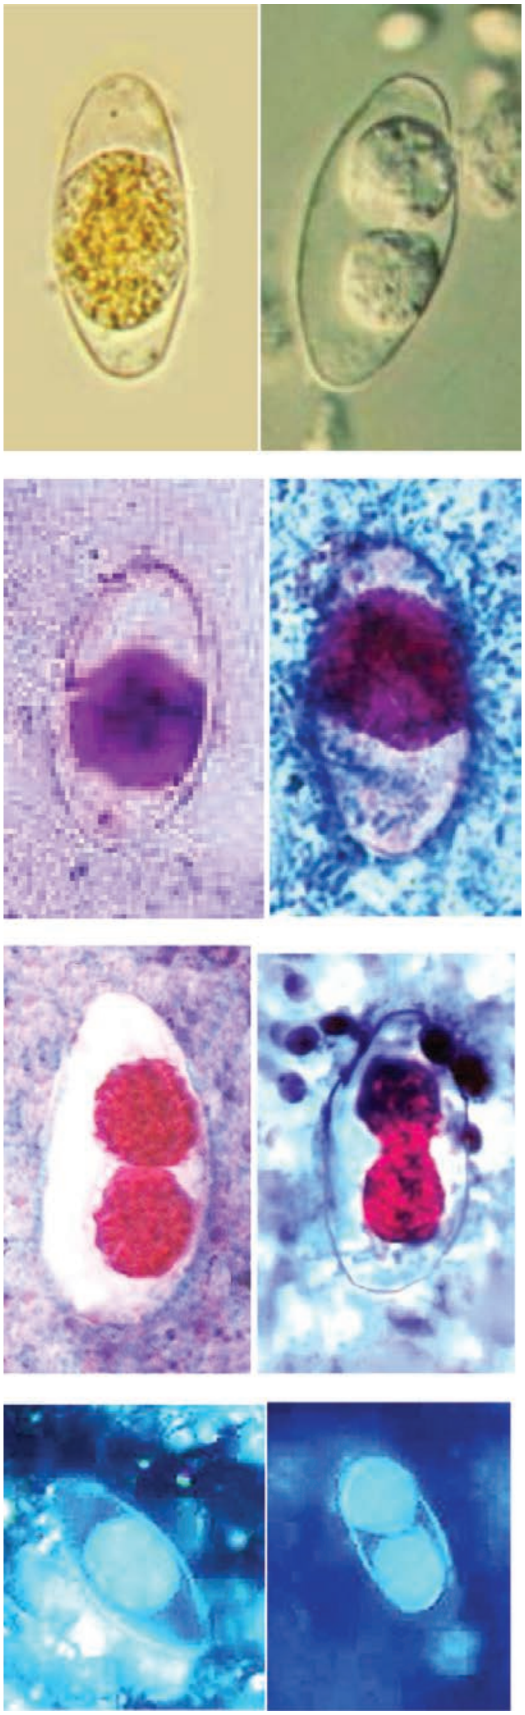

Figure 30.11 *Cystoisospora* (*Isospora*) *belli*. (Top) Wet mounts; immature oocyst (contains single sporoblast) on the left and mature oocyst on the right. (Row 2) Immature oocysts containing a single sporoblast, modified acid-fast stain. (Row 3) Mature oocysts containing two sporoblasts, modified acid-fast stain. (Bottom) Immature (one sporoblast) and mature (two sporoblast) oocysts in unstained wet mount viewed using UV fluorescence microscopy. (Bottom images courtesy of the CDC Public Health Image Library.) doi:10.1128/9781555819002.ch30.f11

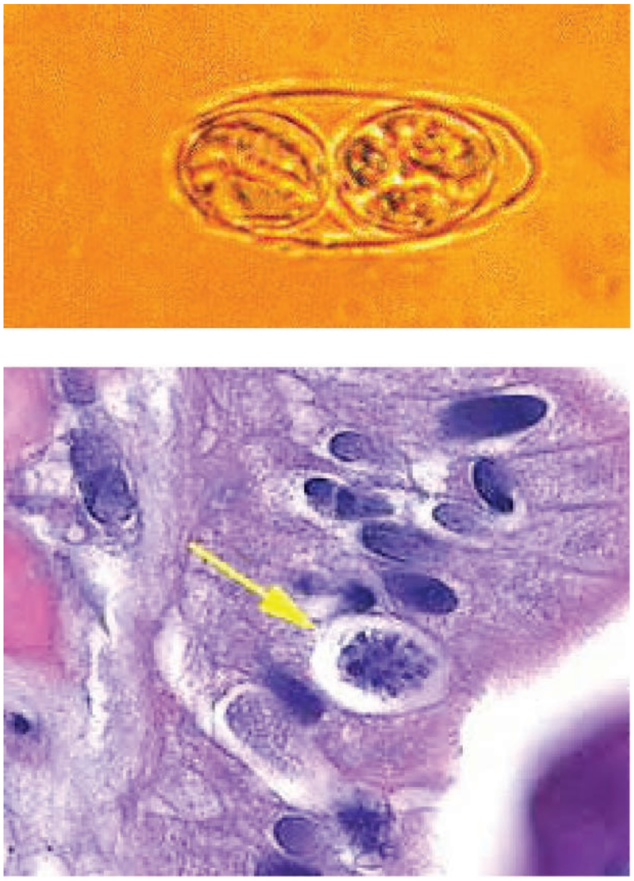

Figure 30.12 *Cystoisospora* (*Isospora*) *belli*. (Upper) Oocyst containing two sporocysts, each containing four sporozoites. (Lower) Developing stages in tissue, stained with hematoxylin and eosin (courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch30.f12

presenting with diarrhea, weight loss, eosinophilia, and low $CD4^+$ cell counts.

Since *C. belli* infects both immunocompetent and immunocompromised adults and children, symptoms range from none to severe diarrhea. Persistent nonbloody diarrhea, similar to that seen with microsporidiosis or cryptosporidiosis, is the major symptom seen in immunocompromised individuals. Pathology with blunting of the villi, villous atrophy, and collagen deposition in the lamina propria is commonly seen. Extraintestinal infections have been detected in AIDS patients, revealing infections in lymph nodes, liver, spleen, and biliary system.

The life cycle of *C. belli* is generally considered to be similar to the life cycles of other coccidia; however, *C. belli* is thought to infect only humans. Oocysts are passed in the stool and are usually underdeveloped and noninfectious when passed. These oocysts are most often seen in wet preparation, such as the direct smear or the concentration sediment.

There has been much speculation over the years that many cases of *Cystoisospora* infection go undetected and that the incidence may be higher than that reported in the literature. However, it is also possible to have a positive biopsy specimen and not recover the oocysts in the stool because of the small numbers of organisms present. The oocyst wall in *C. belli* remains intact, and development can range from little differentiation to the presence of two well-defined sporocysts within the oocyst wall.

Sarcocystis spp.

Sarcocystis spp. require two hosts for completion of the life cycle. Two well-described species are *Sarcocystis* (*bovihominis*) *hominis* (cattle) and *Sarcocystis suihominis* (pigs). When raw or poorly cooked meat from infected animals is ingested by humans, gamogony occurs within the intestinal cells, with the production of sporocysts in the stool. In this case, humans who have ingested meat containing the mature sarcocysts serve as the definitive hosts. There have been reports of fever, severe diarrhea, abdominal pain, and weight loss in compromised hosts. Eosinophilic enteritis and ulcerative obstructive enterocolitis may be seen as occasional complications. In one group of Thai laborers, a 26.6% prevalence of *Sarcocystis* infection was seen. This high prevalence rate was indicative of the local habit of eating raw beef and pork; sarcocystosis could be a significant food-borne zoonotic infection in Thailand (41).

The sporocysts that are recovered in the stool are broadly oval, measuring 9 by 16 μm and containing four mature sporozoites and the residual body. Normally two sporocysts are contained within the oocyst (similar to *C. belli*); however, in *Sarcocystis* infections, the sporocysts are released from the oocyst and normally are seen singly (Fig. 30.13). They tend to be larger than *Cryptosporidium* oocysts, which contain four sporozoites, and so there should be no confusion between the two (42). Differentiation of encysted protozoan parasites in human feces is described in Table 30.11.

When humans serve as the accidental intermediate host, they accidentally ingest oocysts from other animal stool sources. The sarcocysts that develop in human muscle (schizogony) apparently do little if any harm (Fig. 30.14). There is essentially no inflammatory response to these stages in the muscle and no conclusive evidence of pathogenicity of the mature sarcocyst. However, symptoms have definitely been reported in some cases. A number of different morphologic types of skeletal and cardiac muscle sarcocysts have been recovered in humans; sarcocysts have also been found in muscles of the larynx, pharynx, and upper esophagus. Generally, histopathologic diagnoses are myositis with vasculitis and sometimes myonecrosis. No specific therapy is known for this type of infection, although

TABLE 30.10 *Cystoisospora* (*Isospora*) *belli*: parasite development and disease

Characteristic	Description	Comments
Infection source	Transmitted by infective oocysts in fecal-oral transmission	Excystation induced by body temperature with bile or bile salts and trypsin
Infective stage	Mature oocysts containing sporocysts with internal sporozoites; not infectious when passed	Oocyst wall is split, thus releasing sporozoites
Developmental stages	Zoites and meronts develop within epithelial cells; eventually merozoites form macrogametes and microgametes	Small intestine; in immunocompromised, parasite development occurs in biliary epithelial cells, as well; parasite cysts also seen in extraintestinal sites such as lymph nodes, liver, and spleen
Immunocompromised host	Recurrence of infection in AIDS patients following successful chemotherapy; recurrent diarrhea in AIDS patients receiving HAART	May be due to activation of cysts in extraintestinal sites
Cellular and molecular biology	Parasite material difficult to obtain; culture difficult, complete development difficult	Overall, little is known about the biology of this parasite
Clinical aspects	Infects both immunocompetent and immunocompromised patients; 54% have peripheral eosinophilia; vomiting, steatorrhea, headache, fever, malaise; symptoms in children can be severe	Most information comes from disease as seen in Chile; persistent nonbloody diarrhea like that seen with microsporidiosis and cryptosporidiosis
Immunology	CD4 T cells involved	Infection more severe in AIDS patients (low CD4 counts)
Pathology	Moderate to severe villous atrophy; collagen deposition in the lamina propria	Both sexual and asexual stages seen in epithelium, enclosed by parasitophorous vacuole
Diagnosis	Routine fecal ova and parasite examination; concentration important; some molecular tests available	Modified acid-fast stains helpful; auramine-rhodamine; unstained oocysts autofluorescent; intestinal biopsy (routine stains)
Epidemiology	Transmission most common in tropical zones (subequatorial Africa, Caribbean, parts of South America)	Prevalence in populations with high HIV infection is quite variable; percentages vary from 3% to over 20%; rarely seen in HIV-positive children
Treatment	Trimethoprim-sulfamethoxazole recommended	An approved drug, but considered investigational for this condition by the Food and Drug Administration

Adapted from references 36–40.

albendazole has been reported to be helpful (30). Characteristics of this infection can be seen in Table 30.12. In another four cases, the patients presented with lumps, pain in the limbs, or a discharging sinus. Histologic examination of biopsy specimens in all cases revealed characteristic cysts of *Sarcocystis* spp. Again, therapy is not specifically recommended; however, albendazole and steroids were also used in these cases.

In 2012, *Sarcocystis nesbitti* caused an acute relapsing febrile myositis in 89 of 92 participants who attended a retreat on Pangkor Island in Malaysia (43). A case was defined as a person who attended a specified retreat at a hotel on Pangkor Island, Malaysia, from 17 to 19 January 2012, and developed relevant clinical symptoms (fever, headache, myalgia and/or arthralgia) within 28 days upon return. Cases were subsequently defined as "definite sarcocystosis" if there was histological demonstration or nucleotide sequences of *Sarcocystis* spp. from muscle tissue. The remaining cases were defined as "probable sarcocystosis." Although sarcocysts have previously been noted as incidental findings in tongue muscles in autopsies, the presence of sarcocysts in these cases most probably represents a pathological process. Also, these results suggest that *S. nesbitti* has a very high attack rate (97%).

For infections in which humans serve as definitive hosts, prevention involves adequate cooking of beef and pork; for infections in which humans are intermediate hosts, preventive measures involve careful disposal of animal feces possibly containing the infective sporocysts. This may be impossible in wilderness areas, where wild animals may serve as reservoir hosts for many of the different types of organisms that have been grouped under the term "*Sarcocystis lindemanni*." However, evidence of multiple morphologically different cysts indicates that there are probably several species of *Sarcocystis* that cause human infections. Therefore, the name is no longer used.

Microsporidia

The microsporidia are obligate intracellular parasites that have been detected in a variety of animals, particularly invertebrates; the organisms found in humans tend to be quite small, ranging from 1.5 to 3 μm. Until recently, awareness and understanding of human infections have

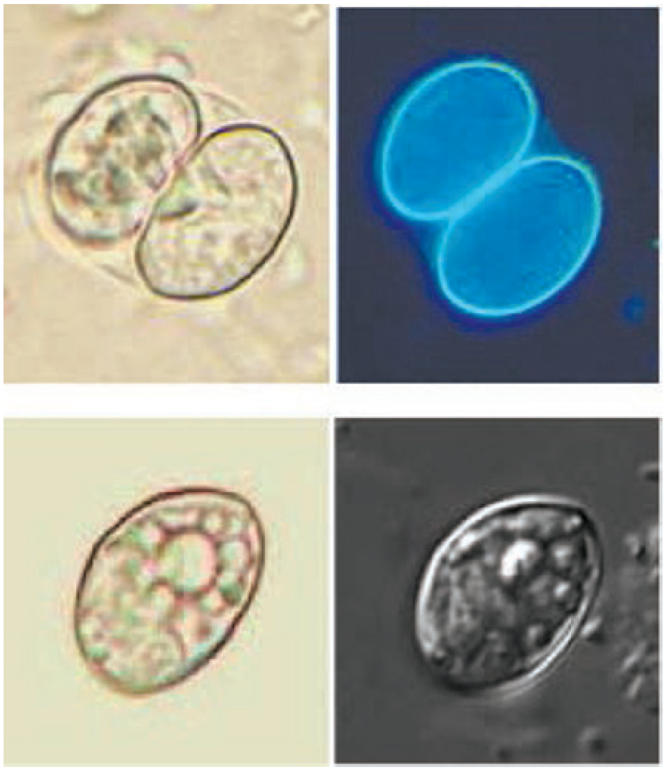

Figure 30.13 *Sarcocystis* sp. (Upper, left) Sporulated oocyst in unstained wet mount; (right) sporulated oocyst in a wet mount viewed under UV microscopy. (Lower, left) Sporocyst released from the oocyst; (right) sporocyst released from the oocyst, wet mount viewed under DIC microscopy. (Courtesy of the CDC Public Health Image Library.)
doi:10.1128/9781555819002.ch30.f13

been marginal; only with increased understanding of AIDS within the immunosuppressed population has attention been focused on these organisms (Tables 30.3, 30.4, and 30.13; Fig. 30.15 and 30.16) (44–58). Limited availability of electron microscopy capability has also played a role in difficulties related to identification and classification of these infections.

Phylogenetic studies have confirmed that the microsporidia evolved from the fungi, being most closely related to the zygomycetes (44). Features shared with fungi include the presence of chitin and trehalose, similarities in cell cycles, and certain gene organizations. Microsporidia are now considered to be highly derived fungi that underwent genetic and functional losses, thus resulting in one of the smallest eukaryotic genomes known. However, at this point, clinical and diagnostic issues and responsibilities may remain with the parasitologists, and these organisms are maintained as a part of this parasitology text. We may be in a transition stage, similar to that seen with *Pneumocystis jiroveci* as it was moved from the parasites to the fungi in terms of classification status.

The organisms are characterized by having spores containing a polar tubule, which is an extrusion mechanism for injecting the infective spore contents into host cells. To date, several genera have been recognized in humans: the more common, *Encephalitozoon* and *Enterocytozoon*, and the less common, *Anncaliia*, *Pleistophora*, *Trachipleistophora*, *Vittaforma*, *Tubulinosema*, and *Microsporidium*, a catch-all genus for organisms that have not yet been classified (or may never be classified due to a lack of specimen). Classification criteria include spore size, configuration of the nuclei within the spores and developing forms, the number of polar tubule coils within the spore, and the relationship between the organism and host cell. Infection occurs with the introduction of infective sporoplasm through the polar tubule into the host cell. The microsporidia multiply extensively within the host cell cytoplasm; the life cycle includes repeated divisions by binary fission (merogony) or multiple fission (schizogony) and spore production (sporogony). Both merogony and sporogony can occur in the same cell at the same time. During sporogony, a thick spore wall is formed, providing environmental protection for this infectious stage of the parasite. An example of infection potential is illustrated by *Enterocytozoon bieneusi*, an intestinal pathogen. The spores are released into the intestinal lumen and are passed in the stool. These spores are environmentally resistant and can then be ingested by other hosts.

Encephalitozoon

Both *Encephalitozoon cuniculi* and *Encephalitozoon hellem* have been isolated from human infections, the first species from the CNS and the second from the eye. The first case occurred in a 9-year-old Japanese boy who presented with neurologic symptoms such as convulsions, vomiting, headaches, fever, and periods of unconsciousness (44). The spores were recovered in the CSF and in urine. This particular patient was treated with sulfisoxazole and recovered. Another case of *E. cuniculi* infection was in a 2-year-old child with a similar neurologic illness; the spores were recovered from the urine. A recent case of keratoconjunctivitis and chronic sinusitis due to infection with *E. cuniculi* has been found in an AIDS patient; the diagnosis was confirmed by electron microscopy (44). Several eye infections with *E. hellem* have been found in AIDS patients, including the first reported case of *E. hellem* infecting not only sinuses and conjunctivae but also the nasal epithelium. In the first case of disseminated *E. hellem* infection in an AIDS patient, a complete autopsy revealed organisms in the eyes, urinary tract, and respiratory tract. The presence of numerous organisms within the lining epithelium of almost the entire length of the tracheobronchial tree was very suggestive of respiratory acquisition. It is also interesting that although *E. cuniculi* and *E. hellem*

TABLE 30.11 Encysted pathogenic protozoan parasites seen in human feces

Protozoan parasite	Size (µm)	Shape	Features
Sarcocystis hominis and *S. suihominis*			Excreted sporulated (immediately infectious)
Oocysts	15–19 by 15–20	Spherical	Contain 2 sporocysts; often seen as single sporocysts released from the oocyst
Sporocysts	15–19 by 8–10	Oval	Contain 4 sporozoites
Cystoisospora (*Isospora*) *belli*	20–33 by 10–19	Ovoid with tapered ends	Excreted unsporulated (not immediately infectious)
Cyclospora cayetanensis	7.7–10	Spherical	Excreted unsporulated (not immediately infectious)
Cryptosporidium hominis and *C. parvum*	4–6	Nearly spherical	Excreted sporulated (immediately infectious); some internal sporozoites difficult to see
Giardia lamblia	11–14	Spherical to ovoid to ellipsoid	4 nuclei, curved median bodies, linear axonemes (immediately infectious)
Dientamoeba fragilis	4–5	Spherical	Distinct cyst wall; cysts quite rare in clinical specimens
Entamoeba histolytica and *E. dispar* (*E. histolytica/E. dispar* group)	10–15	Spherical	Precyst generally contains single nucleus (karyosome with peripheral nuclear chromatin); mature cyst contains 4 nuclei and possible chromatoidal bars (with round, smooth ends) (mature cyst immediately infectious)
Blastocystis spp. (currently discussed with the protozoa)	6–40	Spherical to somewhat oval	Central body form with nuclei around the central body area (immediately infectious as far as known)
Balantidium coli	50–70	Spherical to oval	Large macronucleus, thick wall (infectious)

differ biochemically and immunologically, their fine structure and development are indistinguishable. Some of the eye infections have also suggested a topical route rather than dissemination.

Microsporidiosis is now recognized as an emerging transplant-associated disease and should be considered in febrile transplant recipients when tests for routinely encountered agents are unrevealing. Donor-derived disease is critical to assess when multiple recipients from a common donor are ill (45).

Anncaliia (*Brachiola, Nosema*) spp.

Anncaliia connori (formerly referred to as *Brachiola connori* or *Nosema connori*) was identified in human tissues in a 4-month-old infant with combined immunodeficiency disease who had contracted a disseminated, fatal infection. Parasites were found in the myocardium, diaphragm, arterial walls, kidney tubules, adrenal cortex, liver, and lungs. Concurrently, this patient also had *P. jiroveci* pneumonia. *A. algerae* (formerly *Brachiola algerae* or *Nosema algerae*) is apparently transmitted by a mosquito. Infections have been found in the eye and muscle, possibly from a disseminated case. Both immunocompromised (HIV-negative, but receiving immunosuppressive therapy for rheumatoid arthritis) and immunocompetent patients have become infected. *Anncaliia vesicularum* has also been associated with AIDS and myositis. Muscle tissue obtained at biopsy and examined by light and electron microscopy revealed organisms developing in direct contact with muscle cell cytoplasm and fibers. Apparently, no other tissue types were infected. Clinical and histologic clearing of the infection was achieved after treatment with albendazole and itraconazole.

Pleistophora and *Trachipleistophora* spp.

Microsporidia in the genera *Pleistophora* and *Trachipleistophora* have rarely been identified in humans. However, when *Pleistophora* was found, atrophic and degenerating muscle fibers were full of spores which were seen in clusters of about 12 organisms, each cluster enclosed by an enveloping membrane, the pansporoblastic membrane. The disease was characterized by a 7-month history of progressive generalized muscle weakness and contractions, in addition to fever, generalized lymphadenopathy, and an 18-kg weight loss. Although the patient was diagnosed as having AIDS, the presence of HIV was never demonstrated. Specimens from early biopsies demonstrated atrophic and degenerating muscle fibers; specimens from later biopsies showed fibrosis and scarring. *Trachipleistophora hominis* causes severe myositis and sinusitis and was first found in an AIDS patient. To date, no natural hosts other than humans have been identified; however, when inoculated intraperitoneally into athymic mice, the organisms infect the skeletal muscle, as seen in human infections. *T. antropophtera* is the most recently described microsporidian in humans and has been found in brain tissue of two AIDS patients at autopsy; organisms were also found in the kidneys and heart.

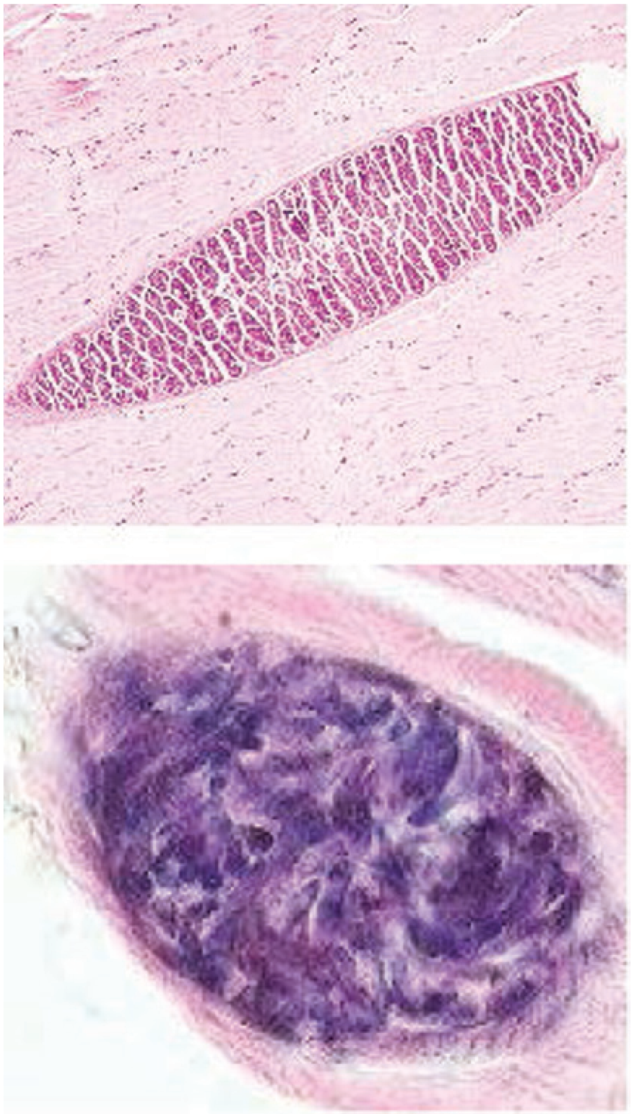

Figure 30.14 *Sarcocystis* sp. in human muscle tissue (note the bradyzoites contained within the sarcocyst, visible in the lower image). doi:10.1128/9781555819002.ch30.f14

Tubulinosema acridophagus

Microsporidiosis subsequently developed in a stem cell transplant patient with multiple myeloma, probably linked to immunosuppressive steroid use. The microsporidian was identified as *Tubulinosema acridophagus*, a new human pathogen (54). Electron microscopy studies revealed spores in skin and peritoneal fluid that were consistent with the original identification. The spores contained the typical polar tubule with 11 to 14 coils. After extensive tissue examination, spores were confirmed in skin, liver, peritoneum, lung, and several eye tissues. *T. acridophagus* species has also been identified from muscle in a patient with non-Hodgkin's lymphoma (55).

Enterocytozoon bieneusi

Although currently there are several genera of microsporidia, one of which is the catchall genus *Microsporidium*, human infections with some genera are more common than with others. A number of infections with *Enterocytozoon bieneusi* have been found in AIDS patients. Chronic intractable diarrhea, fever, malaise, and weight loss are symptoms of *E. bieneusi* infections and are similar to those seen with cryptosporidiosis or isosporiasis. These patients have four to eight watery, nonbloody stools per day, which can be accompanied by nausea and anorexia. There may be dehydration with mild hypokalemia and hypomagnesia, as well as D-xylose and fat malabsorption. The patients tend to be severely immunodeficient, with a CD4 count always below 200/mm^3 and often below 100/mm^3. *E. bieneusi* infection has also been implicated in AIDS-related sclerosing cholangitis.

Dual infections with *E. bieneusi* and *Encephalitozoon intestinalis* have been reported. *E. intestinalis* infects primarily small intestinal enterocytes, but infection does not remain confined to epithelial cells. *E. intestinalis* is also found in lamina propria macrophages, fibroblasts, and endothelial cells. Dissemination to the kidneys, lower airways, and biliary tract appears to occur via infected macrophages. Fortunately, these infections tend to respond to therapy with albendazole, unlike the infections with *E. bieneusi*.

A number of techniques for recovery and identification of microsporidia in clinical specimens are available. Although the organisms can be identified in routine histologic preparations, they do not tend to stain predictably. Occasionally, the spores take on a refractile gold appearance in formalin-fixed, paraffin-embedded, routine hematoxylin-and-eosin-stained sections. Some of the difficulty may be attributed to the use of formalin; alternative fixatives are currently being tried. Spores are occasionally seen very well by using the PAS stain, the methenamine silver stain, tissue Gram stains, or acid-fast stains. The spore has a small, PAS-positive posterior body, the spore coat stains with silver, and the spores are acid-fast variable. There is also evidence to indicate that specimens from plastic-embedded tissues are seen more easily, regardless of the fixative used. Tissue examination by electron microscopy is still considered the best approach; however, this option is not available to all laboratories and is not that sensitive.

Techniques that do not require tissue embedding are also popular. Touch preparations of fresh biopsy material that are air dried, methanol fixed, and Giemsa stained have been used; however, screening must be performed using the 100× oil immersion objective. Another study, involving cytocentrifugation followed by Giemsa staining, found that 27% of 55 AIDS patients with chronic diarrhea were

TABLE 30.12 *Sarcocystis*: parasite development and disease[a]

Characteristic	Infection in muscle:human as accidental intermediate host	Infection in intestine:human as definitive host
Infection source	Food or water contaminated with feces from unknown carnivore or omnivore	Raw or undercooked meat
Infective stage	Oocyst or free sporocysts	Sarcocyst containing bradyzoites
Developmental stages	Intravascular schizonts (not seen); intramuscular sarcocysts	Sexual stages in lamina propria; oocysts passed in feces
Incubation period from ingestion to symptoms	Weeks to months; can last months to years	3–6 h, lasting 36 h
Symptoms	Musculoskeletal pain, fever, fleeting pruritic rash, transient lymphadenopathy, subcutaneous nodules associated with eosinophilia, cardiomyopathy, and bronchospasm	Nausea, loss of appetite, vomiting, stomachache, bloat, diarrhea, dyspnea, and tachycardia
Diagnosis	Biopsy specimen containing sarcocyst; antibodies to bradyzoites (routine histology)	Oocysts or sporocysts in feces, beginning 5–12 days after ingestion (routine ova and parasite examination, particularly concentration)
Therapy (none approved)	Albendazole, anti-inflammatories	None

[a] Adapted from reference 42.

positive for *E. bieneusi*; all results were confirmed by electron microscopy.

Routine staining of clinical specimens (stool, urine, eye specimens) can be performed using a modified trichrome stain in which the chromotrope 2R component added to the stain is 10 times the concentration normally used in the routine trichrome stain for stool. The stool preparations must be *very* thin, the staining time is 90 min, and the slide must be examined at ×1,000 (or higher) magnification. Unfortunately, there are many objects within stool material that are oval, stain pinkish with trichrome, and measure approximately 1.5 to 3 μm. If this stain is used for the identification of microsporidia in stool, positive control material should be available for comparison. The newest approach for the identification of spores in clinical specimens uses antisera in an IFA procedure. Fluorescing microsporidial spores are distinguished by a darker cell wall and by internal visualization of the polar tubule as diagonal lines or cross lines within the cell. In another study with this same antiserum, 9 (33%) of 27 patients diagnosed as having cryptosporidiosis (8 AIDS patients and 1 non-AIDS but immunodeficient patient) were found to have *E. bieneusi* in the stool. Although there is some cross-reactivity with bacteria, this technique offers a more sensitive approach than routine staining methods currently available for the examination of stool specimens. As clinicians begin to suspect these infections and laboratorians become more familiar with the diagnostic methods, the number of positive patients, particularly those who are immunocompromised, may increase dramatically.

Although *E. bieneusi* appears to be the most common human microsporidian, serologic evidence is based primarily on results for *Encephalitozoon cuniculi* as the parasite antigen. Whether these surveys reveal actual infections with this organism or whether there is cross-reactivity with other microsporidians is unknown. However, the data strongly suggest that latent infections with microsporidia occur in a number of groups, ranging from patients with other infections such as tuberculosis, typhoid fever, leprosy, malaria, schistosomiasis, toxoplasmosis, Chagas' disease, and toxocariasis, to normal individuals and a group of homosexual men (56). Serologic evidence of human infection with the microsporidia has been reviewed elsewhere (56, 57). Microsporidian infections in immunocompetent patients may result in a self-cure following mild symptoms over a short time frame, a situation similar to that seen with both cryptosporidiosis and cystoisosporiasis. As awareness of this infection increases and more sensitive diagnostic techniques are developed, we may find that these infections are not uncommon in immunocompetent hosts.

The vast majority of human cases of microsporidiosis have been reported during the past 20 years in patients with HIV/AIDS, while only relatively rare cases have been described in immunocompetent individuals. However, microsporidial infections are being increasingly found in patients following solid-organ transplantation, where the main symptom has been diarrhea. The first case of pulmonary microsporidial infection in an allogeneic bone marrow transplant recipient in the United States and only the second case in the world has been reported (58).

Leishmania spp.

Most *Leishmania* and HIV coinfection cases reported to the World Health Organization come from Southern Europe. Up to 2001, nearly 2,000 cases of coinfection were

TABLE 30.13 Microsporidia: AIDS patients

Findings in AIDS patients	Comments[a]
Intestinal microsporidiosis	High proportion of patients remained symptomatic after 6 mo (54.8% with persistent diarrhea, 51.2% with weight loss); predictors include high HIV RNA viral load and no initiation of protease inhibitor therapy
AIDS patients in Venezuela	The samples from 42 patients were analyzed by separate PCRs to identify *Encephalitozoon intestinalis* and *Enterocytozoon bieneusi*. Microsporidia species showed 36% prevalence: 10 patients had *Encephalitozoon intestinalis*, 4 had *Enterocytozoon bieneusi*, and 4 had both species. An inverse and statistically significant relationship between the CD4 count and the presence of microsporidia in the fecal sample was also found. The high prevalence of microsporidia species observed in the HIV patients studied, with a predominance of *E. intestinalis*, is remarkable.
Children in Spain	1.2% overall and 2% of those with diarrhea (n = 83) had microsporidiosis; different data from those previously reported for adults (13.9%) in the same area, although adult group showed more severely depressed CD4 lymphocyte counts than children did
Children in Uganda	Some 81% of HIV-infected children with persistent diarrhea excreted *Cryptosporidium*, *Enterocytozoon bieneusi*, or both organisms, compared with only 10% of children with persistent diarrhea testing negative for HIV; 74% of isolates were *C. hominis* (the anthroponotic species), 17% were *C. parvum* (the zoonotic species), and 8% were a mixture of the 2 or others
Patients with or without diarrhea in Germany	Prevalence of intestinal microsporidiosis varies from 7 to 50%; most common enteropathogen in 18/50 patients (36%) with diarrhea and 2/47 (4.3%) without diarrhea; microsporidia present in 60% of patients with chronic diarrhea and 5.9% of patients with acute diarrhea (*E. bieneusi* in 18, *E. intestinalis* in 2); prevalence in this group one of the highest in the world
Mucosal abnormalities	Mechanisms appear to be malabsorption caused by reduction of absorptive mucosal surface and impairment of enterocyte function
Epidemiology	
Waterborne outbreak	Of 338 individuals, 261 had HIV, 16 were transplant recipients, and 61 had other sources of immunosuppression; disease appears to be endemic in HIV-positive persons; 200 people involved in waterborne outbreak; no evidence of fecal contamination of water; outbreak ended several months before antiprotease era
Risk factors	Intestinal microsporidiosis in persons with HIV infection and ≤200 CD4 cells/mm^3 is associated with male homosexuality and swimming in pools, suggesting fecal-oral transmission, including sexual and waterborne routes
New disease manifestation	
Nodular skin disease	36-yr-old woman presented with late-stage AIDS and disseminated, nodular cutaneous lesions and underlying osteomyelitis; disseminated microsporidial infection with *Encephalitozoon*-like species diagnosed by EM; long-term clindamycin therapy cured cutaneous infection; response to clindamycin merits further study
Current clinical syndromes	Enteropathy, keratoconjunctivitis, sinusitis, tracheobronchitis, encephalitis, interstitial nephritis, hepatitis, cholecystitis, osteomyelitis, myositis; *E. bieneusi* is the most common cause of intestinal disease (can also disseminate); *E.* (*Septata*) *intestinalis* is associated with disseminated and intestinal disease
Modification of clinical course	Of 37 AIDS patients with *E. bieneusi* diarrhea, 15 showed clearance (40.5%); peripheral blood CD4 cell count of ≤100/mm^3, use of two or more antiretroviral medications, and use of protease inhibitor statistically associated with time to clearance of parasite; albendazole not associated with parasite eradication
Corneal infections	Microsporidia cause keratoconjunctivitis, corneal stromal keratitis, scleritis, and endophthalmitis; the corneal picture resembles herpes simplex virus stromal keratitis or fungal keratitis cases, and is characterized by deep stromal infiltrates with overlying and surrounding stromal edema and keratic precipitates; the diagnosis of microsporidial infection is confirmed by a microscopic examination of smears from patients with ulcerative keratitis or by a histopathological examination of corneal tissues
Zoonotic *Enterocytozoon bieneusi* genotypes in HIV-positive patients	*E. bieneusi* genotypes were detected and differentiated by PCR and DNA sequencing. The infection rates were 5.7% and 4.2% for *E. bieneusi* in HIV-positive and HIV-negative participants, respectively. Prevalent *E. bieneusi* genotypes detected, including EbpC (39), D (12), and type IV (7), which were also potentially zoonotic

[a] Adapted from references 46–53. EM, electron microscopy.

identified, of which 90% were from Spain, Italy, France, and Portugal. However, these figures are probably underreported because they do not account for the large number of cases in Africa and Asia that are missed due to a lack of diagnostic facilities and poor reporting systems. Most cases of coinfection in the Americas are reported in Brazil. In some areas of Africa, the number of coinfection cases has increased dramatically due to population migration

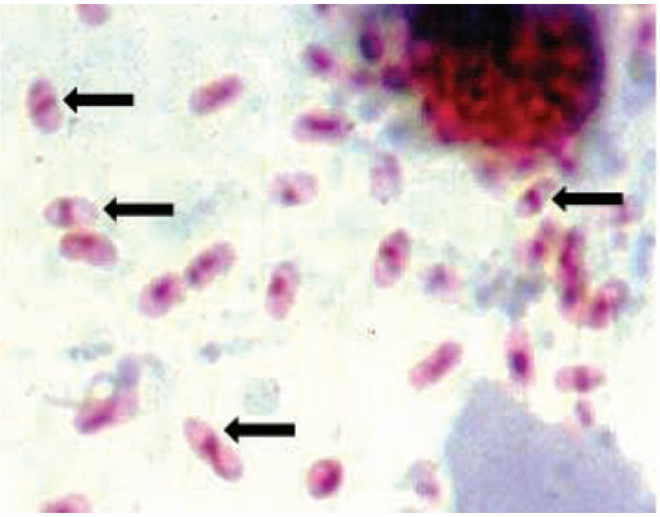

Figure 30.15 Microsporidia. Microsporidial spores seen in nasopharyngeal aspirate from AIDS patient; note the horizontal or diagonal lines (arrows) representing the polar tubules within the spores, stained with Ryan modified trichrome stain. doi:10.1128/9781555819002.ch30.f15

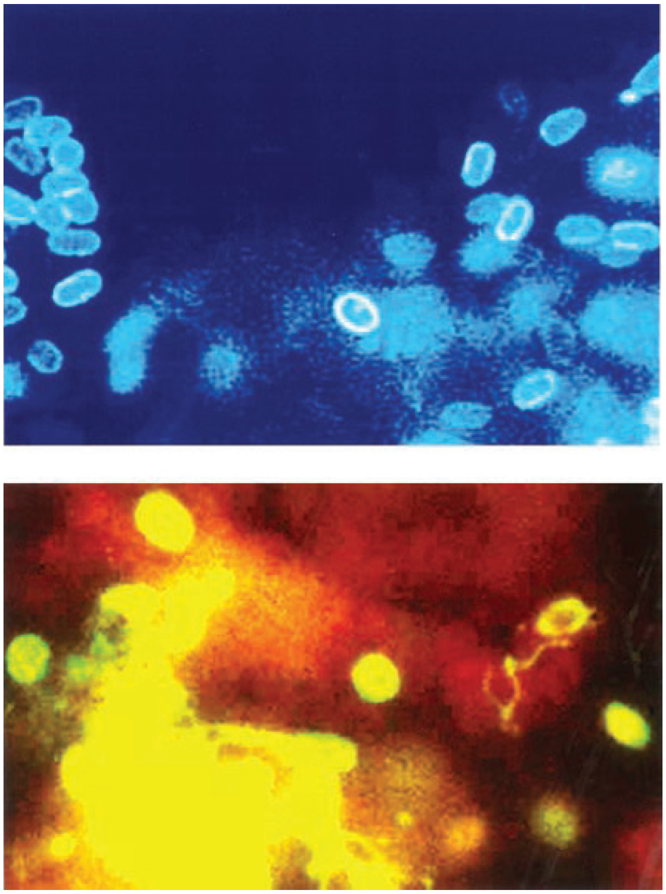

Figure 30.16 Microsporidial spores. (Upper) *Encephalitozoon intestinalis* stained with calcofluor white. (Lower) Monoclonal-antibody-based immunofluorescence identification of *Encephalitozoon hellem* (Courtesy of the CDC Public Health Image Library). doi:10.1128/9781555819002.ch30.f16

and wars. In northwest Ethiopia, up to 30% of all visceral leishmaniasis patients are also infected with HIV. In Asia, coinfections are increasingly being reported in India, which also has the highest global burden of leishmaniasis and a high rate of resistance to antimonial drugs (59–67). Visceral leishmaniasis (VL) continues to increase in frequency in patients who are HIV positive. The majority of cases of leishmaniasis in AIDS patients have been seen in France, Spain, Italy, and Portugal. Like other opportunistic infections, subclinical VL can be found at any stage of HIV-1 infection, but symptomatic cases appear mainly when severe immunosuppression is present. HIV-*Leishmania* coinfection is being seen more and more frequently in the Mediterranean basin (Tables 30.14 and 30.15; Fig. 30.17).

This finding strongly suggests that individuals infected with *Leishmania* spp. without symptoms will express symptoms of leishmaniasis if they become immunosuppressed. Based on the patient's general health status and prior exposure to the infection, leishmaniasis may be seen as an early opportunistic infection or may be seen as a complication late in the course of AIDS. Clinical signs of VL usually occur in the later stages of AIDS. The majority of AIDS patients present with the classic picture of VL; however, asymptomatic cutaneous, mucocutaneous, diffuse cutaneous, and post-kala azar dermal leishmaniasis (usually caused by *L. infantum*) can be seen. Cutaneous lesions in VL are being detected increasingly frequently in patients with HIV infection, and their significance is still somewhat unclear. Lesions often do not present a uniform or specific appearance and have been seen as erythematous papules and hypopigmented macules on the dorsa of the hands, feet, and elbows; small subcutaneous nodules on the thighs; and erythematoviolaceous, scaly plaques on the face. Also, the digestive and respiratory tracts are often parasitized, as well as the pleura and peritoneum. Lesions can also be coinfected with other organisms, such as *Mycobacterium avium-intracellulare*.

The HIV/AIDS pandemic has modified the natural history of leishmaniasis. HIV infection increases the risk of developing VL by 100 to 2,320 times in areas of endemicity, reduces the likelihood of a therapeutic response, and greatly increases the probability of relapse (65, 66). At the same time, VL promotes the clinical progression of HIV disease. Both diseases exert a synergistic detrimental effect on the cellular immune response because they target similar immune cells. VL occurring during HIV infection cannot be cured, even after extensive antileishmanial treatment. The likelihood of a relapse occurring is dependent on the

TABLE 30.14 *Leishmania* infections in immunocompromised patients[a]

Underlying condition	Disease manifestation	Comments
AIDS	VL (southern Spain)	HIV-1 carriers (291) underwent bone marrow aspiration (regardless of symptoms); 32 (11%) showed VL and 13 of these (41%) had subclinical cases; female sex negatively associated with VL; i.v. drug use high, but not independent association; high proportion of cases subclinical; symptomatic cases evident when deep immunosuppression is present
AIDS	VL (Mediterranean area)	*Leishmania*-HIV coinfection common in Mediterranean area; most common species is *L. infantum*; most frequent if CD4 count is <200/mm^3 and in parenteral drug addicts; chronic development with relapses is frequent; most effective diagnostic method is bone marrow culture (NNN); low sensitivity for serologies; PCR useful in asymptomatic cases, for therapeutic control, and in relapses; treatment similar to that in immunocompetent patients; generally necessary to use secondary prophylaxis; mortality rate is high (~25%)
AIDS	VL and possible dissemination	WHO estimates that 2–9 in 100 HIV patients in Africa and Asia will develop *Leishmania*-HIV coinfection; VL most common; unusual locations suggest multiorgan spreading in absence of host immune response; high incidence of recurrence; follow-up required; clear picture of prophylaxis not yet developed
AIDS	VL	Since 1990, 1,616 cases of coinfection reported, mainly from southern Europe (Spain, southern France, Italy); coinfected patients mainly young adults, i.v. drug users; 272 isolates showed 18 different zymodemes, 10 of which were found only during HIV coinfection; new foci emerging (Brazil and East Africa)
AIDS	VL (and mucocutaneous disease in areas where *L. donovani* is not endemic)	15 AIDS patients in Germany, all of whom were severely immunocompromised; 1 was diagnosed at autopsy; 1 mucocutaneous case was diagnosed by nasal biopsy; others were diagnosed by bone marrow (13/13), liver (3/3), and gastrointestinal mucosa (4/4) biopsies; serology positive in only 6/13; VL must be ruled out in every patient with fever and/or pancytopenia and appropriate travel history
AIDS	Case mimicking VL	HIV-positive patient presented with picture of VL coinfection; bone marrow biopsy performed on admission; amastigote forms seen in bone marrow, and organisms grew in culture as promastigotes; molecular analysis revealed that the organisms were not *Leishmania*, but were *Leptomonas pulexsimulantis*, a trypanosomatid found in dog fleas; thus, opportunistic infection with an insect trypanosomatid was suspected and confirmed
Immunosuppressive drugs for organ transplantation or cancer	VL	Immunosuppressive therapy results in reactivation of asymptomatic VL or facilitates new infections
AIDS	CL (Brazil)	IRIS has been found in AIDS patients since the introduction of HAART; syndrome is characterized by clinical manifestations of opportunistic infections when signs of immune reconstitution are observed during therapy; leishmaniasis, suggestive of HAART-induced IRIS, was seen in 2 patients with AIDS; after beginning HAART, 1 patient presented with disseminated CL lesions, whereas the other patient's preexisting lesions worsened and became more extensive; however, their CD4$^+$ T-cell counts were increasing and viral loads were decreasing significantly; the lesions healed with anti-*Leishmania* therapy
AIDS	CL (French Guiana)	In French Guiana, CL in moderately immunosuppressed HIV-infected subjects (CD4$^+$ T-cell count, >200/mm^3) is characterized by a higher rate of recurrence or reinfection and is more difficult to treat than that in HIV-negative subjects
AIDS	CL (Italy)	Patient was HIV infected, an i.v. drug user, with an unusual disseminated CL after an initial visceral disease and after a 13-month maintenance treatment with liposomal amphotericin; severe concurrent immunosuppression probably played a role in leading to this atypical cutaneous form, characterized by diffuse, nonulcerated, nonscabby maculopapular lesions

[a] Adapted from references 59–67. CL, cutaneous leishmaniasis; HAART, highly active antiretroviral therapy; IRIS, immune reconstitution inflammatory syndrome; i.v., intravenous; NNN, Novy-MacNeal-Nicolle medium; VL, visceral leishmaniasis; WHO, World Health Organization.

level of CD4$^+$ cells in the patient. For patients coinfected with HIV-1 and *Leishmania*, the increase in cytokine production induced by the parasite will probably affect virus production not only in macrophages but also in HIV-1-infected CD4$^+$ T cells.

CD4 T-lymphocyte counts are usually less than 50/mm^3 and are almost always less than 200/mm^3. Many physicians think that VL does not cause severe symptoms in these patients but is just one of several opportunistic infections that may coinfect AIDS patients. However, VL

TABLE 30.15 Epidemiological information on *Leishmania*-HIV coinfection[a]

Area	Specific countries	Comments
Southern Europe	France, Italy, Portugal, Spain	Largest number of cases in Spain; Spain has 5–7 times more new infections among IV drug users; 75% patients live in coastal urban areas; spread from urban to rural areas; decrease by end of 1990s due to HAART; >90% of cases are relapses rather than reinfections; 94% of patients with *Leishmania*-HIV coinfection suffered from VL, and 4% had CL
South Asia	Bangladesh, India, Nepal	Currently this area is the main focus of VL in the world, accounting for 67% of total leishmaniasis; many cases underreported; 2 to 3.1 million HIV cases in India; positive rates of coinfection range from 1.5 to 6.3%; no data available from Bangladesh
Americas	Brazil	Epicenter of the HIV/AIDS epidemic in South America; from 2001 to 2005, 16,210 cases of VL were reported in Brazil, and 315 (2%) patients were coinfected with HIV; of 150,000 CL cases reported from 2001 to 2005, 150 (0.1%) patients had HIV coinfection. MCL is frequently observed in HIV-coinfected patients in Brazil (43%), a clinical pattern rarely seen in southern Europe; in Brazil, 43%, 37%, and 20% of the burden of coinfection are due to MCL, VL, and CL, respectively
Sub-Saharan Africa	Burkina Faso	HIV seroprevalence is 2%; CL reported from many areas; major increase in cases since 2000; many unusual forms of CL found (lepromatous/diffuse, ulcerative, infiltrative, papulonodular, psoriasis-like, Kaposi's sarcoma-like, keloid, histoid); rapid relapses seen after therapy in HIV coinfected patients
	Ethiopia	Incomplete information (no current surveillance system); VL endemicity dates back to the 1940s; increase in coinfection from 18.5% in 1998–1999 to 40% in 2006
	Kenya, Uganda, Somalia	Data very limited; risk of coinfection is increasing; no coinfection yet reported in Somalia
	Sudan	15,000–20,000 VL cases; prevalence of AIDS 1.6%; HIV/AIDS cases estimated at 350,000; number on the increase; coinfection now recognized
Overall		1,037 strains of *Leishmania* isolated and identified from HIV+ patients; majority from southwest Europe

[a]Adapted from references 65 and 66. CL, cutaneous leishmaniasis; MCL, mucocutaneous leishmaniasis; VL, visceral leishmaniasis.

can manifest atypical aspects in HIV-positive patients depending on the degree of immunosuppression, and it should be listed among AIDS-defining conditions. The most common symptoms are fever, splenomegaly, hepatomegaly, and pancytopenia.

Data from Spain provide some interesting outcome figures regarding *Leishmania* infections in persons with or without HIV infections. In spite of a good initial response to treatment for VL, 60.6% of the patients had relapsed by the end of 1 year. Mortality from the first episode was 18.5%, and 24% died in the first month after diagnosis of any VL episode. The mean survival of the 29 patients who died was 10.27 months. Survival in patients with and without AIDS at the time of the first episode of VL was compared at 30 months and found to be 30.5 and 53.7%, respectively. A diagnosis of AIDS, at the time of the first episode of VL, and thrombocytopenia were the only risk factors found to be related to survival. Certainly in AIDS patients, VL is a recurrent disease that is highly prevalent and whose clinical course is modified by HIV. VL is a very prevalent disease among HIV-1-infected patients in southern Spain, with a high proportion of cases being subclinical. Symptomatic cases appear mainly when severe immunosuppression is present. There is also an association between VL and the male sex and intravenous drug use. In HIV-infected patients, VL occurs in late stages of HIV disease and often has a relapsing course. Secondary prophylaxis reduces the risk of relapse.

In HIV-1-infected patients with active VL, the sensitivity of a peripheral blood smear is about 50% because of the high parasitemia in these patients. However, in HIV-1-infected patients with subclinical VL, the sensitivity of a routine blood smear is <10%. Unfortunately, in these patients serology and *Leishmania* skin tests have low sensitivities and are little help. Cultures have proven to be effective in diagnosis of VL in patients who are coinfected with HIV-1.

A clinical diagnosis of Old World VL is often made based on clinical findings and local epidemiologic factors. However, confirmation of the diagnosis requires demonstration of the amastigotes in tissues or clinical specimens (blood, buffy coat preparations) or the promastigotes in culture. Detection of parasite genetic material or antigen detection is also sufficient for confirmation. Leishmaniasis should be suspected in individuals who have resided in or traveled to areas where the disease is endemic. The diagnosis would be supported by findings of remittent fevers, hypergammaglobulinemia with anemia, circulating immune complexes, rheumatoid factors, weight loss, leukemia, and splenomegaly. The differential diagnosis of late-stage VL is limited to hematologic and lymphatic malignancies. The diagnosis of early disease is more difficult, and

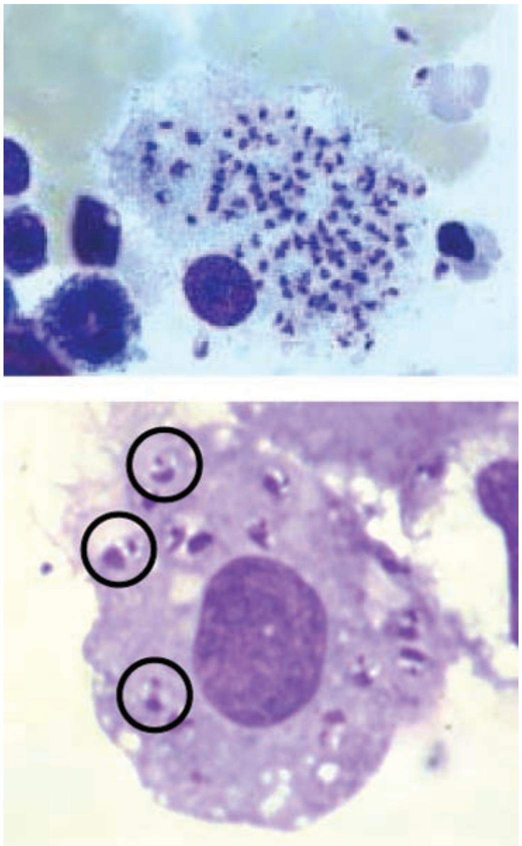

Figure 30.17 *Leishmania donovani* in bone marrow; specimen stained using Giemsa stain. Note the individual amastigotes with the larger nucleus and bar-shaped kinetoplast (circles). doi:10.1128/9781555819002.ch30.f17

the differential would include malaria, brucellosis, enteric fevers, bacterial endocarditis, generalized histoplasmosis, chronic myelocytic leukemia, Hodgkin's disease and other lymphomas, sarcoidosis, hepatic cirrhosis, and tuberculosis. Also, patients with multiple myeloma and Waldenström's macroglobulinemia have monoclonal hypergammaglobulinemia. Mixed cryoglobulinemia secondary to VL has also been reported.

Although the usual route of transmission is through the bite of infected sand flies, parasites can be transmitted in other ways including blood transfusion, sexual contact, congenital transmission, occupational exposure, and shared needles. Apparently, *L. infantum* can circulate intermittently and at low density in the blood of healthy seropositive individuals, who appear to be asymptomatic carriers; this certainly has implications for the safety of the blood supply in certain areas of the world, including southern France, where coinfection with HIV is a problem.

In patients with HIV/*Leishmania* coinfections, there is a high mortality rate due to concurrent illness, complications, and drug toxicity. Pentavalent antimonials and amphotericin B are more toxic to HIV patients, who require close monitoring for pancreatitis, cardiotoxicity, and nephrotoxicity, and these drugs should be avoided if better drugs, such as liposomal formulations of amphotericin B, are available.

Strongyloides stercoralis

In the life cycle of the intestinal nematode *Strongyloides stercoralis*, the larvae migrate through the heart and lungs, pass up the trachea, are swallowed, and finally grow to maturity in the gastrointestinal tract (Tables 30.3, 30.4, and 30.16; Fig. 30.18) (68–77). One significant feature of the *Strongyloides* life cycle is an internal autoinfection capability. Noninfective rhabditiform larvae, which normally pass out in the stool, may transform to infective filariform larvae while still within the gastrointestinal tract or perhaps on the perianal surface. These larvae can then penetrate the bowel wall or skin and reinitiate the life cycle. This cycle can maintain itself at a very low level over a period of many years in an individual without causing symptoms. The only unusual finding in the patient may be an unexplained eosinophilia. Patients who contracted the original infection many years earlier can become severely ill when they become immunosuppressed (Table 30.4). In the compromised patient, the number of larvae and adult worms may increase rapidly, leading to the hyperinfection syndrome and disseminated strongyloidiasis.

Patients in whom systemic *S. stercoralis* infections have been found include those with various leukemias and lymphomas, chronic infections such as leprosy and tuberculosis, and miscellaneous conditions such as kidney disease, organ transplantation, asthma, systemic lupus erythematosus, and various fungal infections. Other conditions include malnutrition, alcoholism, chronic renal failure, and achlorhydria. When migrating *Strongyloides* larvae begin to increase in numbers in the compromised host, the patient may present with abdominal complaints and there may be repeated episodes of unexplained bacteremia or meningitis with enteric bacteria. This occurs when the larvae penetrate the bowel and reinitiate the cycle. In doing so, they carry members of the bowel flora with them. The other consistent finding in these patients is an unexplained eosinophilia, which may range from 10 to 50%. Like *G. lamblia*, *S. stercoralis* resides in the duodenum, and recovery of the larvae in the stool is difficult in patients with low worm burdens. For this reason, additional techniques like the Entero-Test string capsule and the duodenal aspirate may be used. Other techniques for concentrating and recovering *Strongyloides* larvae include the Harada-Mori and petri dish culture techniques, as well as the Baermann apparatus.

TABLE 30.16 *Strongyloides stercoralis* infections in immunocompromised patients[a]

Underlying condition	Disease manifestation	Comments
AIDS and non-Hodgkin's lymphoma	Disseminated disease	After chemotherapy, patient complained of retrosternal pain, dysphagia, dry cough, and upper abdominal discomfort; eosinophilia was 41%; recurrence of lymphoma ruled out; treatment for disseminated atypical mycobacterial infection; biopsy exam of duodenal fluid revealed worms and larvae; albendazole therapy successful
Idiopathic pulmonary fibrosis therapy	Disseminated disease	64-year-old man with pulmonary fibrosis was admitted for shortness of breath and cough; immunosuppressed due to steroids; repeated sputum and stool positive for *S. stercoralis;* died suddenly from severe cardiorespiratory failure while on mebendazole therapy
Nephrotic syndrome therapy	Disseminated disease	Patient with nephrotic syndrome developed disseminated strongyloidiasis after steroid therapy; renal biopsy, time course, resolution of nephrotic syndrome after thiabendazole suggested causal relationship between chronic strongyloidiasis and nephrotic syndrome; early diagnosis important to good clinical outcome
Nephrotic syndrome therapy	Glomerulonephritis	Glomerulonephritis documented
Nephrotic syndrome therapy	Disseminated disease	Problems after administration of steroids
Chronic renal failure	Intestinal disease	Vomiting, diarrhea predominant symptoms; albendazole effective
Immunosuppressive drugs for kidney transplantation	Disseminated disease	Development of strongyloidiasis in renal transplant recipients following cyclosporin A has not been described; *Strongyloides* hyperinfection occurred immediately after cyclosporin A was discontinued; possible transmission by kidney transplant
Adult HTLV-1 infection	Intestinal or disseminated disease	Onset usually follows long period of viral latency; strongyloidiasis is considered a cofactor of leukemogenesis; hypereosinophilia is also seen, could be associated with parasites or leukemic process; cofactors might be important in HTLV-1-associated leukemogenesis; hypereosinophilia affects prognosis
Adult HTLV-1 infection	Intestinal disease	Prevalence of both HTLV-1 and *Strongyloides* increased with age, especially over 50 yr; prevalence of *S. stercoralis* infection significantly higher in HTLV-1 carriers; IgE level low in HTLV-1 carriers and significantly lower in HTLV-1 carriers with *Strongyloides* infection
Adult HTLV-1 infection	Disseminated disease	Strongyloidiasis progresses to hyperinfection or disseminated disease in carriers of HTLV-1; larvae detected in stool; meningitis responded to therapy; larvae still present after thiabendazole; coinfection with *S. stercoralis* is a predisposing factor to meningitis; association may warrant preventive antiparasitic treatment in patients infected with HTLV-1
Adult HTLV-1 infection (Peru)	Disseminated disease including meningitis	*Strongyloides* hyperinfection among Peruvian patients is highly associated with HTLV-1 infection
HTLV-1 infection and ATLL	Intestinal or disseminated disease	ATLL represents ~50% of T-cell lymphomas in Martinique; *Strongyloides* infection during ATLL is linked with high response rate to chemotherapy and prolonged survival; p53 overexpression seen in ~50% of cases of aggressive ATLL from Martinique and is associated with resistance to chemotherapy and short-term survival
HTLV-1 infection	Intestinal disease	*S. stercoralis* hyperinfection syndrome and therapeutic failure in apparently healthy patients with nondisseminated strongyloidiasis may be markers of HTLV-1 infection; HTLV-1 coinfection may also impact clinical course of scabies and HIV disease
Advanced small noncleaved cell lymphoma	Disseminated disease	*S. stercoralis* infection in child mimics relapse (the child was on intensive multiagent chemotherapy for lymphoma, and the treatment was successful in this case); *S. stercoralis* infection in adults being treated for malignant lymphoma is frequently fatal
SLE therapy (active disease)	Disseminated disease	Death due to massive pulmonary hemorrhage induced by filariform infection; diagnosed from bronchoalveolar lavage fluid 2 days before death; importance of checking patients for possible parasitic infections prior to starting therapy, even in areas without endemic infection
Cancer chemotherapy (Mexico)	Intestinal disease	In epidemiologic settings with high prevalence of intestinal parasitic infections, stool exams should be performed and antiparasitic therapy provided before initiating chemotherapy
Ribavirin plus interferon therapy for chronic HCV infection	Disseminated disease	Ribavirin may have immunomodulatory and immunosuppressive action; severe strongyloidiasis reported after use of ribavirin and interferon therapy for HCV infection
Steroids	Intestinal disease	In patients on corticosteroids, vomiting and diarrhea are key symptoms; duodenal mucosa varied from being normal to having severe ulceration; symptoms may be attributed to underlying disease

(continued)

TABLE 30.16 *(continued)*

Underlying condition	Disease manifestation	Comments
Steroids for chronic idiopathic thrombocytopenia	Disseminated disease	Diagnosis difficult due to lack of diarrhea and eosinophilia; negative multiple stool specimens; upper endoscopy revealed larvae, as did sputum specimens; death in spite of thiabendazole therapy
Single-dose steroids prior to radiosurgery	Disseminated disease	Patient received single dose of dexamethasone before stereotactic radiosurgery; fatal disseminated case of strongyloidiasis
Steroids	Intestinal disease (mimicking ulcerative colitis), possibly leading to disseminated disease	*Strongyloides* infection mimics ulcerative colitis over long period; accurate diagnosis is essential
Immunosuppressive drugs	Intestinal disease	Patient with chronic *S. stercoralis* infection initially presented with generalized prurigo nodularis and lichen simplex chronicus (skin nodules, thickened skin)
Diabetes mellitus and malnutrition	Disseminated disease	Repeated vomiting and upper gastrointestinal bleeding; unexplained leukocytosis; pulmonary infiltrates, gastric aspirate leukocytosis, presence of adult worms, eggs, and filariform and rhabditiform larvae in stool specimens; patients died while undergoing treatment with mebendazole
Diabetes mellitus and eosinophilic pleural effusion	Disseminated disease	Fever, exudative type of eosinophilic pleural effusion; bronchial washings contained *S. stercoralis* larvae; patient history extremely important
Unknown	Intestinal disease	Patient admitted for progressive weight loss, abdominal bloating; gastroscopic exam revealed mucosal prepyloric elevations in gastric mucosa; gastric strongyloidiasis confirmed by presence of adult worms, as well as ova and rhabditiform larvae; histologically confirmed case of gastric disease
None (immunocompetent patient)	Eosinophilic pleural effusion	Helminth infections should be considered in cases of eosinophilic pleural effusion
None (immunocompetent patient)	Colitis	Diarrhea, weight loss, microcytic anemia; colonoscopy revealed pancolitis and intense eosinophilic infiltrates; biopsy revealed *S. stercoralis* larvae
None (immunocompetent patient)	Colitis	Poor sensitivity of stool exams, careful search needs to be made in all patients before diagnosis of idiopathic eosinophilic colitis; steroid therapy may have fatal outcome

[a] Adapted from references 68–77. ATLL, adult T-cell leukemia/lymphoma; HCV, hepatitis C virus; SLE, systemic lupus erythematosus.

In individuals with preserved immune function, direct development of *S. stercoralis* is favored, whereas in individuals with lesser immune function, indirect development is relatively more common. These results may explain the notable absence of disseminated strongyloidiasis in patients with advanced HIV disease. Because disseminated infection requires the direct development of infective larvae in the gut, the observed tendency toward indirect development in individuals immunosuppressed by advancing HIV disease is not consistent with the promotion of disseminated infection. However, the two conditions that have been most frequently recognized as predisposing factors for the development of the hyperinfection syndrome are corticosteroid use and human T-lymphotropic virus type 1 (HTLV-1) infection. Reviews of disseminated disease in organ transplant patients, asthmatics, those with chronic lung disease, and those with autoimmune disease indicate that corticosteroid therapy has been a common denominator in the development of severe infection. There also seems to be an association between HIV infection/alcoholism and *S. stercoralis* infection.

The typical rhabditiform larvae of *S. stercoralis* are characterized by a short buccal capsule or mouth opening and the presence of a genital primordial packet of cells. In contrast, the rhabditiform larvae of hookworm have a much longer buccal capsule and essentially no genital primordial cells present.

Whenever one is working with material from a patient suspected of having strongyloidiasis, one should use extreme care because of possible filariform larvae in the specimen. Gloves must be worn to prevent skin penetration by these larval forms.

As we prolong life for more individuals, the medical community must become aware of some of the parasitic

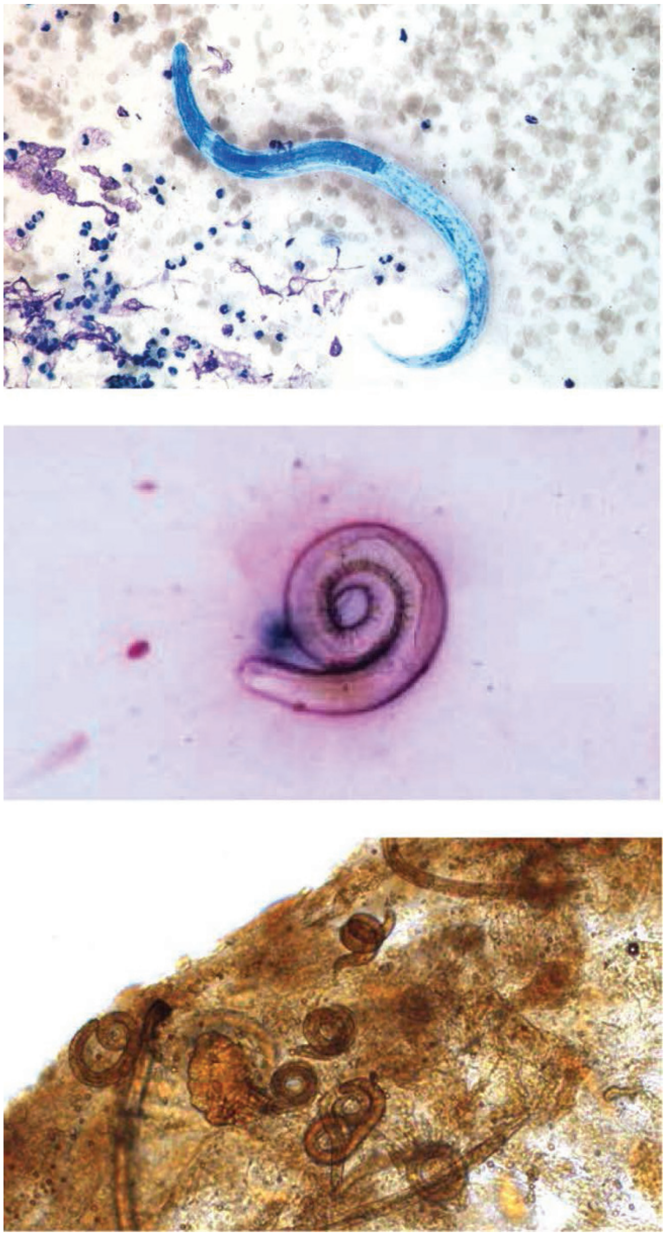

Figure 30.18 *Strongyloides stercoralis*. (Top) Rhabditiform larvae seen in bronchoalveolar lavage fluid specimen, Giemsa stain (larvae can also be seen in sputum in heavy infections or in the hyperinfection syndrome). (Middle) Larva from sputum, Gram stain. (Bottom) Tracheal aspirate containing many larvae (courtesy of Marc Roger Couturier, ARUP Laboratories, Department of Pathology, University of Utah).
doi:10.1128/9781555819002.ch30.f18

infections that may pose a threat to the life of the compromised patient. Awareness is the first step in preventing more serious disease. Obtaining a migration history is important with each patient; migrant patients may have acute illness or chronic conditions related to exposure in their country of origin. Early detection and treatment for tuberculosis, hepatitis B virus, *Strongyloides*, and schistosomiasis may improve outcomes. Expansion of refugee screening programs to include all migrants should always be considered.

Plasmodium spp.

According to the latest estimates, released in December 2013, there were about 207 million cases of malaria in 2012 (135 million to 287 million) and an estimated 627,000 deaths (range of 473,000 to 789,000). Malaria mortality rates have fallen by 45% globally since 2000 and by 49% in the World Health Organization African Region. Most deaths occur among children living in Africa, where a child dies every minute from malaria.

There are many neglected nonenteric protozoa able to cause serious morbidity and mortality in humans, particularly in the developing world (Tables 30.3, 30.4, and 30.17; Fig. 30.19) (78–83). These diseases are often more severe in the presence of HIV. While information regarding neglected tropical diseases caused by *Plasmodium* is abundant, these protozoa are often not a first consideration in Western countries where they are not endemic. Those at risk include semi-immune HIV-infected women, people with HIV/AIDS, and international travelers from areas of nonendemicity because they lack immunity (immunologically naive).

Coinfection with malaria and HIV in pregnant women is common in sub-Saharan Africa and causes serious sequelae for both mother and newborn child. The increased prevalence and intensity of parasitemia (placental and peripheral infection and parasite density) in HIV-infected women are well known. Similarly, malaria infection seems to be associated with higher viral loads. Women with malaria infection of the placenta also have a higher risk of passing HIV infection to their newborns.

By increasing the malaria parasite biomass in sub-Saharan Africa, the HIV-1 epidemic may also increase the emergence of antimalarial drug resistance, potentially affecting the health of the whole population in countries where both HIV-1 and malaria are endemic. HIV infection is also associated with an increased frequency of clinical malaria and parasitemia. This association tends to become more pronounced with advancing immunosuppression. However, the prevalence of malaria and HIV and the extent of geographic overlap vary widely within each region, even in countries with a high prevalence of both infections. Transmission of malaria and HIV can also result from inadequate blood transfusion practices and, for HIV, the use of unsafe injections. It has also been documented that HIV-infected persons with a low CD4 cell count and anemia have an increased risk of antimalarial treatment failure.

TABLE 30.17 Characteristics of blood parasite infections in immunocompromised patients

Organism	Comments
Plasmodium spp.	Coinfection with malaria and HIV in pregnant women is common in sub-Saharan Africa and causes serious sequelae for both mother and newborn child; women with malaria infection of the placenta also have a higher risk of passing HIV infection to their newborns; HIV infection is also associated with an increased frequency of clinical malaria and parasitemia; HIV-infected persons with a low CD4 cell count and anemia have an increased risk of antimalarial treatment failure
Babesia spp.	Severe disease has been described in HIV-infected patients, even those with intact spleens; immunosuppressed patients with *Babesia* infection may present with systemic complications and may require prolonged courses of antimicrobial therapy to contain and ultimately eradicate infection; patients who do not respond to a course of standard therapy are likely to have medical conditions that severely impair immune function; complications in these patients include anemia severe enough to require a blood transfusion or exchange transfusion, the presence of pulmonary edema or acute respiratory distress syndrome, and/or impairment of renal function severe enough to require dialysis.
Trypanosoma cruzi, American trypanosomiasis	Chagas' disease caused by *Trypanosoma cruzi* is a well-recognized opportunistic infection associated with AIDS; *T. cruzi* infection has been classified as an AIDS-defining opportunistic parasitosis by the Centers for Diseases Control and Prevention since 2004; the most common symptoms of Chagas' disease reactivation are subcutaneous nodules (chagoma), panniculitis, myocarditis with signs of heart failure, fever, meningitis, encephalitis, and stroke, but other symptoms, such as fatigue, anorexia, and diarrhea, are also seen; immunosuppressed patients with chronic infection can develop reactivations, which can be very severe and are associated with high mortality

When the diagnosis of malaria is considered, only a single blood specimen may be submitted to the laboratory for examination; however, single films or specimens cannot be relied on to exclude the diagnosis, especially when partial prophylactic medication or therapy is used. Partial use of antimalarial agents may be responsible for reducing the numbers of organisms in the peripheral blood, thus leading to a blood smear that contains few organisms, which then reflects a low parasitemia when in fact serious disease is present. Patients with a relapse case or an early primary case may also have few organisms in the blood smear.

It is recommended that both thick and thin blood films be prepared on admission of the patient, and at least 200 to 300 oil immersion fields should be examined on both films before a negative report is issued. Since one set of negative films will not rule out malaria, additional blood specimens should be examined over a 36-h time frame. Although Giemsa stain is recommended for all parasitic blood work, the organisms can also be seen if other blood stains, such as Wright's stain, are used. Blood collected with the use of EDTA anticoagulant is acceptable; however, if the blood remains in the tube for any length of time, true stippling may not be visible within the infected RBCs (*Plasmodium vivax*, as an example). Also, when using anticoagulants, it is important to remember that the proper ratio between blood and anticoagulant is necessary for good organism morphology. Heparin can also be used, but EDTA is preferred.

Sensitivity of the rapid malaria tests remains a problem, particularly for nonimmune populations. Parasite densities of >100 parasites/μl (0.002% parasitemia) should be detected and are reasonable targets to expect from dipsticks for *Plasmodium falciparum* diagnosis. However, this level of sensitivity is at the lower end of the capability of most devices using capture methods for HRP-2 or pLDH. Currently, the BinaxNOW Malaria Test is FDA approved (Alere, Inc., Waltham, MA).

Malaria is one of the few parasitic infections considered to be immediately life-threatening, and a patient with the diagnosis of P. falciparum *or* P. knowlesi *malaria should be considered a medical emergency because the disease can be rapidly fatal. Any laboratory providing the expertise to identify malarial parasites should do so on a 24-h basis, 7 days per week.*

Babesia spp.

Intraerythrocytic protozoa of the genus *Babesia* parasitize numerous vertebrates, predominantly in tropical and subtropical regions. Human disease has mostly been reported from temperate zones. Severe disease has been described in HIV-infected patients with one of the temperate species causing malaria-like disease in humans, raising the possibility that tropical species present a risk for patients with AIDS. Severe, persistent, and/or recrudescent *Babesia microti* parasitemia has occurred in immunosuppressed HIV-infected patients with intact spleens (Tables 30.3, 30.4, and 30.17; Fig. 30.20) (84–86). Babesiosis should be considered in the differential diagnosis of HIV-infected patients with fevers and/or anemia in areas where the infection is endemic. HIV-infected patients who are severely immunosuppressed, even those without a history of splenectomy, may present with severe manifestations of babesiosis and develop a chronic infection, which may require therapy to prevent relapse of disease. The inability of the innate immune system to clear parasites results in high levels of circulating parasitized RBCs.

The mechanism of parasitic persistence has not been totally delineated. A number of studies have implicated

gamma interferon (IFN-γ) as one of the critical cytokines for control of the early stages of infection. Natural killer cells are a major source of IFN-γ; however, in HIV-infected patients less IFN-γ is secreted. Additionally, T cells have been shown to play a critical role in the resolution of babesiosis.

In one study of immunosuppressed patients with babesiosis, most case patients experienced B-cell lymphoma and were asplenic or had received rituximab before babesial illness. There may be a direct association between certain primary or acquired immunodeficiency syndromes and the failure to contain acute babesial illness. These immunosuppressed patients with *Babesia* infection may present with systemic complications and may require prolonged courses of antimicrobial therapy to contain and ultimately eradicate infection. Patients who do not respond to a course of standard therapy are likely to have medical conditions that severely impair immune function.

Diagnosis of *B. microti* infection is normally based on the presence of symptoms consistent with babesiosis and the recognition of organisms by microscopic examination of stained thick and thin blood films. Symptoms include fever, chills, sweats, fatigue, headache, and myalgia. Complications in these patients include anemia severe enough to require a blood transfusion or exchange transfusion, the presence of pulmonary edema or acute respiratory distress syndrome, and/or impairment of renal function severe enough to require dialysis.

American Trypanosomiasis

One of the most prevalent parasitic infections that have spread from Latin America to areas of nonendemicity such as the United States, Canada, and Europe is Chagas' disease, or American trypanosomiasis. Its etiological agent, *Trypanosoma cruzi*, has not traditionally been considered an opportunistic agent, but in recent decades there have been many reports of reactivation in immunocompromised patients. Chagas' disease caused by *T. cruzi* is a well-recognized opportunistic infection associated with AIDS. *T. cruzi* infection has been classified as an AIDS-defining opportunistic parasitosis by the CDC since 2004. To date, the cases reported largely represent reactivation of chronic infection, which is most commonly manifested by meningoencephalitis (Tables 30.3, 30.4, 30.17; Fig. 30.21) (87–92). Reactivation is defined as an increase in parasitemia that can be detected by diagnostic methods, even in patients who are asymptomatic. The appearance of symptoms represents a worsening of the underlying disease. The most common symptoms of Chagas' disease reactivation are subcutaneous nodules (chagoma), panniculitis, myocarditis with signs of heart failure, fever, meningitis, encephalitis, and stroke, but other symptoms, such as fatigue, anorexia, and diarrhea, are also seen.

T. cruzi infection occurs primarily in rural regions, and HIV infection occurs primarily in urban regions. Clinical reactivation generally occurs in persons with CD4$^+$ T-cell counts <200 cells/mm^3 and most commonly involves the CNS. Lesions are often multiple, with preferential involvement of the white matter. Hemorrhagic foci can produce mass effects simulating brain tumors. Histologically, brain lesions exhibit necrosis, hemorrhage, and inflammatory infiltrates. Amastigote forms of the parasite are abundant in glial cells and macrophages. Myocarditis is a common autopsy finding in persons who have died of meningoen-

Figure 30.19 Morphology of malaria parasites. Column 1 (reading down), *Plasmodium vivax* (note enlarged infected RBCs): (1) early trophozoite (ring form) (note one RBC contains two rings—not that uncommon); (2) older ring, note ameboid nature of rings; (3) late trophozoite with Schüffner's dots (note enlarged RBC); (4) developing schizont; (5) mature schizont with 18 merozoites and clumped pigment; (6) microgametocyte with dispersed chromatin. Column 2, *Plasmodium ovale* (note enlarged infected RBCs): (7) early trophozoite (ring form) with Schüffner's dots (RBC has fimbriated edges); (8) early trophozoite (note enlarged RBC, Schüffner's dots, and RBC oval in shape); (9) late trophozoite in RBC with fimbriated edges; (10) developing schizont with irregular-shaped RBC; (11) mature schizont with eight merozoites arranged irregularly; (12) microgametocyte with dispersed chromatin. Column 3, *Plasmodium malariae* (note normal or smaller than normal infected RBCs): (13) early trophozoite (ring form); (14) early trophozoite with thick cytoplasm; (15) late trophozoite (band form); (16) developing schizont; (17) mature schizont with nine merozoites arranged in a rosette; (18) macrogametocyte with compact chromatin. Column 4, *Plasmodium falciparum*: (19) early trophozoites (the rings are in the headphone configuration with double chromatin dots); (20) early trophozoite (accolé or appliqué form); (21) early trophozoites (note the multiple rings per cell); (22) late trophozoite with larger ring (accolé or appliqué form); (23) crescent-shaped gametocyte; (24) crescent-shaped gametocyte. Column 5, *Plasmodium knowlesi* (with the exception of image 29, these were photographed at a higher magnification; note normal or smaller than normal infected RBCs; courtesy of the CDC Public Health Image Library): (25) early trophozoite (ring form); (26) early trophozoite with slim band form; (27) late trophozoite (band form); (28) developing schizont; (29) mature schizont with merozoites arranged in a rosette; (30) microgametocyte with dispersed chromatin. Note: Without the appliqué form, Schüffner's dots, multiple rings per cell, and other developing stages, differentiation among the species can be very difficult. It is obvious that the early rings of all four species can mimic one another very easily. Remember: One set of negative blood films cannot rule out a malaria infection. (Figure courtesy of Garcia LS, *Clin Lab Med* **30**:93–128, 2010.) doi:10.1128/9781555819002.ch30.f19

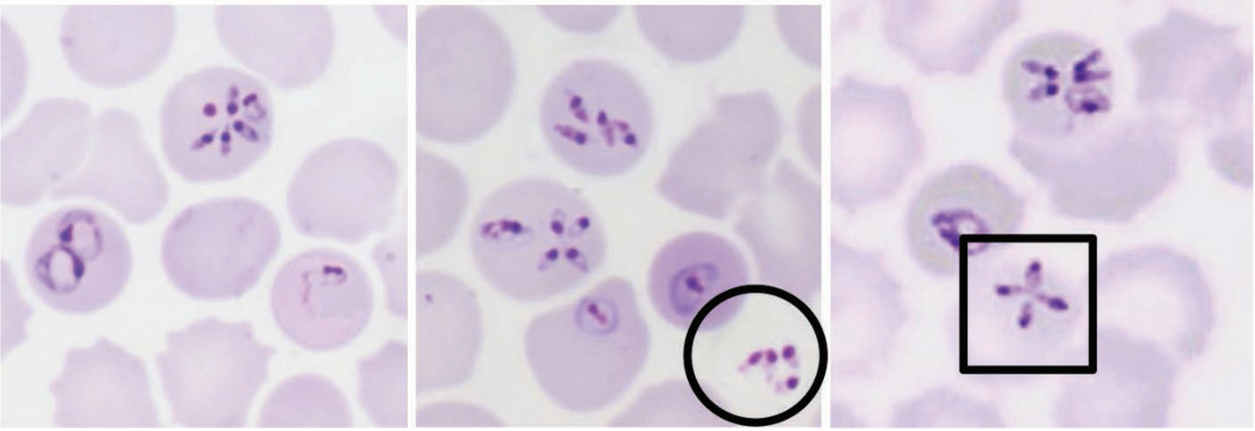

Figure 30.20 Three examples of blood films containing the ringlike forms of *Babesia* spp. Various ring forms, multiple rings per cell; some rings present outside of the red blood cells (circle); note the typical image of the "Maltese cross" configuration of the four rings (square). Note: it is rare to see *Plasmodium* rings outside of the RBC.
doi:10.1128/9781555819002.ch30.f20

cephalitis. Such myocarditis is often clinically silent. When present, clinical manifestations include arrhythmias and congestive heart failure. Immunosuppressed patients with chronic infection can develop reactivations, which can be very severe and are associated with high mortality.

The higher levels of parasitemia observed in HIV-infected individuals with symptoms of Chagas' disease are useful in diagnosis. Direct microscopic examination of blood and CSF may reveal *T. cruzi* trypomastigotes. This disease confirmation may precede clinical symptoms or it may be discovered with the onset of symptoms.

If fever and other systemic signs are present, direct examination of the buffy coat may also reveal motile trypanosomes. Blood culture and xenodiagnosis are of considerable use; the latter is generally unavailable outside of regions of endemicity.

Crusted Scabies

Scabies is a highly contagious infestation of the itch mite, *Sarcoptes scabiei*. Symptoms are related to pruritic dermatitis, and apparently transmission can occur through person-to-person direct skin contact or via fomites (Tables 30.3 and 30.4 and Fig. 30.22) (93–95). Outbreaks of scabies in hospitals or institutions, particularly for the elderly or developmentally disabled, have been documented worldwide. These outbreaks are particularly severe when associated with crusted scabies; such patients may be infected with thousands of mites on the skin. This infection has been linked with cellular immune deficiencies, including AIDS. Other potential problems include a decreased awareness of itching and the use of topical corticosteroids to reduce itching. Because of the number of mites present, these patients are extremely contagious, from sloughing skin, direct contact, and environmental contamination. Another potential problem is the fact that the symptoms mimic those of many other dermatologic conditions. Burrows may not be evident, and hyperkeratotic, crusted, scaling, fissured plaques are present over the scalp, face, and back, with associated gross nail thickening. The number of documented reports, particularly in AIDS patients, suggests that crusted scabies may become more common in the future.

Crusted scabies should be considered in the differential diagnosis of a generalized cutaneous eruption in a HTLV-1-positive patient. Patients with crusted scabies from an HTLV-1-endemic population should be tested for a possible HTLV-1 infection. Infection with HTLV-1 is an important cofactor related to crusted scabies in Peru. Testing for HTLV-1 in all crusted scabies cases is highly recommended, especially when no other risk factors are apparent. These patients may be at increased risk of progressing to adult T-cell leukemia/lymphoma. Definitive parasitic diagnosis can be difficult; difficulties in management have led to renewed interest in both scabies and pediculosis. The diagnosis of scabies should always be considered in patients with advanced malignancies and associated pruritus.

The diagnosis of crusted scabies can easily be missed. Serpiginous tracks were noted on the surface of Sabouraud's dextrose agar used for fungal culture of the skin scrap-

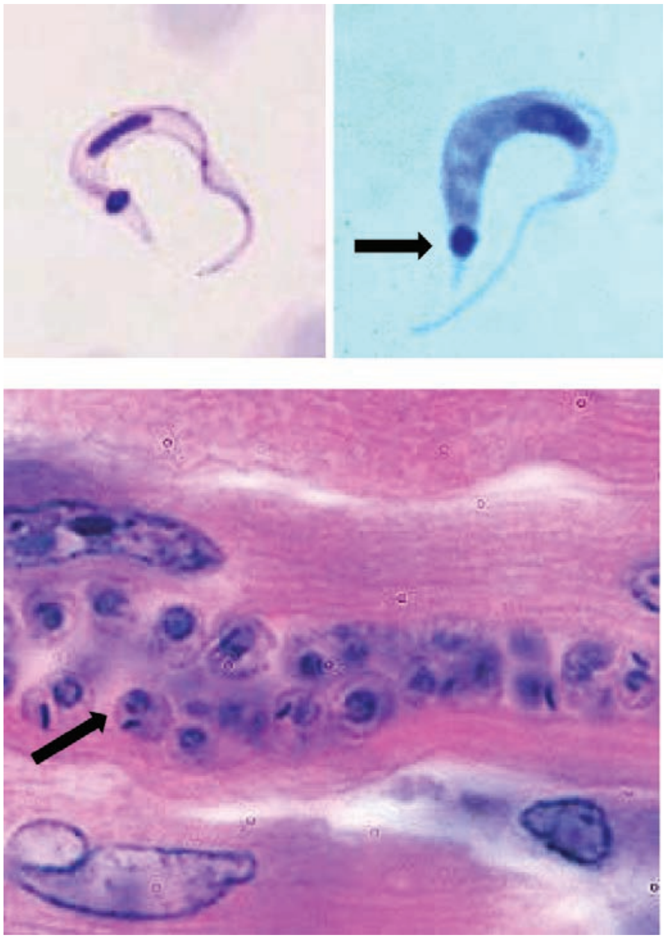

Figure 30.21 (Upper) *Trypanosoma cruzi* trypomastigotes in a peripheral blood smear; note the large kinetoplast (arrow). (Lower) Amastigote in cardiac muscle; note the actual amastigote with nucleus and kinetoplast (arrow).

ings from an elderly long-term-care facility resident. This unusual laboratory manifestation alerted clinical microbiologists to the possible diagnosis of scabies. Although many microbiology laboratories are aware of these unusual findings, personnel can forget to consider scabies in such situations.

Ivermectin is increasingly being used to treat scabies, especially crusted scabies. However, treatment failures, recrudescence, and reinfection can occur, even after administration of multiple doses. Clinical and *in vitro* evidence of ivermectin resistance has been found in several patients with multiple recurrences of crusted scabies who had previously received 30 to more than 50 doses of ivermectin over a 4-year time frame. As predicted, ivermectin resistance in scabies mites can develop after intensive ivermectin use.

Health Care-Associated (Nosocomial) Infections

Nosocomial infections are those that are hospital acquired or hospital associated. According to some publications, nosocomial infections are estimated to complicate the course of 5 to 10% of all hospitalized patients in acute-care facilities (1, 2). These infections are a significant cause of morbidity, mortality, and increased hospital costs, largely as a result of the increased length of stay. Over the past few years, escalating medical costs and the introduction of outpatient surgery have resulted in shorter hospital stays and much higher volumes of outpatient surgical procedures. Unfortunately, these changes have tended to mask true surgical infection rates. Also, postoperative surgical-site infections are often not apparent until after the patient's discharge (3). Since 1976, hospital accreditation by the Joint Commission on Accreditation of Healthcare Organizations (now The Joint Commission) requires the use of a nurse epidemiologist or infection control nurse whose primary responsibility is to identify, track, and control infections associated with hospitalization (4).

Most studies of the incidence of health care-associated infections ignore parasitic infections. Based on data from 1,265 intensive care units in 75 countries, it was found that the proportion of parasites in these infections was 0.48% overall and 0.25% in Western Europe (5). Parasites have been observed to be etiological agents of diarrhea in 12 to 17% of health care-associated epidemics and 1% of endemic outbreaks (5), this figure being higher in surgical wards (19.8%) (6, 7); protozoa such as *Cryptosporidium* spp., *Entamoeba histolytica*, *Giardia lamblia*, and *Blastocystis* spp. were detected most frequently.

Individuals in the institution who fall within the surveillance parameters of the nurse epidemiologist include both patients and employees. Although we usually consider patients to be more prone to infections, some microorganisms can also infect healthy adults (8).

Definition: A health care-associated infection is defined as one diagnosed during or after hospitalization that was neither present nor incubating at the time of admission (1, 2).

doi:10.1128/9781555819002.ch31

One of the problems with this definition is the difficulty involved in accurately differentiating community-acquired from hospital-acquired infections, particularly when employees are involved. Depending on the individual's immune status, incubation periods may also vary.

Although any organism can infect a susceptible host, the organisms most often considered to cause possible nosocomial infections, particularly in the immunologically compromised, include the following:

Fungi: *Aspergillus* spp., *Candida* spp., *Mucor* spp., *Cryptococcus neoformans*, *Nocardia asteroides*

Algae: *Prototheca* spp.

Bacteria: *Escherichia coli*, *Klebsiella* spp., *Proteus* spp., *Pseudomonas* spp., *Staphylococcus* spp., *Legionella* spp.

Viruses: Cytomegalovirus, varicella-zoster virus, HIV, rubella virus, rotavirus, enterovirus

Parasites: *Giardia lamblia*, *Entamoeba histolytica*, free-living amebae, *Toxoplasma gondii*, *Cryptosporidium* spp., the microsporidia, *Strongyloides stercoralis*, *Trypanosoma* spp., *Plasmodium* spp., *Babesia* spp., *Hymenolepis nana*, *Taenia solium*

Ectoparasites: *Pediculus* spp., *Sarcoptes scabiei*, dipterous fly larvae (myiasis)

Although most health care-acquired infections are bacterial, fungal, or viral in origin, a few can be caused by parasites. The patient may actually have acquired the infection (*T. gondii*, *S. stercoralis*) many years before hospitalization. These latent infections can often be reactivated when the patient becomes debilitated for some reason, particularly when the immune system is involved.

Other areas within an institution must be considered, including interaction between food service personnel and patients and employees. Public health requirements for checking food handlers have varied over the years, but as a result of cost containment measures, the general trend is to refrain from special laboratory work or routine screening procedures for employees. Parasite transmission possibilities are presented in Table 31.1. Not every organism is listed; however, those that represent actual possibilities for transmission are emphasized.

Sometimes patients are placed in isolation settings (enteric precautions), which may not be appropriate or necessary for the organism or infection involved. A good example is a patient with amebic dysentery. If the patient has diarrhea or dysentery, the organism stage being passed in the stool is the trophozoite. The trophozoite stage is noninfectious for others. The cyst form, which is passed in more normal, formed stools, is the infective stage for humans. The trophozoites do not form cysts after the stool is passed outside of the body. Therefore, this patient with amebic dysentery does not pose an infection threat to others.

An example in which the need for enteric precautions would be recommended is a patient with diarrhea caused by *Cryptosporidium*. The oocysts are immediately infective on passage, and often large numbers of organisms are passed in the stool, which may vary from formed to watery. There are several reports of suspected transmission of *Cryptosporidium* from patients to health care workers (9–13).

Infection with blood and tissue parasites can occur by accidental needlestick, contact with blood (open wound, mucous membranes, eye), transfusion, or organ transplantation (14). Such transmission of babesiosis has also been documented (15).

Gastrointestinal Infections

Nosocomial gastroenteritis can be defined as an acute infectious gastrointestinal illness acquired by a hospitalized patient, specifically unexplained diarrhea for 2 days, or the onset of infectious diarrhea somewhere in the hospital or medical center setting. In general, requests for ova and parasite identification are not indicated for patients with nosocomial diarrhea (16). Patients at highest risk for gastrointestinal infections include neonates, the elderly, patients with achlorhydria, and those who are immunosuppressed (16). Risk factors can be categorized as those within the host and those outside the host. Risk factors within the host include impaired immunity, reduced gastric acidity, and alterations in the normal intestinal flora or intestinal motility. Risk factors outside the patient include those that alter host resistance or increase the possibility of colonization. The transmission of organisms is generally via the fecal-oral route; some of the organisms can survive for long periods outside the body. Parasites that have been implicated in health care-associated infections include *Cryptosporidium* spp., *E. histolytica*, and *G. lamblia*. Although little is known about transmission of microsporidia, potentially infectious spores can be found in the hospital environment, particularly in stools from severely immunocompromised patients (e.g., those with AIDS). The presence of infective spores in human clinical specimens suggests that precautions when handling body fluids and personal hygiene measures such as hand washing may be important in preventing primary infections in the health care setting. However, comprehensive guidelines for disease prevention will require more definitive information regarding sources of infection and modes of transmission (17).

Cryptosporidium spp.

Although cryptosporidiosis is a well-recognized occupational hazard for persons exposed to naturally infected calves and other animals, cases of cryptosporidiosis have also been reported among persons exposed to experimentally infected animals (18). Five veterinary students who

TABLE 31.1 Possible parasite transmission in a health care setting (nonlaboratory)

Organism[a]	Mode of transmission	Comments
Protozoa (intestinal)		
Entamoeba histolytica[b] (C)	Accidental ingestion of infective cysts, trophozoites, oocysts, or spores in food or water contaminated with fecal material (fecal-oral transmission)	These organisms could be important in a food handler situation. Treatment of carriers and excellent hygiene measures would prevent or eliminate any problems. *Cryptosporidium* is an example where "enteric precautions" would be appropriate (severe diarrhea with stool containing large numbers of infective oocysts).
Entamoeba dispar (C)		
Entamoeba coli (C)		
Entamoeba hartmanni (C)		
Endolimax nana (C)		
Iodamoeba bütschlii (C)		
Blastocystis spp.[b] (C)		
Giardia lamblia[b] (C)		
Dientamoeba fragilis[b] (T)		
Cryptosporidium spp.[b] (O)		
Cyclospora cayetanensis[b] (O)		
Cystoisospora belli[b] (O)		
Microsporidia[b] (S)		
Helminths (intestinal)		
Enterobius vermicularis (E)	Inhalation or ingestion of infective eggs	Very common in children, asymptomatic
Strongyloides stercoralis (IL)	Skin penetration of infective larvae from stool material	Possible, particularly in a compromised patient
Hymenolepis nana (E)	Ingestion of infective eggs (fecal-oral)	Could lead to infection with the adult worm in humans
Taenia solium (E)	Ingestion of infective eggs (fecal-oral)	Could cause cysticercosis
Blood and tissue protozoa		
Leishmania spp. (cutaneous)	Direct contact or inoculation of infectious material from patient's lesion could lead to infection; blood transfusion; organ transplantation	A rare possibility, but it has been documented (accidental person-to-person transmission)
Trypanosoma spp.	Blood transfusion, organ transplantation	Significant problem in areas of endemicity
Toxoplasma gondii	Blood transfusion, organ transplantation	
Ectoparasites		
Pediculus spp.	Transmission of lice and mites is usually seen in groups with very close contact (institutionalized settings).	Confinement in close quarters often lends itself to a transmission problem with lice and mites.
Sarcoptes scabiei		
Dipterous fly larvae	Myiasis could occur anywhere.	Protection of wounds from flies would solve the potential problem.

[a] C, cyst; T, trophozoite (may be transmitted inside helminth eggs); O, oocyst; E, egg; IL, infective larvae; S, spore.

[b] Potentially pathogenic intestinal protozoa.

had direct (four) or indirect (one) contact with experimentally infected calves became ill 6 to 7 days later and had diarrhea for 1 to 13 days; one student was hospitalized. A researcher developed gastrointestinal symptoms 5 days after a rabbit, which was infected with oocysts through a gastric tube, coughed droplets of inoculum onto his face as he was removing the tube. The researcher's stool, which was first obtained for testing the day after he became ill, was positive for oocysts. A veterinary scientist developed flu-like symptoms 7 days after smelling for gastric odor to check the position of a gastric tube in an infected calf; she was unaware of other exposures to *Cryptosporidium*. She developed gastrointestinal symptoms 10 days after this exposure, and oocysts were found in a stool specimen about a week later.

Cryptosporidium can also be transmitted within the hospital setting. At least nine cases of occupational transmission of *Cryptosporidium* from human patients to health care workers have been reported (18). The infected staff members were symptomatic and had oocysts identified from stool examinations. These individuals included a nurse caring for an infected bone marrow transplant recipient, a nurse doing night duty on a ward where an infected 13-month-old boy was a patient, a nurse caring for infected patients before and after renal transplantation, and five nurses caring for an infected patient with AIDS. Patient-to-patient transmission of *Cryptosporidium* in hospitals has also been reported.

Cryptosporidiosis has been implicated as one of the more important opportunistic agents seen in patients with AIDS (19–21). One of the most interesting cases was such an outbreak in a hospital in Copenhagen. As many as 18 HIV-positive patients in a short time were infected with *Cryptosporidium* spp. Epidemiological investigation showed that the source of the parasite was a patient with cryptosporidiosis and a history of psychosis, who, through frequent use of the ice machines, contaminated ice cubes with *Cryptosporidium* oocysts. These oocysts are very resistant to environmental conditions, even on a dry surface. Thus, contamination of ice in a very short period of time resulted in the spread of the pathogen among people with impaired immunity (22).

Unfortunately, at the time of this writing, no totally effective therapy for cryptosporidiosis has been identified, despite testing of over 100 drugs. Consequently, finding this parasite in an immunocompromised host, especially one with AIDS, usually carries a poor prognosis. Also, reports of respiratory tract and biliary tree infections confirm that the developmental stages of this organism are not always confined to the gastrointestinal tract. The more than 4,000 published papers related to cryptosporidiosis that are currently in the literature include information on health care-related transmission, day care center outbreaks, and a number of waterborne outbreaks.

The presence of a thin-walled autoinfective oocyst may explain why a small inoculum can lead to an overwhelming infection in a susceptible host and why immunosuppressed patients may have persistent, life-threatening infections in the absence of documentation of repeated exposure to oocysts. Oocysts undergo sporogony while they are in the host cells and are immediately infective when passed in the stool. In contrast, the oocysts of *Cyclospora cayetanensis* and *Cystoisospora belli* do not sporulate until they are passed from the host and are exposed to oxygen and temperatures below 37°C.

Oocysts recovered in clinical specimens are difficult to see without special stains, such as the modified acid-fast, Kinyoun's, or Giemsa preparations, or the direct fluorescent-antibody, enzyme-linked immunosorbent assay, or immunochromatographic immunoassay methods (23–26). The four sporozoites can be seen within the oocyst wall in some of the organisms, although they are not always visible in freshly passed specimens.

Clinical symptoms include nausea, low-grade fever, abdominal cramps, anorexia, and 5 to 10 watery, frothy bowel movements a day, which may be followed by constipation. Some patients present with diarrhea as described above, and others have relatively few symptoms, particularly later in the course of the infection. In patients with the typical watery diarrhea, the stool specimen contains very little fecal material and is mainly water and mucus flecks. Often, the organisms are entrapped in the mucus, and diagnostic procedures are performed accordingly. Generally a patient with a normal immune system will have a self-limited infection; however, patients who are compromised may have a chronic infection with a wide range of symptoms (asymptomatic to severe).

Occasionally, these patients require fluid replacement, and the diarrhea may persist for more than 2 weeks. This is particularly true in infants, in whom excessive fluid loss may last for more than 3 weeks. Failure to thrive has also been attributed to chronic cryptosporidiosis in infants. Since diarrheal illness is a major cause of morbidity and mortality in young children living in developing countries, it is likely that cryptosporidiosis plays a major role in the overall health status of these children. It has also been suggested that *Cryptosporidium* may be implicated in the respiratory disease that often accompanies diarrheal illness in malnourished children.

The duration and severity of diarrheal illness depend on the immune status of the patient. The most severely immunocompromised patients cannot self-cure, the illness becomes progressively worse with time, and the sequelae may be a major factor leading to death. The length and severity of illness may also depend on the ability to reverse the immunosuppression. In these patients, *Cryptosporidium* infections are not always confined to the gastrointestinal tract; additional symptoms have been associated with extraintestinal infections (respiratory problems, cholecystitis, hepatitis, and pancreatitis). Data for a small series of patients indicated that those with CD4 counts of 180 cells/mm^3 or greater cleared the *Cryptosporidium* infection over a period of 7 days to 1 month. These data are important in predicting the natural progression of the infection and in designing therapeutic trials.

Previously, most human cases have been diagnosed after examination of small- or large-bowel biopsy material, often by both light and electron microscopy. Although examination of flotation material by phase-contrast microscopy has proven to be an excellent procedure for the recovery and identification of *Cryptosporidium* oocysts, many laboratories have neither access to such equipment nor experience with phase-contrast microscopy. Also, since the organism is considered infectious for laboratory personnel, fixed specimens can be processed by using several acid-fast stains, many of which are very satisfactory in demonstrating the organisms in stool material (27).

Respiratory cryptosporidiosis has been found in AIDS patients. Sputum specimens from immunodeficient patients with undiagnosed respiratory illness should be submitted in 10% formalin and examined for *Cryptosporidium* oocysts by the same techniques as those used for stool samples. Infection of the gallbladder and biliary tree should result in oocysts being passed in the stool.

The use of fecal immunoassays has proven to be very helpful in providing more sensitive methods of detecting organisms in stool specimens. Fluorescent-antibody procedures with good specificity and sensitivity have been developed, as have enzyme immunoassay procedures and immunochromatographic cartridges, also with excellent specificity and sensitivity. Some of these reagents, particularly the combination direct fluorescent-antibody product used to identify both *Giardia* cysts and *Cryptosporidium* oocysts, are being widely used in water testing and outbreak situations (23–26).

The infections tend to be self-limiting in patients who have an intact immune system (28). One method of treating patients who are receiving immunosuppressive drugs is to discontinue such a regimen. Other approaches with specific therapeutic drugs such as spiramycin have been tried, but the results to date are somewhat controversial. Data indicate that paromomycin may be a potential therapeutic agent for extended clinical trials. Ongoing studies of immunologic intervention hold promise, but this technique currently is not widely available.

Information on the epidemiology of cryptosporidiosis is well defined, and the potential pathogenicity of *Cryptosporidium* in humans has been widely recognized. The organism is transmitted by oocysts that are fully sporulated and infective at the time they are passed in stool. Oocysts are resistant to some of the disinfectants routinely used in medical care facilities. They are susceptible to ammonia, 10% formalin in saline, freeze-drying, and exposure to temperatures below freezing or above 65°C for 30 min. Commercial bleach in a 50% solution is effective.

Direct person-to-person transmission is likely and may occur through direct or indirect contact with stool material. Direct transmission may occur during sexual practices involving oral-anal contact. Indirect transmission may occur through exposure to positive specimens in a laboratory setting or through exposure to contaminated surfaces, food, or water.

The epidemiologic considerations for cryptosporidiosis emphasize transmission by environmentally resistant oocysts, numerous potential reservoir hosts for zoonotic transmission, documentation of person-to-person transmission in day care centers, transmission within the health care setting, occurrence of asymptomatic infections (infective, carrier state), widespread environmental distribution resulting in the probability of waterborne transmission, and the link between cryptosporidiosis and severe, life-threatening disease in individuals with impaired immune function.

Giardia lamblia

A "debilitating bout" of giardiasis thought to have represented patient-to-staff transmission has been reported. The case involved an orthopedic surgeon caring for two preschool-age patients with giardiasis. In changing the leg cast of one child, the physician noted that the cast was noticeably stained with moist and dry feces. The physician became ill approximately 2 weeks later and had giardiasis confirmed with routine stool examinations. Although he typically washed his hands before and after changing casts, he rarely wore a mask; infection may have been caused by inhalation of infectious cysts in the plaster dust.

G. lamblia is worldwide in distribution and is apparently more prevalent in children than in adults and more common in warm climates than in cool ones. It is the most commonly diagnosed flagellate in the intestinal tract, and it may be the second most commonly diagnosed intestinal protozoan in some areas of the world, with *Blastocystis* being first. Despite disagreement concerning the species names *intestinalis* and *duodenalis*, both continue to be used to describe this organism. Since the majority of health care workers within the United States are used to "*Giardia lamblia*" and continue to report the presence of the organism by using this name, it will continue to be used throughout this text to refer to organisms found in humans as well as other mammals.

The most common location of the organisms is in the crypts within the duodenum. Again, for reasons that are not totally known, cyst formation takes place as the organisms move down through the colon. The trophozoite is usually described as being teardrop shaped from the front, with the posterior end being pointed. When examined from the side, the trophozoite resembles the curved portion of a spoon. The concave portion is the area of the sucking disk. The cysts may be either round or oval, and they contain four nuclei, axonemes, and median bodies. Often, some cysts appear to be shrunk or distorted, and one may see two halos, one around the cyst wall itself and one inside the cyst wall around the shrunken organism. The halo effect around the outside of the cyst is particularly visible on the permanent stained smear.

Although the organisms in the crypts of the duodenal mucosa may reach very high densities, they may not cause any pathologic changes. The organisms feed on the mucus secretions and do not penetrate the mucosa. Although organisms have been seen in biopsy material inside the intestinal mucosa, others have been seen only attached to the epithelium. In symptomatic cases, there may be irritation of the mucosal lining, increased mucus secretion, and dehydration. Other symptoms include epigastric pain, flatulence, and diarrhea with increased fat and mucus in the stool but no blood. Weight loss often accompanies these symptoms. Although there is speculation that the organisms coating the mucosal lining may act to prevent fat absorption, this does not completely explain why the uptake of other substances normally absorbed at other intestinal levels is prevented. Occasionally, the gallbladder is also involved, causing gallbladder colic and jaundice. *G. lamblia* has also been detected in bronchoalveolar lavage fluid.

Although patients with symptomatic giardiasis usually have no underlying abnormality of serum immunoglobulins, patients with immunodeficiency syndromes, particularly common variable hypogammaglobulinemia, have a high incidence of giardiasis. Giardiasis was the most common cause of diarrhea in these patients and was associated with mild to severe villous atrophy. Successful treatment of giardiasis led to symptomatic cure and improvement in mucosal abnormalities, with the exception of nodular lymphoid hyperplasia.

With the advent of AIDS, there was speculation that *G. lamblia* might be an important pathogen in this group of individuals. However, to date, clinical findings do not seem to confirm this possibility (29, 30).

Routine stool examinations are normally recommended for the recovery and identification of intestinal protozoa. However, because *G. lamblia* organisms are attached so securely to the mucosa by means of the sucking disk, a series of even five or six stools may be examined without recovery of the organisms. The organisms also tend to be passed in the stool on a cyclical basis. The Entero-Test capsule can be helpful in recovering the organisms, as can the duodenal aspirate. Although cysts can often be identified on the wet stool preparation, many infections may be missed without the examination of a permanent stained smear (31). Material from the string test (Entero-Test) or mucus from a duodenal aspirate should be examined as a wet preparation for motility; however, motility may be represented by nothing more than a slight flutter of the flagella because the organism will be caught up in the mucus. After diagnosis, the rest of the positive material can be preserved as a permanent stain.

Immunoassays to detect *Giardia* antigen in feces have also been developed (24–26, 32). The enzyme-linked immunosorbent assays are more sensitive than microscopic examinations. Fluorescence methods involving monoclonal antibodies have also proven to be extremely sensitive and specific in detecting *G. lamblia* in fecal specimens, as have the rapid cartridges. All of the fecal immunoassays for *Giardia* tend to have comparable sensitivities and specificities; choice often depends on which method fits into the laboratory work flow. Automated molecular PCR panels, including some parasites such as *Giardia*, *Cryptosporidium*, *Cyclospora*, and *Entamoeba histolytica*, are also available. Other potential targets include *Blastocystis* spp., *Dientamoeba fragilis*, and the microsporidia.

Unfortunately, serodiagnostic procedures for giardiasis do not yet fulfill the criteria necessary for wide clinical use, particularly since they may indicate either past or present infection. In contrast, the detection of antigen in stool or visual identification of organisms with monoclonal antibody reagents indicates current infection. With the increase in the prevalence of *Giardia* infections and awareness of particular situations such as nursery school settings, perhaps additional detection assays will emerge as rapid and reliable immunodiagnostic procedures. Because giardiasis may not produce any symptoms at all, demonstration of the organism in symptomatic patients may not rule out other possibilities such as peptic ulcer, celiac disease of some other etiology, strongyloidiasis, and possibly carcinoma.

If giardiasis is diagnosed, the patient should be treated. Giardiasis can be eliminated from most patients by metronidazole (33). Tinidazole has also been used and has proven to be more effective than metronidazole as a single dose (33).

In the absence of a parasitologic diagnosis, the treatment of suspected giardiasis is a common question with no clear-cut answer. The approach depends on the alternatives and the degree of suspicion of giardiasis, both of which will vary among patients and physicians. However, it is not recommended that treatment be given without a good parasitologic workup, particularly since relief of symptoms does not allow a retrospective diagnosis of giardiasis; the most commonly used drug, metronidazole, also targets organisms other than *G. lamblia*.

The third question involves treatment of a patient who is asymptomatic. Generally, it is recommended that all cases of proven giardiasis be treated because the infection may cause subclinical malabsorption, symptoms are often periodic and may appear later, and a carrier is a potential source of infection for others (33).

G. lamblia is transmitted by ingestion of viable cysts. Although contaminated food or drink may be the source, intimate contact with an infected individual may also provide the infection mechanism. This organism tends to be found more frequently in children or in groups that live in close quarters (4, 34–40). Often, there are outbreaks due to poor sanitation facilities or breakdowns in sanitation as evidenced by infections in travelers and campers. There is also an increase in the prevalence of giardiasis in the male homosexual population, probably as a result of anal or oral sexual practices.

During the past few years, this infection has received much publicity. With increased travel, there has been a definite increase in symptomatic giardiasis within the United States. Various surveys show infection rates of 2 to 15% in various parts of the world.

Entamoeba histolytica

Although *E. histolytica* is not generally associated with health care-associated infections, reports indicate that transmission is certainly possible (41). Istre et al. reported on 36 cases of amebiasis during a 30-month period in patients who had received colonic irrigation therapy (42).

Epidemiologic studies implicated the colonic irrigation machine; testing indicated that after routine cleaning, the machine was contaminated with *E. histolytica*. Patients at greatest risk were those who received colonic irrigation immediately after a patient with amebiasis and bloody diarrhea. Evidence supports the possibility of transmission if endoscopic equipment is not thoroughly cleaned and disinfected after use in a patient infected with *E. histolytica*.

Since *E. histolytica* can easily be confused with macrophages (trophozoites) and polymorphonuclear leukocytes (cysts) found in stool, it is important to recognize the possibility of false-positive results (in which other protozoa or human cells are confused with this organism). Recognizing the possibility of error is particularly important in a potential "outbreak" situation. These types of diagnostic errors, whereby large numbers of patients were diagnosed with amebiasis, have been documented; in one report, on review, 34 of 36 patients who were diagnosed with amebiasis were found to be negative for *E. histolytica* (43).

Over the years, some workers came to believe that what was called *E. histolytica* was really two separate species of *Entamoeba*, one being pathogenic and causing invasive disease (*E. histolytica*) and the other being nonpathogenic and causing mild or asymptomatic infections (*E. dispar*). Although this was controversial, current knowledge indicates that pathogenic *E. histolytica* is the etiologic agent of amebic colitis and extraintestinal abscesses while nonpathogenic *E. dispar* causes no intestinal symptoms and is not invasive in humans (44). Unfortunately, with the exception of some newly introduced immunoassay procedures, most laboratories will continue to use routine methods for the identification of organisms in the *Entamoeba* genus; unless the trophozoites contain ingested erythrocytes, identification to the species level is not possible unless confirmed using molecular methods or the fecal immunoassay specifically for *E. histolytica*. The organisms should be reported as *E. histolytica/E. dispar* with appropriate reporting to public health agencies. In these cases, the approach to the patient will be based on clinical findings and physician decisions regarding therapy. Diagnostic reagents for confirmation of true pathogenic *E. histolytica* and for the *E. histolytica/E. dispar* group are commercially available. As with *Cryptosporidium* spp. and *Giardia lamblia*, automated molecular PCR panels also include *E. histolytica*.

Microsporidia

The evolutionary relationship of microsporidia to fungi, either as sister group or internal branch within the fungi, has been extensively debated over the years. The main difficulties for inferring microsporidian relationships stem from their highly divergent molecular sequences and the challenges these represent for reliable phylogenetic analyses. It appears that that microsporidia share a particularly close evolutionary relationship with the zygomycetes; however, actual classification of the microsporidia remains undecided (45).

Although the epidemiology of the microsporidia has not yet been thoroughly defined, it is highly likely that the spores shed in human clinical specimens (stool, urine, sputum, etc.) are immediately infectious. These infectious spores can be found in hospital and laboratory environments and are associated primarily with clinical specimens from immunocompromised patients, such as those with AIDS or transplant recipients. Precautions should be used when handling body fluids from these patients. Microsporidial infections in all body sites have been documented; this fact needs to be considered when determining the housing and care of the patient (28). Precautions would be very similar to those used for patients diagnosed with disseminated cryptosporidiosis, in which infectious organisms could be found in multiple clinical specimens.

Microsporidia are becoming more widely recognized as causative agents of ocular, gastrointestinal, renal, pulmonary, and sinus diseases in both immunocompetent and immunosuppressed patients. Ocular microsporidiosis can be isolated or may present as part of systemic infection. Recent reports indicate an increasing number of cases of ocular microsporidiosis in immunocompetent individuals. The ocular infection occurs mainly in two forms: keratoconjunctivitis, which is seen in immunocompromised individuals, and stromal keratitis, seen in immunocompetent individuals. The ocular cases which present with superficial keratitis in AIDS patients differ from the cases seen in immunocompetent individuals, which present mainly as deep stromal keratitis. Again, these ocular specimens will most likely contain infectious spores; thus handling precautions are highly recommended.

Specific infection control guidelines for inpatients with microsporidiosis have yet to be developed, but information suggests that all body fluids that may contain infectious spores should be handled accordingly. Standard precautions used within the institution and laboratory environments should be sufficient to prevent accidental infection with microsporidial spores.

Cystoisospora (*Isospora*) *belli*

C. belli is thought to be the only species of *Cystoisospora* that infects humans, and no other reservoir hosts are recognized for this infection. Transmission is through ingestion of water or food contaminated with mature, sporulated oocysts. Sexual transmission by direct oral contact with the anus or perineum has also been postulated, although this mode of transmission is probably much less common.

The oocysts are very resistant to environmental conditions and may remain viable for months if kept cool and moist; oocysts usually mature within 48 h following stool evacuation and are then infectious. Although it is not considered a "common" parasite, occasional positive specimens are seen in many laboratories. Since transmission is through the ingestion of infective oocysts, there is certainly the possibility that this parasite could be transmitted within the laboratory or in the patient care setting, particularly if the laboratory was involved in sporulation studies leading to infective oocysts.

Examination of a fecal specimen for the oocysts is recommended. However, wet-preparation examination of fresh material either as the direct smear or as concentrated material is recommended rather than the permanent stained smear. The oocysts are very pale and transparent and can easily be overlooked. They can also be very difficult to see if the concentration sediment is from polyvinyl alcohol-preserved stool. The light level should be reduced, and additional contrast should be obtained with the microscope for optimal examination conditions. It is also quite possible to have a positive biopsy specimen but not recover the oocysts in the stool because of the small numbers of organisms present. These organisms are acid fast and can also be demonstrated by using auramine-rhodamine stains.

Hymenolepis nana

Although *H. nana* can be transmitted by the eggs and does not require an intermediate host to complete its life cycle, the significance of this infection in the health care setting is unknown. However, it is important to remember that the eggs passed in the stool are mature and infective for patients and health care workers who may come in contact with fresh fecal material. Certainly, these infections have been documented in food handlers in many areas throughout the world.

Taenia solium

Health care-associated transmission of the infective eggs of *Taenia solium*, causing cysticercosis, has not been documented. However, an individual infected with adult *T. solium* and passing eggs could certainly serve as a potential reservoir for serious transmission potential. It is important to remember that the eggs passed in the stool are mature and infective for patients and health care workers. This is true even when proglottids are submitted to the laboratory in preservative; the eggs within the uterine branches will remain viable and infectious. Thus, handling of fresh fecal material requires careful adherence to precautions, hopefully eliminating the possibility of transmission of infectious eggs.

Cysticercosis is endemic in most of Latin America, sub-Saharan Africa, and vast parts of Asia, including the Indian subcontinent. It has also been increasingly diagnosed in developed countries because of migration of people from endemic zones and exposure in travelers. Humans get infected by the fecal-oral route, most often from a direct contact with an asymptomatic *T. solium* carrier (46).

Blood and Tissue Infections

Plasmodium spp.

Health care-associated malaria represents person-to-person transmission of parasite-infected erythrocytes through blood transfusion, needlestick injury, improper use of blood glucometers, multidose heparin vials, organ transplantation, contaminated catheters that deliver contrast medium, or rarely, open wounds. Worldwide, transfusion malaria is the most common and significant health care-related parasitic infection, although it is rare within the United States (14, 47, 48). These infections have occurred after transfusion not only of whole blood but also of white blood cells, fresh plasma, and platelets (14). Malaria infections have also originated through renal transplants (14). It is interesting that malaria infections have been transmitted from recipient to donor in a person-to-person transfusion situation in which backflow of blood has been a problem (47). Most cases of posttransfusion malaria may go unsuspected, with an incubation period of up to 4 weeks. Donors implicated in transfusion-transmitted malaria tend to be "semi-immune" with a very low parasite load; therefore, detection using antigens or PCR may not guarantee identification of the infected donor. Often the infectious dose from these donors may be 1 to 10 parasites in a unit of blood (49). All species of *Plasmodium* can survive and remain potentially invasive for 7 days in preserved blood and up to 2 years in frozen blood. The source of infection may be not only whole blood, but also the blood products derived from infected donors, such as concentrated red blood cells, white blood cells, platelets and cryoprecipitate.

In one situation, *Plasmodium falciparum* malaria was diagnosed in two patients who had been treated in the same emergency room. The two patients were in the room for 9 hours, positioned 7 m apart, and were given several emergency diagnostic and therapeutic treatments. Case 1 had pulmonary tuberculosis; he received intravenous fluid via a peripheral vein, his gastrostomy incision site was disinfected, and the dressing was changed. Intervention for Case 2 consisted of blood examination, central vein catheter insertion, intubation, mechanical ventilation, and cardiac massage. Case 2 died of falciparum malaria on the day of emergency room admission; Case 1 died of falciparum malaria 3 weeks after admission. Subsequent interviews revealed that three nurses and one emergency worker handled both patients. To confirm this possible health care-associated transmission, sequence analysis of parasites was performed. PCR and sequencing confirmed that the two patients were infected with the same organism. Case 1 had not visited an area of malaria endemicity for over 30 years; he had previously received blood transfusions, but it was confirmed that the donor's blood was malaria-free. There were no mosquitoes inside or outside the hospital. Also, natural transmission of malaria by a mosquito was not possible, because, aside from the inhospitable environmental conditions of the hospital for *Anopheles*, the time period was too short. Unfortunately, no foci of exposure to contaminated intravenous solutions, catheters, syringes, or other devices were identified, since the investigation took place 20 days after the assumption of nosocomial transmission (50).

Malaria induced via contaminated needles shared among drug addicts has been well known for many years. Also, patient-to-staff malaria transmission via needlestick injury has been documented, with most cases involving nurses or physicians who were exposed during venipuncture or preparation of blood smears (14).

In another case, transmission of *P. falciparum* was reported and confirmed by molecular genotyping from improper use of saline flush syringes in a tertiary care hospital in the United States. Although hospital policy had strict guidelines for using multidose devices and did not allow the reuse of single-use devices, interviews of seven nurses, including those who cared for the two patients, showed that two nurses admitted reusing saline flushes on the same patient, and four nurses had observed saline flushes being reused in the same patient unit (51).

An outbreak of chloroquine-resistant *P. falciparum*, in which a multidose heparin vial was implicated as the source of infection, was reported from Venezuela. The vial was apparently contaminated by the blood of a parenteral drug abuser who had asymptomatic malaria and who had received 2 days of intravenous fluid therapy (52).

In three cases involving suspected malaria transmission by renal transplantation, the donors were strongly seropositive or had a positive blood smear. However, all three patients were from areas where malaria was endemic, and the stress of surgery and immune system suppression could have also stimulated recrudescence of the infection (14). Transmission of malaria has also been documented through liver transplantation; unfortunately, the recipient died. Based on therapeutic toxicity for *Plasmodium* spp., the use of organs from donors infected with malaria carries risks that may limit transplantation from such donors (53).

Babesia spp.

The majority of cases in the United States are caused by *Babesia microti* and occur in the Northeast and upper Midwest. A small number of infections caused by *Babesia duncani* and *B. duncani*-like organisms have been reported on the West Coast from California to Washington State. Additionally, *Babesia divergens*-like organisms have been reported in Kentucky, Missouri, and Washington State. In Europe, almost all reported cases have been due to *B. divergens*, and a few have been caused by the EU1 species, now called *Babesia venatorum*. Sporadic cases of babesiosis have also been reported in Asia, Africa, Australia, and South America. As the frequency of clinical cases has risen, there has been an associated increase in transfusion-transmitted *Babesia*, making babesiosis the most frequent transfusion-transmitted infection with approximately 162 cases reported since 1980 and 12 associated fatalities in the period 2005–2008 (54). While the current strategy of blood screening via donor questionnaires permanently excludes prospective blood donors with a history of babesiosis, it appears to be of limited value because infected blood donors usually experience asymptomatic infection or remain infectious long after symptoms have resolved.

Transmission of babesiosis through routine blood transfusion, frozen-thawed blood, and platelets has also been documented (14, 55). Although needlestick or open-wound transmission of *Babesia* spp. has not been reported, it is certainly possible, particularly in the health care setting. Refrigeration of *B. divergens* results in parasite morphology changes and a decrease in parasite numbers. However, there are sufficient parasites that survive 31 days of storage at 4°C and yield high end-point parasitemia. The risk of infection through contact with ticks is probably low.

Trypanosoma brucei gambiense and *T. brucei rhodesiense*

Although patients with African trypanosomiasis are usually symptomatic, those in the early stages of the infection may be asymptomatic and appear to be healthy potential blood donors. These types of patients are probably responsible for the rare transfusion cases reported. However, contaminated needlestick injuries and open-wound contact with contaminated blood are also potential means of transmission in the health care setting.

Trypanosoma cruzi

Although *Trypanosoma cruzi* is normally transmitted by the feces of an infected triatomid bug, transmission of the organism via blood transfusion is the second most common means of acquiring the infection. In areas where infection is highly endemic, as many as 62% of blood donors are seropositive for *T. cruzi* antibody (56). One study from Los Angeles County of 1,027 consecutive blood donations found 2.4% to be seropositive for *T. cruzi* antibody by an indirect fluorescent-antibody assay (57). In another study, lookback analysis was able to identify the first two cases of probable transfusion-transmitted *T. cruzi* infection since implementation of the national screening program, which increases the total number of reported cases in the United States to eight. Considering this information, concerns regarding the safety of the blood supply are reasonable and understandable (58). Transmission via kidney transplants has also been well documented (59).

The entry of large numbers of immigrants from Central America has contributed to growing concerns, particularly with respect to transfusion-related transmission of *T. cruzi* in areas of the world where the infection is not endemic or, if endemic, has not been a problem. Since there are triatomid bugs capable of becoming infected with *T. cruzi* within the southwestern United States, the presence of more people with latent infections also presents some concerns (60). Currently, it is estimated that 300,000 people with Chagas' disease live within the United States, and one in 354,000 blood donors might have acquired *T. cruzi* within the United States (60). In another reference, it is estimated that as of 2009, 409,000 United States residents have Chagas' disease; over a period of 20+ years, as many as 300 patients may have contracted Chagas' disease through transplantation (81).

The reported rate of confirmed *T. cruzi* infection in volunteer U.S. blood donors is approximately 1 in 27,500, so with about 30,000 tissue donors annually in the United States, tissue banks should expect to encounter one or two *T. cruzi*-infected tissue donors each year. Solid organ donation of the heart, liver, kidney and kidney/pancreas combination, lungs, bone marrow, and cord blood from infected donors has resulted in transmission to recipients in both endemic and nonendemic countries. Transmission of *T. cruzi* through donor kidneys has been documented in Latin America, where serologic screening of organ donors and recipients is not standard practice. Three cases of recipient infection from a single donor from Central America have been reported in the United States; the cases involved kidney and pancreas, kidney alone, and liver. One of the recipients died of myocarditis (53).

Tissue donation presents a unique situation with the possibility of parasites infecting blood and tissue in the deceased donor prior to tissue recovery, chemical processing, irradiation, or lyophilization during tissue processing, and short-term storage at refrigerated temperatures and long-term storage at frozen temperatures. The ability of *T. cruzi* to survive long periods of storage at +4 and −80°C suggests that *T. cruzi*-infected tissues stored under these conditions are potentially infectious. Viable parasites capable of infecting cells in culture were present at 1 year at −80°C frozen storage even in the absence of cryoprotectant.

In the United States, nine cases of *T. cruzi* transmission from solid organ donation have been documented. Eight reported cases of *T. cruzi* transmission via blood transfusion have been reported; blood donor screening was implemented in the United States in 2007 (61). Current Food and Drug Administration guidance specifies that all blood donors must be asked about a history of Chagas' disease. However, it has been determined that the Chagas' history question has no real value, while testing donor units provides the best option for detection of potentially positive donors (62). Proposed testing options for transplant donors include automatic testing based on the medical patient questionnaire, testing of all recipients, testing all individuals of Latin origin, and testing of all organ donors (81).

The oral consumption of Amazonian palm berry or açaí juice, probably contaminated with triatomid bug feces on the fruit or with bugs that were accidentally crushed during the preparation process, is another possible means of *T. cruzi* transmission in some areas of the world. Without subsequent pasteurization, the organisms remain viable, especially if the juice is not frozen.

Contaminated needlestick injuries, accidental exposure to positive cultures, processing infective tissues, and open-wound contact with contaminated blood are also potential means of transmission in the health care setting (18).

Leishmania donovani

Although transfusion-induced visceral leishmaniasis has been described only rarely, like other infections mentioned above it may be underreported in areas of endemicity where confirmation of the route of infection may be difficult. Certainly, exposure to contaminated blood or animals would represent a potential source of infection.

Toxoplasma gondii

It is well documented that immunosuppression (advanced HIV disease, medications used in cancer therapy or organ transplantation) can result in disease reactivation and severe morbidity or mortality. Health care-associated infection with *Toxoplasma gondii*, primarily in cardiac or renal transplant patients, has been documented (14, 63). However, the efficacy of trimethoprim-sulfamethoxazole for the prevention of toxoplasmosis transmission dramatically reduces the risk to organ recipients from infected donors. Most serious infections in immunocompromised patients result from reactivation of a latent infection. Transmission from a patient to a health care worker via needlestick injury or exposure to blood (open wound) has not been documented.

Studies have revealed associations between *T. gondii* antibody seropositivity (indicating infection) and the presence of various psychiatric disorders in humans (e.g., schizophrenia, bipolar illness, suicide attempts, episodes of self-directed violence, and memory impairment in the elderly). Although these results are interesting and potentially indicate another reason to prevent toxoplasmosis, additional studies are needed to fully explain possible relationships between *T. gondii* infection and mental illness, and how the strain and stage of *T. gondii* (oocyst versus tissue cyst) may impact this relationship (64).

Infections with Ectoparasites

Ectoparasites of nosocomial significance include lice (head, body, pubic), scabies and other mites, and myiasis. Head and pubic lice and scabies are fairly common in many parts of the world, including the United States. These infestations are generally not serious problems within the health care setting, with the exception of scabies, which has the potential to cause large outbreaks.

Pediculus spp. and *Phthirus pubis*

Infection with lice belonging to the genus *Pediculus* are common and are usually found on one part of the body such as head, body, or pubic hair. The head louse, *Pediculus humanus capitis*, is found most often in school-age children, and nosocomial transmission is generally not a problem, with possible exceptions characterized by close patient-to-patient contact in pediatric wards or institutional settings.

Pediculus humanus corporis (body louse) is well known for its association with poverty and poor personal hygiene. Since transmission is through contact with or exchange of contaminated clothing or bedding, this does not seem to represent a large potential problem. However, the potential for transmission varies throughout the world.

Phthirus pubis (pubic louse) infestation occurs most commonly in sexually active adults, with a direct skin-to-skin transfer. It is unlikely that transmission within the health care setting would cause any problems.

Sarcoptes scabiei

Scabies is a highly contagious infestation of the itch mite, *Sarcoptes scabiei*. Symptoms are related to pruritic dermatitis, and apparently, transmission can occur through person-to-person direct skin contact or via fomites. Outbreaks of scabies in hospitals or institutions, particularly for the elderly or developmentally disabled, have been documented worldwide (65). These outbreaks are particularly severe when associated with crusted (Norwegian) scabies; such patients may be infected with thousands of mites on the skin. This infection has been linked to cellular immune deficiencies including AIDS (66). Other potential problems include a decreased awareness of itching and the use of topical corticosteroids (65). Because of the number of mites present, these patients are extremely contagious via sloughing skin, direct contact, and environmental contamination. Another potential problem is the fact that the symptoms mimic those of many other dermatologic problems. Burrows may not be evident, and hyperkeratotic, crusted, scaling, fissured plaques are present over the scalp, face, and back, with associated gross nail thickening. The number of documented reports of scabies, particularly in AIDS patients, suggests that health care-associated scabies may become more common in the future.

Missed diagnoses of scabies during emergency room visits may result in nosocomial spread and increase the unnecessary use of prophylactic treatments. Emergency room overcrowding, time constraints, and less severe illness compromise recognition of scabies in this setting. Health care workers should be alert for signs of scabies infestations under these conditions.

Although outbreaks of other mites, including the pigeon mite *Dermanyssus gallinae*, have been described, it is not clear whether these infestations are a problem. It has also been suggested that these cases may be misdiagnosed as scabies (65).

Myiasis

Myiasis refers to infestation of the body by larvae of a number of fly species. These cases occur when flies are attracted to patient blood or body tissue fluids and deposit eggs into an open wound or patient body opening such as the nose or ear. Often, these patients are not totally conscious, or they may be debilitated or immobile. It is generally thought that these cases are underreported for a number of reasons, some of which are related to institutional risk management decisions. A study from Brisbane, Australia, reported 14 infestations, 6 of which were health care-associated, during a period of 17 months (67). Almost all reported cases of nosocomial myiasis (nasal, submandibular, oral, ulcer, unbroken skin, wound, vaginal, nasotracheal, conjunctival, surgical incision) have been in patients with underlying disease or trauma.

Ophthalmomyiasis, caused by infestation of the eye by dipterous fly larvae, can result in symptoms ranging from minor irritation to blindness, disfigurement, or death. Infestations with the sheep botfly, *Oestrus ovis*, are normally associated with normal hosts, while infestations with others, including *Cochliomyia hominivorax*, seem to occur more commonly in compromised hosts (68).

Infections in the Pediatric Patient

Specific infections that can be acquired in the pediatric patient include those caused by *Cryptosporidium* spp., *G. lamblia*, *P. humanus capitis*, and *S. scabiei*. Although less is known about microsporidia, the infective spores could be transmitted in a hospital setting, particularly if spores are present in stool specimens, urine, or other body fluids from immunocompromised or immunocompetent patients.

Cryptosporidium spp.

Cryptosporidium infection is discussed above in the section on gastrointestinal infections. It is also important to remember than this organism has been isolated from other body sites, particularly in severely immunocompromised patients. Cryptosporidiosis has also been linked to infections in nursery schools and should certainly be considered in this setting.

Giardia lamblia

Infection has been well documented in the pediatric population. Giardiasis is most frequently associated with nursery school outbreaks and is thoroughly discussed above in the section on gastrointestinal infections.

Pediculus humanus capitis

Although pediculosis is a well-known problem among young children, lice are not as likely to be spread to other patients except in chronic ambulatory-care situations such as psychiatric wards or pediatric ward playrooms. Under these circumstances, patients should be screened prior to admission.

Sarcoptes scabiei

Prevalence of the itch mite infection, or scabies, varies among young children; sexually active adolescents and adults are also susceptible to infection. The small size of the mite contributes to the problem and to possible transmission to medical staff and other patients. Although intimate contact is considered the most likely mode of transmission, fomite transmission is an alternative method, particularly with crusted scabies. It is generally recommended that if two or more patients and one or more staff members exhibit the symptoms of scabies (pruritus with or without crusting or scaling) or have positive skin scrapings, total treatment should be given. It is also important that posttreatment surveillance and testing be continued for at least 3 months.

Infections in the Compromised Patient

Compromised patients have poor host defenses, usually for one of three reasons: underlying disease (immunosuppression or immunodeficiencies in either the cellular or humoral mechanisms of the immune system or both), therapy for disease (chemotherapy, radiation), or hospital-based procedures and contact with infected persons (catheterization, broad-spectrum antibiotics, nebulizers, inhalation procedures, person-to-person contact, food sources, contaminated equipment, etc.).

In addition to *Cryptosporidium*, *E. histolytica*, *G. lamblia*, and microsporidia as mentioned above, *S. stercoralis*, free-living amebae, *Toxoplasma*, *Trypanosoma* spp., and *Leishmania* spp. cause severe disease in the compromised patient and can be transmitted in the hospital setting.

S. stercoralis has become extremely important, particularly with respect to compromised patients (69) and military personnel and travelers who may have been in an area of endemic infection many years before (70). More than 30 to 40 years after acquisition of the original infection, persistent undiagnosed disease can be found in these individuals. If, for any reason, they become immunocompromised, the result can be disseminated disease leading to the hyperinfection syndrome and death (71–73).

The life cycle of *S. stercoralis* is one of the more complex parasite cycles. Human infection is acquired by skin penetration of the filariform larvae (infective larvae) from the soil. After penetration of the skin, the larvae are carried via the cutaneous blood vessels to the lungs, where they break out of the pulmonary capillaries into the alveoli. They then migrate via the respiratory tree to the trachea and pharynx, are swallowed, and enter the mucosa in the duodenum and upper jejunum. Development usually takes about 2 weeks, after which the females begin egg production. The eggs are oval and thin shelled and measure 50 to 58 μm by 30 to 34 μm (generally a bit smaller than hookworm eggs). The eggs usually hatch, and the rhabditiform larvae (noninfective larvae) pass out of the intestinal tract in the feces. These larvae are passed out onto the soil in the feces and develop into free-living male and female worms, eventually producing infective filariform larvae (egg, noninfective larvae, and infective larvae). In temperate climates, the free-living male and female worms do not develop; however, the rhabditiform larvae that pass out in the stool develop into the filariform (infective) larvae, which are then ready to infect the next host through skin penetration.

In situations in which autoinfection occurs, some of the rhabditiform larvae that are within the intestine develop into the filariform larvae while passing through the bowel. These larvae can then reinfect the host by (i) invading the intestinal mucosa, traveling via the portal system to the lungs, and returning to the intestine or (ii) being passed out in the feces and penetrating the host on reaching the perianal or perineal skin.

It is generally accepted that the life cycle presented above is correct; the skin-penetrating larvae travel from the skin to the intestine via an obligatory route that includes the blood, lungs, trachea, and upper gastrointestinal tract (the standard pulmonary route). It is also assumed that following autoinfection, the larvae follow the same route to return to the duodenum, where they mature. However, review information and data from Schad et al. (74) indicate that the pulmonary route is just one of several possible pathways to the duodenum, regardless of whether the larvae penetrate the skin or the intestine. In spite of some caveats, these studies definitely challenge the current accepted understanding of the life cycle. The pulmonary migration route for all skin-penetrating nematodes may not be as universally applicable as was once thought.

As judged from the life cycle, the three areas of primary involvement are the skin (cutaneous), the lungs (pulmonary), and the intestinal mucosa (intestinal). Initial skin penetration usually causes very little reaction, although there may be some pruritus and erythema if the number of penetrating larvae is large. With repeated infections, the patient may mount an allergic response that will prevent the parasite from completing the life cycle. The larvae may be limited to skin migration or larva migrans.

Larval migration through the lungs may stimulate symptoms, depending on how many larvae are present and the intensity of the host immune response. Some patients are asymptomatic, whereas others present with pneumonia. With a heavy infective dose or in the hyperinfection syndrome, individuals often develop cough, shortness of breath, wheezing, fever, and transient pulmonary infiltrates (Loeffler's syndrome). Cases in which the larvae could even be found in the sputum have been reported (75, 76).

In heavy infections, the intestinal mucosa may be severely damaged with sloughing of tissue, although this type of damage is unusual. The symptoms may mimic peptic ulcer with abdominal pain, which may be localized in the right upper quadrant. Radiographic findings may mimic Crohn's disease of the proximal small intestine (77). In an immunocompetent patient, there is a leukocytosis with a peripheral eosinophilia of 50 to 75%, while in patients with chronic infections, the eosinophilia may be much lower. Some of these chronic infections have lasted over 30 years as a result of the autoinfective capability of the larvae. One case of chronic strongyloidiasis persisted for approximately 65 years (78).

Autoinfection is probably the mechanism responsible for long-term infections that persist for years after the person has left the area of endemic infection. The parasite and host reach a status quo so that neither suffers any serious damage. If for any reason this equilibrium is disturbed and the individual becomes immunosuppressed, the infection proliferates, with large numbers of larvae being produced and found in every tissue of the body. Several conditions, including the increased use of immunosuppressive therapy, predispose an individual to the hyperinfection syndrome. In addition to suffering tissue damage from the migrating larvae, the patient may die from sepsis, primarily as a result of the intestinal flora. Other causes of death include peritonitis, brain damage, and respiratory failure. Few cases of reactive arthritis have been reported, but the number of cases may be underestimated. A case of reactive arthritis combined with uveitis associated with a long-standing, heavy *Strongyloides* infection was detected in a 32-year-old patient positive for human T-cell leukemia virus type 1. Treatment with thiabendazole and ivermectin resulted in rapid improvement.

Confirmation of the infection depends on recovery and identification of the adult worms, larvae, or eggs from the stool, duodenal material, or sputum. Fecal specimens may not be positive, even after performance of the routine ova and parasite examination, including the concentration procedure. The number of larvae found in the stool also varies from day to day.

Some reports indicate that sampling of duodenal contents may recover larvae if stools are negative, while others indicate that duodenal sampling may not be effective. Special techniques that have been recommended for the recovery of duodenal contents include the Entero-Test capsule. There are also special concentration techniques (Baermann) and methods for larva culture (Harada-Mori, petri dish). These techniques provide a means of larval recovery from large amounts of stool material, and often the filariform larvae are recovered. To differentiate the *Strongyloides* filariform larvae from those of hookworm, one should examine the tail under a microscope. *Strongyloides* filariform larvae have a slit in the tail, while hookworm filariform larvae have a pointed tail.

Agar plate cultures are also possible; stool is placed onto agar plates, and the plates are sealed to prevent accidental infections and then held for 2 days at room temperature. As the larvae crawl over the agar, they carry bacteria with them, thus creating visible tracks over the agar. The plates are examined under the microscope for confirmation of larvae, the surface of the agar is then washed with 10% formalin, and larval identification is confirmed via wet examination of the sediment from the formalin washings.

Debilitated or compromised patients should always be suspected of having strongyloidiasis, particularly if there are unexplained bouts of diarrhea and abdominal pain, repeated episodes of sepsis and/or meningitis with intestinal bacteria, or unexplained eosinophilia. However, a recent comparative study of the occurrence of *Strongyloides* infection in 554 AIDS and 142 non-AIDS patients demonstrated similar prevalences of infection in the two groups, thus indicating no significant statistical differences (79).

At present, the recommended drug of choice is ivermectin or albendazole. In some cases, additional drugs or repeated therapy may be necessary. Patients with the hyperinfection syndrome should be hospitalized during therapy for proper monitoring.

Contact with contaminated infective soil, feces, or surface water should be avoided. Individuals found to have the infection should be treated. *All patients who are going to receive immunosuppressive drugs should be screened for strongyloidiasis before therapy.*

Laboratory Infections

Safety precautions tend to be emphasized in clinical laboratories, particularly microbiology laboratories. However, general safety regulations pertaining to laboratory coats, hand washing, and use of disinfectants, as well as to prohibitions of eating, drinking, and smoking, fail to address the specifics of possible parasite transmission.

In laboratories where extensive diagnostic testing is performed, exposure to possible infectious parasites may result from the handling of specimens, drawing of blood, various types of concentration procedures, organism cultures, and animal inoculation studies. Relevant parasites and their possible routes of infection are presented in Tables 31.2 and 31.3. Information on resistance to antiseptics and disinfectants can be found in Table 31.4.

Intestinal Protozoa

Intestinal protozoa, such as *G. lamblia*, *Dientamoeba fragilis*, *E. histolytica*, *Blastocystis* spp., microsporidia, and the coccidia, particularly *Cryptosporidium* spp., cause human disease, and the protozoan cysts, oocysts, and spores can be accidentally transmitted from one person to another. The cysts, oocysts, and spores are resistant to many disinfectants. Of those currently available, ozone is the most effective protozoan cysticide, followed by chlorine dioxide, iodine, and free chlorine, all of which appear to be more effective than the chloramines. Cyst forms, including oocysts, are the most resistant to chemical disinfection. Although the exact mechanisms of resistance are not thoroughly understood, these resistant stages probably take up fewer disinfectant molecules from solution than do stages like the trophozoite (Table 31.4).

Relatively few cases of laboratory-acquired infections with intestinal protozoa have been reported; however, a few cases have been detected. A worker who "checked in several hundred stool specimens, stamping numbers and dates on report cards, many of which had been contaminated from leaky containers," became infected with *G. lamblia* (18). The infection was confirmed by finding the flagellates in the stool. A laboratory technician who examined numerous stool specimens from a patient infected with *C. belli* became ill about a week later, and *C. belli* was confirmed to be present in his stool. While infecting a rabbit using a capsule containing about 400 *Cystoisospora* oocysts, two researchers were sprayed in their faces with droplets when the rabbit regurgitated the material and vigorously shook its head; both individuals became ill about 2 weeks later (18).

Free-Living Amebae

A number of studies have investigated the responses of trophozoites and cysts of *Acanthamoeba* spp. to disinfectants in various solutions used to disinfect contact lenses; infections with these organisms have led to serious eye infections, particularly keratitis. These infections can be very difficult to treat if not recognized early, and eradication of the free-living amebae is also very difficult. These protozoa are capable of forming biofilms on contact lenses and could adversely affect the effectiveness of chemical agents used for disinfection. For those laboratories that routinely culture specimens for the free-living amebae, handling of the specimens and/or culture material represents a potential source of transmission and infection.

Plasmodium spp.

In a series of 34 cases of laboratory-acquired malaria, 15 were due to *P. falciparum*, 10 were due to *P. cynomolgi*, and 9 were due to *P. vivax*. The majority of cases were reported from the United States and Europe, with 19 being vector borne, 10 being parenteral, and 5 occurring through a break in the skin. All patients were symptomatic (18, 80).

It has also been documented that research workers can be accidentally infected from a mosquito, possibly one that escaped from a mosquito colony. Strict containment measures should be in place. Another possible route of infection involves mosquito dissection, during which infective sporozoites could be accidentally injected.

Trypanosoma brucei gambiense and *T. brucei rhodesiense*

Cases of laboratory-acquired African trypanosomiasis can result from contact with blood or tissue from infected persons or animals. Six laboratory-acquired cases have been caused by *T. brucei gambiense*, and two have been

TABLE 31.2 Possible parasite transmission in a health care setting (laboratory)

Organisms[a]	**Mode of transmission**	**Comments**
Protozoa (intestinal)		
Entamoeba histolytica[b,c] (C) *Entamoeba dispar* (C) *Entamoeba coli* (C) *Entamoeba hartmanni* (C) *Endolimax nana* (C) *Iodamoeba bütschlii* (C) *Blastocystis* spp.[b] (C) Free-living amebae *Giardia lamblia*[b,c] (C) *Dientamoeba fragilis*[b] (T) *Cryptosporidium* spp.[b,c] (O) *Cyclospora cayetanensis*[b] (O) *Cystoisospora belli*[b,c] (O) Microsporidia[b] (S)	Accidental ingestion of infective cysts, trophozoites, oocysts, or spores in food or water contaminated with fecal material; also, direct transfer of stool material via fomites (fecal-oral transmission) Contamination of hands, eyes when handling free-living ameba cultures; inhalation of infectious aerosols; splashes to eyes or mucous membranes	Transmission becomes more likely when fresh stool specimens are being processed and examined; submission of fecal specimens in preservatives or fixatives would decrease risks. Wearing gloves, using capped centrifuge tubes, and working in biological safety cabinet would decrease the risk of acquiring *Cryptosporidium* infections. *Not recommended:* use of potassium dichromate as collection fluid and use of sugar-flotation on fresh stool. Immunocompromised employees must be educated regarding risk factors; they may elect not to work with certain organisms or perform certain procedures.
Helminths (intestinal)		
Enterobius vermicularis (E)[c]	Inhalation or ingestion of infective eggs	Very common in children, asymptomatic
Strongyloides stercoralis (IL)[c]	Skin penetration of infective larvae from stool material	Exposure would be very possible or even likely when working with stool cultures or concentrates for larva recovery.
Hymenolepis nana (E)	Ingestion of infective eggs (fecal-oral)	Ingestion of infective eggs can lead to the adult worm in humans.
Taenia solium (E)	Inhalation or ingestion of infective eggs (could lead to cysticercosis)	Exposure very likely when working with gravid proglottids (ink injection for identification of worm to species level).
Blood and tissue protozoa		
Leishmania spp.[c]	Direct contact or inoculation of infectious material from patient lesion; accidental inoculation of material from culture or animal inoculation studies	Culture forms and organisms from hamster would be infectious.
Trypanosoma spp.[c]	Same as for *Leishmania* spp.; also handling arthropod vectors	Cultures and special concentration techniques would represent possible means of exposure.
Plasmodium spp.[c,d]	Accidental inoculation could transmit any of the five species; mosquito transmission	Blood and culture material should always be handled carefully (avoid open cuts, etc.).
Toxoplasma gondii[c]	Inhalation or ingestion of oocysts in cat feces (veterinary situation); accidental inoculation of tachyzoites from culture, tube of blood, or animal isolation (mouse peritoneal cavity); needles, spills, mucous membrane contamination; tissue culture work	Although many people already have antibodies to *T. gondii*, indicating past exposure, there have been documented laboratory accidents in which the individual became ill because of the large infecting dose.
Ectoparasites		
Pediculus spp.	Specimens submitted on hair could be easily transmitted in the laboratory.	Careful handling and fixation of the arthropods would prevent any potential problems with transmission.
Sarcoptes scabiei	Transmission via skin scraping, etc., would be possible but not that likely.	Careful handling and preparation of specimens with KOH would tend to prevent any problems.
Dipterous fly larvae (myiasis)	Transmission could occur anywhere.	Protection from flies would solve the potential problem.

[a] C, cyst; T, trophozoite; O, oocyst; IL, infective larvae; E, egg; S, spore.

[b] Potentially pathogenic intestinal protozoa.

[c] Laboratory infections documented: *Leishmania* spp., *Trypanosoma cruzi*, *Trypanosoma brucei gambiense*, *Trypanosoma brucei rhodesiense*.

[d] Mosquito transmission.

TABLE 31.3 Potential exposures to laboratory-acquired parasitic infections[a]

- Parenteral or aerosolization
  - Recapping a needle
  - Removing a needle from the syringe
  - Leaving a needle on the counter, point up
  - Dropping a syringe
  - Breaking hematocrit tube while pressing the end into clay
  - Performing venipuncture on agitated patient
  - Sudden animal movement during an inoculation procedure
  - Creating aerosols during tapeworm proglottid injection
  - Creating aerosols while working with cultures (blood parasites, free-living amebae)
  - Centrifugation
  - Blenders, shakers, sonicators, other mixing instruments
  - Pouring and decanting fluids
  - Spillage of infectious material
  - Lyophilization and filtration under vacuum
  - Egg inoculation and harvesting
  - Animal and insect bites and scratches
  - Injecting animals
- Animal or vector bites
  - Being bitten by an infected animal (mouse, hamster)
  - Being bitten by infected mosquito (mosquito colony)
- Skin exposure
  - Not wearing gloves during procedure
  - Not wearing laboratory coat (closed sleeves, closed front over clothes)
  - Accidentally touching face or eyes during handling of infectious materials
  - Exposing of eyes, nose, and mouth to potential aerosols
- Ingestion
  - Mouth pipetting
  - Being sprayed with inoculum droplets from coughing or regurgitating animal
  - Contaminated articles or fingers placed in mouith
  - Consumption of food in workplace
- Other reasons for potential exposures
  - Working in disorganized laboratory bench setting
  - Working too fast
  - Not receiving proper training
  - Assuming that the agent is not infectious to humans
  - Assuming that the agent(s) is no longer viable
  - Using defective equipment

[a] Adapted from a number of sources, including reference 18.

TABLE 31.4 Resistance to antiseptics and disinfectants, from most to least resistant

Type of organism	Example(s)
Prions	Creutzfeldt-Jacob disease, bovine spongiform encephalopathy
Coccidia	*Cryptosporidium* spp.
Spores	*Bacillus*, *Clostridium difficile*
Mycobacteria	*Mycobacterium tuberculosis*, *M. avium*
Cysts	*Giardia lamblia*
Small nonenveloped viruses	Poliovirus
Trophozoites	*Acanthamoeba*
Gram-negative bacteria (nonsporulating)	*Pseudomonas*
Fungi	*Candida*, *Aspergillus*
Large nonenveloped viruses	Enteroviruses, adenovirus
Gram-positive bacteria	*Staphylococcus aureus*, *Enterococcus*
Lipid-enveloped viruses	HIV, hepatitis B virus

caused by *T. brucei rhodesiense*. In these cases the route of exposure was usually parenteral, and all patients were symptomatic.

Trypanosoma cruzi

Infection can occur from exposure to the feces of infected triatomine bugs, by handling cultures or blood specimens, and possibly by inhaling aerosolized organisms. The predominant stage of the parasite in culture is the epimastigote stage; however, the infectious trypomastigotes can also be found. *T. cruzi* can infect laboratory personnel through needlestick injuries, through preexisting microabrasions of the skin, or through intact mucous membranes.

Sixty-five cases of laboratory-acquired *T. cruzi* infection have been reported, although in many cases, the actual geographic site was unknown. While the route of exposure for many of the cases was unknown, parenteral infection was identified for 11 individuals. The clinical status of the infected individuals was generally unknown; however, 24 of 47 were symptomatic, with 9 severe cases and 1 death (18, 80).

Leishmania spp.

In laboratory settings, leishmaniasis could be acquired through contact with an infected sand fly; containment measures for infected flies should be strictly followed. Transmission can also occur through contact with parasite cultures or clinical specimens from infected persons or animals (e.g., needlestick injuries or microabrasions of the skin). Although fewer parasites are found in patient blood specimens than in cultures or infected tissues, blood should be handled with care.

Twelve cases of laboratory-acquired leishmaniasis caused by six different species have been reported. Although most of the infected persons developed cutaneous leishmaniasis, sometimes with associated local lymphadenopathy, one person developed visceral leishmaniasis and one developed mucosal leishmaniasis as sequelae of cutaneous leishmaniasis. All patients were symptomatic, with two having severe disease (18).

Toxoplasma gondii
